CONTRIBUTORS xxvii

PART I CIVIL AND ENVIRONMENTAL ENGINEERING 1

1 New and Emerging Technologies in Structural Health Monitoring 3

Merit Enckell, Jacob Egede Andersen, Branko Glisic, and Johan Silfwerbrand

1.1 Introduction, 5

1.2 Background, 6

1.3 New and Emerging Technologies, 8

1.4 Fiber-Optic Technology, 16

1.5 Acoustic Emission, 24

1.6 Radar Technology, 27

1.7 Global Positioning System, 31

1.8 Corrosion Monitoring Systems, 33

1.9 Weigh-in-Motion (WIM) Systems, 35

1.10 Components of Structural Health Monitoring System, 37

1.11 Structural Health Monitoring System Design, 41

1.12 System Procurement and Installation, 44

1.13 Application of Structural Health Monitoring Systems, 47

1.14 Discussion, 67

1.15 Conclusion, 69

Acknowledgments, 70

References, 71

2 Applications of GIS in Engineering Measurements 79

Gary S. Spring

2.1 Introduction, 79

2.2 Background, 80

2.3 Basic Principles of GIS, 81

2.4 Measurement-Based GIS Applications, 96

2.5 Implementation Issues, 97

2.6 Conclusion, 100

References, 102

3 Traffic Congestion Management 105

Nagui M. Rouphail

3.1 Introduction and Background, 105

3.2 Scope of the Chapter, 106

3.3 Organization of the Chapter, 107

3.4 Fundamentals of Vehicle Emission Estimation, 107

3.5 Inventory of Traffic Congestion Management Methods, 112

3.6 Assessing Emission Impacts of Traffic Congestion Management, 119

3.7 Summary, 128

Acknowledgments, 129

References, 129

4 Seismic Testing of Highway Bridges	133
Eric V. Monzon, Ahmad M. Itani, and Gokhan Pekcan	
4.1 Introduction,	133
4.2 Similitude Requirements,	134
4.3 Specimen Fabrication,	141
4.4 Input Motion,	148
4.5 Instrumentation,	150
4.6 Data Acquisition and Processing,	155
4.7 Results,	157
References,	158
5 Measurements in Environmental Engineering	159
Daniel A. Vallero	
5.1 Introduction,	159
5.2 Environmental Sampling Approaches,	166
5.3 Laboratory Analysis,	169
5.4 Measurement Uncertainty,	183
5.5 Measurement Decision Making,	186
5.6 Environmental Indicators,	191
5.7 Extending Measurement Data Using Models,	199
5.8 Summary,	200
Nomenclature,	200
References,	202
6 Hydrology Measurements	205
Todd C. Rasmussen	
6.1 Introduction,	206
6.2 Precipitation,	209
6.3 Evapotranspiration,	212
6.4 Surface Flow,	216
6.5 Groundwater,	219
6.6 Soil Water,	223
6.7 Water Quality,	226
Suggested Readings,	231
7 Mobile Source Emissions Testing	233
Mohan Venigalla	
7.1 Testing for Regulatory Compliance,	234
References,	240

PART II MECHANICAL AND BIOMEDICAL ENGINEERING 241

8 Dimensions, Surfaces, and their Measurement 243

Mikell P. Groover

8.1 Dimensions, Tolerances, and Related Attributes, 244

8.2 Conventional Measuring Instruments and Gages, 245

8.3 Surfaces, 254

References, 256

9 Mass Properties Measurement 259

David Tellet

9.1 Introduction, 260

9.2 Mass and Weight, 262

9.3 Measurement Methodology, 264

9.4 Weight and Mass Measurement, 274

9.5 Center of Gravity Measurement, 275

9.6 MOI Measurement, 280

9.7 POI Measurement, 284

9.8 Measuring Large Vehicles, 287

9.9 Sources of Uncertainty, 292

References, 300

10 Force Measurement 301

Patrick Collins

10.1 Introduction, 302

10.2 Force Transducers, 303

10.3 Universal Testing Machines, 306

10.4 The Strain Gauge Sensor, 307

10.5 Resonant Element Transducers, 311

10.6 Surface Acoustic Wave Transducers, 314

10.7 Dynamometers, 317

10.8 Optical Force Transducers, 317

10.9 Magneto-Elastic Transducers, 320

10.10 Force Balance Transducers, 321

10.11 Force Transducer Characteristics, 321

10.12 Calibration, 323

10.13 Conclusion, 329

Glossary of Terms, 329

References, 340

11 Resistive Strain Measurement Devices 343

Mark Tuttle

11.1 Preliminary Discussion, 343

11.2 Resistance Metal Strain Gages, 349

11.3 Semiconductor Strain Gages, 363

11.4 Liquid Metal Strain Gages, 365

References, 366

12 Vibration Measurement 367

Sheryl M. Gracewski and Nigel D. Ramoutar

12.1 Introduction, 367

12.2 One-Degree-of-Freedom System Response, 369

12.3 Multi-Degree-of-Freedom Systems and the Frequency Response Function, 373

12.4 Vibration Measurement Equipment and Techniques, 388

12.5 Experimental Modal Analysis, 405

12.6 Applications of Vibration Measurement, 423

Nomenclature, 428

References, 431

13 Acoustical Measurements 433

Brian E. Anderson, Jonathan D. Blotter, Kent L. Gee, and Scott D. Sommerfeldt

13.1 Introduction, 434

13.2 Fundamental Measures, 436

13.3 Microphones, 445

13.4 Sound Pressure Level Measurements, 451

13.5 Measurement of Sound Isolation, 454

13.6 Room Acoustics Measurements, 457

13.7 Community and Environmental Noise, 463

13.8 Sound Intensity Measurements, 465

13.9 Sound Power Measurements, 472

13.10 Sound Exposure Measurements, 476

References, 479

14 Temperature Measurement 483

Peter R. N. Childs

Summary, 484

14.1 Introduction, 484

14.2 Selection, 487

14.3 Invasive Temperature Measurement, 489

14.4 Semi-Invasive Methods, 511

14.5 Noninvasive Methods, 514

14.6 Conclusions, 519

Nomenclature, 519

References, 521

15 Pressure and Velocity Measurements 527

Richard S. Figliola and Donald E. Beasley

15.1 Pressure Concepts, 528

15.2 Pressure Reference Instruments, 530

15.3 Pressure Transducers, 536

15.4 Pressure Transducer Calibration, 543

15.5 Pressure Measurements in Moving Fluids, 544

15.6 Modeling Pressure and Fluid Systems, 548

15.7 Design and Installation: Transmission Effects, 548

15.8 Fluid Velocity Measuring Systems, 552

Nomenclature, 563

References, 564

16 Luminescent Method for Pressure Measurement 567

Gamal E. Khalil, Jim W. Crafton, Sergey D. Fonov, Marvin Sellers, and Dana Dabiri

16.1 Introduction, 567

16.2 Principles of Pressure-Sensitive Paint, 569

16.3 Pressure-Sensitive Luminescent Dyes, 571

16.4 PSP Polymer and Binder, 572

16.5 Measurement Methods, 574

16.6 Pressure-Sensitive Paint Measurements, 588

Acknowledgments, 611

References, 612

17 Flow Measurement 615

Jesse Yoder

17.1 New-Technology and Traditional Technology Flowmeters, 616

17.2 Trends in Flow Measurement, 627

Further Readings, 628

18 Heat Flux Measurement 629

Thomas E. Diller

18.1 Introduction, 630

18.2 Important Issues, 631

18.3 Gages Based on Spatial Temperature Difference, 634

18.4 Gages Based on Temperature Change with Time, 643

18.5 Gages Based on Active Heating Methods, 648

18.6 Calibration and Errors, 653

References, 655

19 Heat Transfer Measurements for Nonboiling Two-Phase Flow 661

Afshin J. Ghajar and Clement C. Tang

19.1 Introduction, 661

19.2 Experimental Setup for Horizontal and Slightly Inclined Pipes, 662

19.3 Instruments for Measurement and Data Acquisition, 666

19.4 Heat Transfer Experiment Procedures, 667

19.5 Verifying the Functionality of the Experimental Setup, 670

19.6 Experimental Results of Two-Phase Flow, 673

19.7 Concluding Remarks, 682

Nomenclature, 683

References, 684

20 Solar Energy Measurements	687
Tariq Muneer and Yieng Wei Tham	
20.1 Introduction,	688
20.2 Measurement Equipment,	694
20.3 Equipment Error and Uncertainty,	703
20.4 Operational Errors,	704
20.5 Diffuse Radiation Data Measurement Errors,	704
20.6 Types of Sensors and their Accuracy,	711
20.7 Modern Developments,	711
20.8 Data Quality Assessment,	714
20.9 Statistical Evaluation of Models,	716
20.10 Outlier Analysis,	722
Acknowledgments,	722
References,	723
21 Wind Energy Measurements	727
Peter Gregg	
21.1 Introduction,	728
21.2 Concepts,	728
21.3 Measurements,	731
21.4 Evaluation,	739
References,	747
22 Human Movement Measurements	749
Rahman Davoodi	
22.1 Introduction,	749
22.2 Characterization of Human Movement,	750
22.3 Optical Motion Capture Systems,	751
22.4 Magnetic Motion Capture Systems,	754
22.5 Inertial Motion Capture Systems,	756
22.6 Discussion,	761
Acknowledgment,	762
References,	762
23 Flow Measurement	765
Arnold A. Fontaine, Keefe B. Manning, and Steven Deutsch	
23.1 Introduction,	765
23.2 Flow Measurement Applications,	768
References,	799

PART III INDUSTRIAL ENGINEERING 803

24 Statistical Quality Control 805

Magd E. Zohdi

24.1 Measurements and Quality Control, 805

24.2 Dimension and Tolerance, 805

24.3 Quality Control, 806

24.4 Interrelationship of Tolerances of Assembled Products, 812

24.5 Operation Characteristic (OC) Curve, 812

24.6 Control Charts for Attributes, 812

24.7 Acceptance Sampling, 815

24.8 Defense Department Acceptance Sampling by Variables, 817

Further Readings, 817

25 Evaluating and Selecting Technology-Based Projects 819

Hans J. Thamhain

25.1 Management Perspective, 819

25.2 Quantitative Approaches, 821

25.3 Qualitative Approaches, 826

25.4 Recommendations, 828

Variables and Abbreviations, 831

References, 831

26 Manufacturing Systems Evaluation 833

Walter W. Olson

26.1 Introduction, 833

26.2 Components of Environmentally Conscious Manufacturing, 834

26.3 Manufacturing Systems, 835

26.4 System Effects on ECM, 838

26.5 Assessment, 840

26.6 Summary, 844

References, 845

27 Measuring Performance of Chemical Process Equipment 847

Alan Cross

27.1 Introduction, 847

27.2 Direct Fired Heater Measurement and Process Control Instrumentation, 848

27.3 Crushing and Grinding Equipment Measurements, 851

References, 858

28 Industrial Energy Efficiency 859

B. Gopalakrishnan, D. P. Gupta, Y. Mardikar, and S. Chaudhari

28.1 Introduction, 860

28.2 Literature Review, 863

28.3 Data Analysis of Energy Efficiency Measures, 864

28.4 Energy Efficiency Measures in Major Energy Consuming Equipment, 872

28.5 Case Studies of Development of Energy-Efficiency Measures, 879

28.6 Conclusion, 881

Acknowledgments, 881

References, 881

29 Industrial Waste Auditing	885
C. Visvanathan	
29.1 Overview,	885
29.2 Waste-Minimization Programs,	886
29.3 Waste-Minimization Cycle,	888
29.4 Waste Auditing,	890
29.5 Conclusion,	909
Further Readings,	910
30 Organizational Performance Measurement	911
Jennifer A. Farris, Eileen M. Van Aken, and Geert Letens	
30.1 Introduction,	911
30.2 Summary,	940
References,	940
INDEX	

VOLUME 2

PART IV MATERIALS PROPERTIES AND TESTING 945

31 Viscosity Measurement	947
Ann M. Anderson, Bradford A. Bruno, and Lilla Safford Smith	
31.1 Viscosity Background,	947
31.2 Common Units of Viscosity,	949
31.3 Major Viscosity Measurement Methods,	959
31.4 ASTM Standards for Measuring Viscosity,	974
31.5 Questions to Ask When Selecting a Viscosity Measurement Technique,	976
References,	979
32 Tribology Measurements	981
Prasanta Sahoo	
32.1 Introduction,	982
32.2 Measurement of Surface Roughness,	983
32.3 Measurement of Friction,	988
32.4 Measurement of Wear,	992
32.5 Measurement of Test Environment,	994
32.6 Measurement of Material Characteristics,	998
32.7 Measurement of Lubricant Characteristics,	1001
32.8 Wear Particle Analysis,	1004
32.9 Industrial Measurements,	1005
32.10 Summary,	1006

33 Corrosion Monitoring 1007

Pierre R. Roberge

33.1 What is Corrosion Monitoring?, 1007

33.2 The Role of Corrosion Monitoring, 1008

33.3 Corrosion Monitoring System Considerations, 1010

References, 1116

34 Surface Properties Measurement 1121

Mrinalini Mulukutla and Sandip P. Harimkar

34.1 Introduction, 1121

34.2 Surface Properties, 1122

34.3 Microstructural Analysis, 1125

34.4 Compositional Analysis, 1128

34.5 Phase Analysis, 1130

34.6 Mechanical Testing, 1131

34.7 Corrosion Properties, 1141

34.8 Standards for Surface Engineering Measurement, 1145

References, 1147

35 Thermal Conductivity of Engineering Materials 1151

Juergen Blumm

35.1 Introduction, 1151

35.2 Stationary Methods for Measurement of the Thermal Conductivity, 1157

35.3 Transient Methods for the Measurement of the Thermal Conductivity, 1163

35.4 Test Results on Various Engineering Materials, 1173

References, 1188

36 Optical Methods for the Measurement of Thermal Conductivity 1189

Prabhakar R. Bandaru and Max S. Aubain

36.1 Thermal Boundary Resistance May Limit Accuracy in Contact-Based Thermal Conductivity (k) Measurements, 1189

36.2 Optical Measurements of k May Avoid Contact-Related Issues, 1192

36.3 Thermoreflectance (TR), 1196

36.4 Characteristics of Thermoreflectance from Si Thin Films—Modeling and Calibration, 1199

36.5 Experimental Procedures, 1202

36.6 Results and Discussion, 1204

36.7 Summary and Outlook, 1208

Acknowledgments, 1209

References, 1209

37 Selection of Metals for Structural Design 1213

Matthew J. Donachie

37.1 Introduction, 1214

37.2 Common Alloy Systems, 1215

37.3 What are Alloys and What Affects their Use?, 1215

37.4 What are the Properties of Alloys and How are Alloys Strengthened?, 1218

37.5 Manufacture of Alloy Articles, 1221

37.6 Alloy Information, 1221

37.7 Metals at Lower Temperatures, 1231

37.8 Metals at High Temperatures, 1233

37.9 Melting and Casting Practices, 1236

37.10 Forging, Forming, Powder Metallurgy, and Joining of Alloys, 1242

37.11 Surface Protection of Materials, 1245

37.12 Postservice Refurbishment and Repair, 1248

37.13 Alloy Selection: A Look at Possibilities, 1249

37.14 Level of Property Data, 1252

37.15 Thoughts on Alloy Systems, 1252

37.16 Selected Alloy Information Sources, 1259

Further Readings, 1261

38 Mechanical Properties of Polymers 1263

Daniel Liu, Jackie Rehkopf, and Maureen Reitman

38.1 Microstructure and Morphology of Polymers—Amorphous Versus Crystalline, 1264

38.2 General Stress–Strain Behavior, 1265

38.3 Viscoelasticity, 1271

38.4 Mechanical Models of Viscoelasticity, 1272

38.5 Time–Temperature Dependence, 1274

38.6 Deformation Mechanisms, 1274

38.7 Crazing, 1277

38.8 Fracture, 1279

38.9 Modifying Mechanical Properties, 1284

38.10 Load-Bearing Applications: Creep, Fatigue Resistance, and High Strain Rate Behavior, 1285

References, 1290

39 Electrical Properties of Polymers 1291

Evaristo Riande and Ricardo Diaz-Calleja

39.1 Introductory Remarks, 1291

39.2 Polarity and Permittivity, 1292

39.3 Measurements of Dielectric Permittivity, 1293

39.4 Polarization and Dipole Moments in Isotropic Systems, 1297

39.5 Thermostimulated Depolarization Currents, 1316

39.6 Conductivity in Polyelectrolytes and Polymer-Electrolytes as Separators for Low Temperature Fuel Cells and Electrical Batteries, 1318

39.7 Semiconductors and Electronic Conducting Polymers, 1324

39.8 Ferroelectricity, Pyroelectricity, and Piezoelectricity in Polymers, 1328

39.9 Nonlinear Polarization in Polymers, 1331

39.10 Elastomers for Actuators and Sensors, 1333

39.11 Electrical Breakdown in Polymers, 1336

References, 1338

40 Nondestructive Inspection 1343

Robert L. Crane and Jeremy S. Knopp

40.1 Introduction, 1344

40.2 Liquid Penetrants, 1347

40.3 Radiography, 1351

40.4 Ultrasonic Methods, 1361

40.5 Magnetic Particle Method, 1370

40.6 Thermal Methods, 1373

40.7 Eddy Current Methods, 1375

References, 1410

41 Testing of Metallic Materials 1413

Peter C. McKeighan

41.1 Mechanical Test Laboratory, 1414

41.2 Tensile and Compressive Property Testing, 1418

41.3 Creep and Stress Relaxation Testing, 1420

41.4 Hardness and Impact Testing, 1422

41.5 Fracture Toughness Testing, 1425

41.6 Fatigue Testing, 1429

41.7 Other Mechanical Testing, 1433

41.8 Environmental Considerations, 1434

Acknowledgments, 1436

References, 1436

42 Ceramics Testing 1437

Shawn K. McGuire and Michael G. Jenkins

42.1 Introduction, 1437

42.2 Mechanical Testing, 1438

42.3 Thermal Testing, 1451

42.4 Nondestructive Evaluation Testing, 1458

42.5 Electrical Testing, 1460

42.6 Summary, 1461

References, 1461

43 Plastics Testing 1463

Vishu Shah

43.1 Introduction, 1464

43.2 Mechanical Properties, 1464

43.3 Thermal Properties, 1481

43.4 Electrical Properties, 1484

43.5 Weathering Properties, 1488

43.6 Optical Properties, 1492

Further Readings, 1496

44 Testing and Instrumental Analysis for Plastics Processing:

Key Characterization Techniques 1499

Maria del Pilar Noriega

44.1 FTIR Spectroscopy, 1499

44.2 Chromatography (GC, GC-MSD, GC-FID, and HPLC), 1500

44.3 DSC and Thermogravimetry (TGA), 1510

44.4 Rheometry, 1518

References, 1527

45 Analytical Tools for Estimation of Particulate Composite

Material Properties 1529

Tarek I. Zohdi and Magd E. Zohdi

45.1 Introduction, 1529

45.2 Concepts in Statistical Quality Control, 1530

45.3 Effective Property Estimates, 1531

45.4 Summary, 1535

References, 1537

PART V INSTRUMENTATION 1539

46 Instrument Statics 1541

Jerry Lee Hall, Sriram Sundararajan, and Mahmood Naim

46.1 Terminology, 1541

46.2 Static Calibration, 1544

46.3 Statistics in the Measurement Process, 1547

References, 1570

47 Input and Output Characteristics 1573

Adam C. Bell

47.1 Introduction, 1574

47.2 Familiar Examples of Input–Output Interactions, 1575

47.3 Energy, Power, Impedance, 1578

47.4 Operating Point of Static Systems, 1586

47.5 Transforming the Operating Point, 1598

47.6 Measurement Systems, 1602

47.7 Distributed Systems in Brief, 1607

47.8 Concluding Remarks, 1609

References, 1610

48 Bridge Transducers 1611

Patrick L. Walter

48.1 Terminology, 1612

48.2 Flexural Devices in Measurement Systems, 1612

48.3 The Resistance Strain Gage, 1615

48.4 The Wheatstone Bridge, 1625

48.5 Resistance Bridge Balance Methods, 1634

48.6 Resistance Bridge Transducer Measurement System Calibration, 1636

48.7 Resistance Bridge Transducer Measurement System Considerations, 1646

48.8 AC Impedance Bridge Transducers, 1655

References, 1660

Further Readings, 1661

49 Signal Processing 1663

John Turnbull

49.1 Frequency-Domain Analysis of Linear Systems, 1663

49.2 Basic Analog Filters, 1666

49.3 Basic Digital Filter, 1672

49.4 Stability and Phase Analysis, 1680

49.5 Extracting Signal from Noise, 1682

References, 1683

50 Data Acquisition and Display Systems 1685

Philip C. Milliman

50.1 Introduction, 1686

50.2 Data Acquisition, 1687

50.3 Process Data Acquisition, 1688

50.4 Data Conditioning, 1691

50.5 Data Storage, 1699

50.6 Data Display and Reporting, 1704

50.7 Data Analysis, 1707

50.8 Data Communications, 1708

50.9 Other Data Acquisition and Display Topics, 1712

50.10 Summary, 1715

References, 1715

PART VI MEASUREMENT STANDARDS 1517

51 Mathematical and Physical Units, Standards, and Tables 1719

Jack H. Westbrook

51.1 Symbols and Abbreviations, 1720

Bibliography for Letter Symbols, 1731

Bibliography for Graphic Symbols, 1737

51.2 Mathematical Tables, 1742

51.3 Statistical Tables, 1765

51.4 Units and Standards, 1775

Bibliography for Units and Measurements, 1802

51.5 Tables of Conversion Factors, 1802

51.6 Standard Sizes, 1833

51.7 Standard Screws, 1886

PREFACE

The idea for the *Handbook of Measurement in Science and Engineering* came from a Wiley book first published over 30 years ago. It was *Fundamentals of Temperature, Pressure and Flow Measurements*, written by a sole author, Robert P. Benedict, who also wrote Wiley books on gas dynamics and pipe flow. Bob was a pleasant, unassuming, and smart man. I was the Wiley editor for professional-level books in mechanical engineering when Bob was writing such books, so I knew him as a colleague. I recall meeting him in the Wiley offices at a time when he seemed to be having some medical problems, which he was reluctant to talk about. Recently, I discovered a book published in 1972 by a London firm, Pickering & Inglis, which specializes in religion. This book was *Journey Away From God*, an intriguing title. The author's name was Robert P. Benedict. I do not know whether the two Benedicts are in fact the same person, although Amazon seems to think so. (See the Robert P. Benedict page.) In any case, I do not recall Bob's mentioning the book when we had an occasion to talk.

The moral of this story, if there is one, is that the men and women who contributed the chapters in this handbook are real people, who have real-world concerns, in addition to the expertise required to write about technology. They have families, jobs, careers, and all manner of cares about the minutia of daily life to deal with. And that they have been able to find the time and energy to write these chapters is remarkable. I salute them.

I have spent a lot of time in my life writing and editing books. I wrote my first Wiley book somewhat earlier than Bob Benedict wrote his. When Wiley published *Temperature Control* in 1967, I was in my mid-twenties and was a practicing engineer, working on temperature control of the Apollo inertial guidance system at the MIT Instrumentation Lab, where I had done my bachelor's thesis. One of the coauthors of my book was to have been a Tufts Mechanical Engineering Professor by the name of John Sununu (yes, *that* John Sununu), but he and the other coauthor dropped out of the project before the contract was signed. So I wrote the short book myself.

Bob Benedict's measurement book, the third edition of which is still in print, surfaced several years ago, during a discussion I was having with one of my Wiley editors,

Bob Argentieri, about possible projects we could collaborate on. It turned out that no one had attempted to update Benedict's book. I have not been a practicing engineer for some time, so I was not in a position to do an update as a single author—or even with a collaborator or two. Most of my career life has been in scientific and technical publishing, however, and for over a decade I have conceived of, and edited, numerous handbooks for several publishers. (I also write fiction, but that is another story.) So, it was natural for me to think about using Benedict's book as the kernel of a much larger and broader reference work dealing with engineering measurements. The idea, formed during that discussion, that I might edit a contributed handbook on engineering measurements took hold, and with the affable and expert guidance of my other Wiley editor, George Telecki, the volume you are holding in your hands, or reading on an electronic device, came into being.

Like many such large reference works, this handbook went through several iterations before the final table of contents was set, although the general plan for arrangement of chapters has been the same throughout the project. The initial print version of the handbook is divided into two volumes. The chapters are arranged essentially by engineering discipline. The first volume contains 30 chapters related to five engineering disciplines, which are divided into three parts:

- Part I, Civil and Environmental Engineering, which contains seven chapters, all but one of them dealing with measurement and testing techniques for structural health monitoring, GIS and computer mapping, highway bridges, environmental engineering, hydrology, and mobile source emissions (the exception being the chapter on traffic congestion management, which describes the deployment of certain measurements);
- Part II, Mechanical and Biomedical Engineering, which contains 16 chapters, all of them dealing with techniques for measuring dimensions, surfaces, mass properties, force, resistive strain, vibration, acoustics, temperature, pressure, velocity, flow, heat flux, heat transfer for non-boiling two-phase flow, solar energy, wind energy, human movement, and physiological flow;
- Part III, Industrial Engineering, which contains seven chapters dealing with statistical quality control, evaluating and selecting technology-based projects, manufacturing systems evaluation, measuring performance of chemical process equipment, industrial energy efficiency, industrial waste auditing, and organizational performance measurement.

The second volume contains 23 chapters divided into three parts:

- Part IV, Materials Properties and Testing, which contains 15 chapters dealing with measurement of viscosity, tribology, corrosion, surface properties, and thermal conductivity of engineering materials; properties of metals, alloys, polymers, and particulate composite materials; nondestructive inspection; and testing of metallic materials, ceramics, plastics, and plastics processing;
- Part V, Instrumentation, which contains five chapters covering electronic equipment used for measurements;
- Part VI, Measurement Standards, which contains three chapters covering units and standards, measurement uncertainty and error analysis.

Major reference works, like this handbook, are generally incomplete when they are first published. Editors cannot wait for tardy contributors, some contributors simply cannot manage to deliver their chapters no matter how much time they are given, and contributors cannot be secured for all the chapters an editor has in mind for a reference work. Among the topics that were either contracted for but were not delivered or for which contributors were not found are surveying engineering, engineering seismology, construction materials properties, turbulence, water quality, wastewater engineering, trace gases in the atmosphere, experimental methods, experimental design, shape and deformation, thermal systems, energy audits, electrical properties of materials, rheology, software engineering, biomedical electronics, physiology, dielectric properties of tissues, productivity, remote sensing, and data analysis.

Of course, such a list, when combined with the chapters being published, does not exhaust the list of possible topics for a measurements handbook. Be that as it may, the usual practice has been to attempt to include additional topics, together with updates of existing chapters, in new editions of a reference work, which tend to appear in 5-to-10-year, or longer, intervals. I have done this successfully in the *Mechanical Engineers' Handbook* that I edit for Wiley. That work is now, in its forthcoming fourth edition, a four-volume handbook, in contrast to the single-volume first and second editions.

In the case of this measurements handbook, however, George Telecki has proposed that the online version be dynamic, with 20 or so articles added annually. Furthermore, coverage will be expanded beyond engineering disciplines to include chemistry, life sciences, and physics, thereby justifying the handbook's title, *Handbook of Measurement in Science and Engineering*. In addition, existing chapters will be updated as the need arises. I have campaigned for years to get my publishers to adopt this scheme, and I am gratified that Wiley intends to pursue it. I will attempt to get the others to follow suit.

Thanks to Kari Capone for shepherding the manuscript toward production and to the stalwarts Kristen Parrish and Shirley Thomas, for bringing the handbook home. Thanks, also, to my wife Arlene, who helps me with everything else.

1.1 INTRODUCTION

Structural Health Monitoring (SHM) and modern sensory technology together with advanced data acquisition are currently available for various applications. The area of monitoring is also very wide and incorporates several disciplines. Civil engineers working with monitoring have to cooperate very closely with various kinds of specialists to assure that the chosen monitoring system provides the information that they are looking for.

Organized SHM became a well-known concept during the last decades. Health Monitoring according to Aktan et al. (2000), may be defined as

the measurement of the operating and loading environment and the critical responses of a structure to track and evaluate the symptoms of operational incidents, anomalies, and/or deterioration or damage indicators that may affect operation, serviceability, or safety reliability

SHM helps to control and verify structural behavior: the condition or changes in the condition of a structure. SHM gives more improved and precise information than visual inspection about the real condition of the structure at real time. Decision making concerning the maintenance, economy, and the safety of the structures is easier with an appropriate Structural Health Monitoring System (SHMS).

Factors such as shortened construction periods, increased traffic loads, new high speed trains causing new dynamic and fatigue problems, new materials, new construction solutions, slender constructions, limited economy, and need for timesaving demanded for better control as well as verification and benefited for SHM.

Old deteriorated structures, especially, the ones that do suffer about fatigue effects may have malfunction and could collapse. But also structures that are not at the end of their lifetime do fail. Some serious collapses have taken place in recent years, for example, Sport Arena Bad Reichenhall in south Germany and Arena in Katowice, south Poland in 2006; I-35W Mississippi River bridge in Minnesota, United States in 2007. Many people were killed and injured caused by these mentioned collapses. The newly built bridges called Gröndal Bridge and Alvik Bridge in Stockholm revealed extensive cracking in the webs of their concrete hollow box girder sections just after a few years of operation (Sundquist and James, 2004), and two tension rods and a crossbeam from a recently installed repair collapsed in Oakland Bay Bridge, San Francisco in 2009, causing the bridge to be closed temporarily. Structures also do collapse during the construction period, and workers may be killed or injured as recently for the cable-stayed bridge across the Chambal River in India. SHM can start with a sensor installation and monitoring already during the construction period and therefore provide information throughout the whole life span of the structure: construction, testing, operation and also demolition. It may capture the behavior that visual inspection does not accomplish and therefore there is possibility that it may save human life.

The rapid development of technology in the fields of sensors, data acquisition and communication, signal analysis and data processing provide SHM with great profit. Buildings, bridges, wind farms, nuclear power plants, geotechnical structures, historical buildings and monuments, dams, offshore platforms, pipelines, ocean structures, airplanes, wind plants, turbine blades, and so on, may be objects for monitoring activities. The monitoring can be periodic or continuous, short term or long term, local or global, and the monitoring system can consist of a few sensors up to hundreds or even thousands of them depending on the demands of the monitoring object.

Structural Health Monitoring System for a structure consists of sensors, data acquisition systems, data transfer and storage systems, data management that normally includes data analysis as well as presentation, and data interpretation. The number of sensors used in monitoring is endless. Different applications with various techniques such as electrical, optical, acoustical, and geodetical are available. Various parameters such as strain, displacement, inclination, stress, pressure, humidity, temperature, different chemical quantities, and environmental parameters such as wind speed and direction can be monitored.

Conventional sensors used for civil engineering such as strain gauges, traditional accelerometers, inclinometers, load cells, vibrating wires, linear variable differential transformers (LVDT) are able to measure many parameters and have a long experience in use. On the other hand, the evolution of emerging technologies together with computer-based data acquisition, advanced signal and data communication have made the evaluation of new techniques and sensors for civil engineering purposes possible.

Fiber-optic sensors, microelectromechanical systems (MEMS), optical distance measurement techniques, acoustic emission, and different type of lasers and radars have been under great development in recent years and are now available on the market. They are characterized by high accuracy, straightforward usage, and data-collecting concept. These techniques often allow very delicate measuring in harsh conditions and in various applications. The automatic collection of the data saves time, and it has advantages with respect to manual measurements. The reliability and durability of the sensors become significant when choosing the appropriate instrumentation. These new high-tech sensors also allow for not only high accuracy but also high precision, high and constant sensitivity, stability over time, no drift, and they are often temperature compensated.

The market with fiber-optic sensors and their applications is massive. There are several different techniques and various kinds of sensors that also can be modified for unique monitoring needs for a particular structure. Fiber-optic sensors allow for measurements that have been unpractical or too costly with the traditional sensor technology. Hundreds measuring points along the same fiber, as well as distributed sensing, versatility, insensitivity for electromagnetic fields, operability under extreme climate conditions and also the fact that there is no need for protection against lightning are some of the advantages over the electrical-based counterparts (Ross and Matthews, 1995).

Numerous different monitoring projects have taken place in recent years, and SHM has become a standard when designing large or complicated structures all over the world. It is now an essential implement in managing structures for civil engineers as well as owners. The modern sensory technology is also more commonly used as well as accepted by the civil engineering society.

As the subject is large and the number of emerging technologies and SHM applications is numerous, the chapter principally brings up and discusses the subjects mainly from the civil engineering point of view. The most common techniques that are suitable for civil engineering applications are presented and discussed and examples are given.

1.2 BACKGROUND

Testing and measuring of certain desired parameters have taken place in the field of civil engineering in the latest century (Mufti, 2001). Steel strains, rock stresses, concrete curing temperature, shrinkage and stresses, pressure of the concrete in formworks, vibrations, and many other phenomena that engineers felt uncertain about have been measured and recorded.

Lack of knowledge or experience was the driving force. The earliest reference to dynamic testing in the late nineteenth century can be seen in Salawu and Williams (1995). But as the Tacoma Narrows Bridge collapsed in 1940, it forced the engineers to face the problem with long-span bridge aerodynamics (Miyata et al., 2002; Miyata, 2003). As a result, the dynamic measuring techniques developed and increased significantly in the following decades. These activities were small scale and not really organized structural monitoring. The technology was not yet well developed in term of automation and data handling. The amount of data was held in small portions in order to be handled and used in a decent way.

Damage identification in aerospace and mechanical engineering started the organized SHM but were followed by civil engineering society. Organized SHM activities were acknowledged in the last decades. The subject also emerged various engineering disciplines as the new sensor technology and information technology entered the field. At present, many civil engineering structures are monitored continuously and true real-time information of these structures is provided.

Furthermore, a lot of discussion is going on between scientists and other related disciplinary in order to create standards and international guidelines. The concept “Health Monitoring” was defined by Aktan et al. (2000). They also published the report “Development of a Model health Monitoring Guide for major Bridges” (Aktan et al., 2001). ISIS Canada Research Network was established in 1995. ISIS published a report “Guidelines for Structural health Monitoring” in 2001 (Mufti, 2001) and several others design manuals and reports are published up today. International Society for Structural Health Monitoring of Intelligent Infrastructure (ISHMII), a nonprofit organization was founded in 2003. The aim of the Society is to advance the understanding and the application of SHM in the civil engineering infrastructure, in the service of the engineering profession and society. ISHMII also publish a paper called *The Journal of Civil Structural Health Monitoring (JCSHM)*. JCSHM publishes articles to advance the understanding and the application of health monitoring methodologies for the condition assessment and management of the civil infrastructure systems.

The European Union project, sustainable bridges also started to work with functional requirements for railway bridges in 2003. The goal was to achieve increased capacities required to meet future demands for increased traffic levels and heavier axle loads. The activities would also deal with efficient condition monitoring systems for railway bridges, and numerous reports were published and can be seen in www.sustainablebridges.net/.¹

Farrar and Worden (2007) gives an introduction to SHM. A very comprehensible and extensive paper about SHM of civil infrastructure that illustrates the different topics of SHM of dams, bridges, offshore, buildings, towers, nuclear installations, tunnels, and excavations can be seen in Brownjohn (2007). Problems, challenges, and limitation of development of SHM are brought up in these papers, the subject that is very important but still left out completely by many other authors. Some standards are also already created and can be seen in BSI (2004).

Recently, the SmartEN research project for research into smart use of wireless sensor networks and the integration of SHM monitoring results with Maintenance Management Systems for the optimization of maintenance have been formed funded by the European Commission seventh framework for research. These developments open up a completely novel area of multidisciplinary research toward the “smart” management of sustainable

¹Accessed January 27, 2010.

environment. Even though there are top research institutions working in the field of wireless sensors and others in the civil infrastructure reliability and management (Stochastic Optimization Methods for Infrastructure Management with Incomplete Monitoring Data Le Thanh Nam, 2009, Kyoto University), most of the activity is fragmented and there is no significant activity in performing multidisciplinary structured research for developing integrated smart and dynamic systems for effective management of the built and natural environment. The aim of SmartEN is to fill this gap and push innovation through the development of an ITN network that will focus on the development and effective integration of emerging technologies targeting key application areas of current interest to the European Commission and internationally.

Major construction projects such as large bridges, dams, high-rise buildings, nuclear power plants, offshore structures, tunnels, and harbor structures demand a lot of investment and resources. Their malfunction or collapse may cause severe damage to the society, its inhabitants or to the environment. Therefore, need to control these structures have emerged needs for monitoring that in turn has been adapted to smaller scale projects.

1.3 NEW AND EMERGING TECHNOLOGIES

1.3.1 General

Established technologies are well known and have a proper long-term experience. Emerging technologies, on the other hand, are science-based innovations that have the potential to create a new industry or transform an existing one (Day et al., 2000). Emerging technologies demand for new kind of thinking in order to prevail and copy with them. They are also characterized with certain ambiguity and complexity as they are in accelerating change.

Authors of this chapter have been working with established as well as new and emerging technologies: both in theory and practice. Several both small-scale and large-scale installations, testing and measuring campaigns are completed and Structural Health Monitoring Systems are designed, mostly for international major bridges but also for other applications such as high-rise buildings, tunnels, machinery, and heritage structures. The authors' intention is to provide a comprehensive presentation about the subjects as well as about related tasks. This will help the reader to understand the new challenges in order to accomplish sustainable SHM with new and emerging technologies.

Due to tremendous change in information technologies and sensor development, it is possible today to measure nearly any asked parameter and also perform automatic data processing and analysis in real time and with remote access. Sophisticated systems are present: over icing, corrosion, vibration, deflection, chemical concentration, humidity, strain, stresses and combined as well as distributed parameters can be measured. Some new technologies are better established like fiber-optic sensors but there are still a lot of challenges as research is ongoing and new sensors enter the field constantly.

A lot of work needs also be done in order to guarantee severity and long-term function of these innovative systems; one of the main tasks is to provide for defect localization as well as prediction of the future condition of the structure by automatic data analysis. New and emerging technologies have many advantages compared with old technologies such as adaptability, reliability, possibility for sophisticated measurements in real-time, and in harsh conditions. There are also disadvantages as some uncertainty is present. People working with new and emerging technologies need to be open for new ideas, ways of

thinking and able to have a idea about the future development in order to find flexible, adaptable solutions that will meet the requirement not only now but also in the future. The following sections present some new and emerging technologies and areas that the authors' find interesting and relevant for civil engineering structures. A few technologies are then presented in more detail.

1.3.2 Fiber-Optic Sensors (FOS)

The development that made possible to optical communication was first, the invention of the laser in 1960; and second, the invention of optical fiber. Anyhow, the first optic fibers had a lot of losses and it took some years before the discovery of low-loss silica-glass fiber led to the technology of fiber-optic communications. Telecommunication systems made fiber optics familiar to everybody. The use of fiber-optic applications in different kinds of engineering fields made also a huge expansion in the last decades, especially in communications. Fiber-optic sensory technology provides accurate, wide bandwidth measurements of various parameters in diverse harsh environments where the traditional techniques might fail. Many sensors do not need calibration, have no drift, allow either parallel or serial multiplexing, perform static and/or dynamic measurements and are insensitive to electromagnetic interference.

1.3.3 The Global Positioning System (GPS)

U.S. Department of Defense started the project for Global Positioning System in early 1970s to overcome the limitations of previous navigation systems. GPS system was created and realized, and it is a space-based global navigation satellite system that provides reliable location and time information in all weather and at all times and anywhere on or near the Earth. In order to work properly, GPS needs an unobstructed line of sight to four or more GPS satellites. The system that was developed as a military system became fully operational in 1993, and it is maintained by the U.S. Government (El-Rabbany, 2002). Nowadays, it is also available for civil use and civil engineering needs. Dynamic deformation monitoring of structures, such as long bridges, towers, and tall buildings, is now possible using GPS technology. GPS can also monitor a wide variety of other structures and geologic features: dams, landslides, platforms, slopes, pipelines, volcanoes, retaining walls, constructions zones and railways, just to mention some.

1.3.4 Microelectromechanical Systems (MEMS)

Microelectromechanical Systems is the technology of the very small devices or systems that combine electrical and mechanical components (EMPA, 2004; Leondes, 2006). These devices usually range in size from a micrometer to a millimeter. They are fabricated using modified silicon fabrication technology, molding and plating, wet etching and dry etching, electro discharge machining and other technologies capable of manufacturing very small devices. A particular system can accommodate from a few to millions devices. These systems can sense, control and activate mechanical processes on the micro scale. On the macro scale they are able to function individually or in arrays.

Accelerometers, inertial sensors, optical scanners, fluid pumps, chemical, flow, humidity, temperature, and pressure sensors are a few application examples. Accelerometers based on MEMS technologies are fairly new but perhaps the simplest

MEMS device possible, consisting of little more than a suspended cantilever beam or seismic mass with some type of deflection sensing and circuitry. MEMS Accelerometers are available in single axis, dual axis, and three axis models and in wide variety of ranges. Use of these accelerometers in the automotive industry has pushed their cost down radically and they are now available on the market for civil engineering monitoring purposes. A SHM project with MEMS Accelerometers can be seen in Wiberg (2006).

MEMS industry is still a young industry. MEMS will certainly invade more and more area as new products are invented, and frequency response and sense range are getting wider. Sensors based on MEMS technology are also getting more reliable, and their sensitivity is better and even the price is dropping down.

1.3.5 Corrosion Monitoring

Reinforced concrete (RC) structures and steel structures in aggressive environments are exposed to chemical attacks. For that reason, SHM techniques for evaluating the condition of these structures are essential. Maintenance and repair may be very expensive: if errors can be identified at an early stage of their occurrence, a lot of capital can be saved. Corrosion monitoring has many applications in the construction and maintenance of civil structures. High-rise buildings, bridges, dams, spillways, flood control channels, tunnels, piers, pylons, and harbor constructions are continuously monitored.

Parameters to be measured in RC structures are chloride concentration, resistivity, and temperature. The market provides with new innovative devices and methods, and a lot of research is ongoing as corrosion cost a lot of money for governments. The movement of aggressive substances in concrete occurs due to differentials in humidity, ionic concentration, and pressure and temperature within the microstructure of concrete cover (Srinivasan et al., 2009). The moisture content and temperature of the concrete can be monitored during the curing process to ensure maximum strength of the concrete (Dunn et al., 2010). Once construction is complete, the instrumentation can be used to conduct long-term monitoring of corrosion conditions over time.

1.3.6 B-WIM, WIM

Weigh-in-motion or weighing in motion (WIM) devices capture detailed data for each individual vehicle as vehicles drive over a measurement site. The following parameters can be measured dynamic weights of all axles, gross vehicle weights, axle spacing, vehicles distance and speed, vehicle classification according to various schemes, and statistic representations for all types of traffic parameters.

Modern WIM systems are efficient as they are capable of measuring at normal traffic speeds. Bridge weigh-in-motion (B-WIM) is the process by which axle and gross vehicle weights of trucks traveling at highway speeds can be determined from instrumented bridges. B-WIM systems are performed by attaching strain transducers to the soffit of a bridge and placing sensors for detecting axles in order to provide information on vehicle velocity, axle spacing and position of each vehicle. This is called nothing-on-the-road (NOR) or free-of-axle detector (FAD). B-WIM system and a wide range of field trials have been completed in recent years. These systems are becoming increasingly accurate, and they are exceptionally durable as no contact with tires is required (Obrien et al., 2008).

1.3.7 Nondestructive Testing (NDT)

Nondestructive testing is a commonly used tool in several engineering fields as well as in medicine and arts. McCann and Forde (2001) give an overview to NDT methods as applied to the civil engineering. The basic principles of NDT methods are described, and the main NDT methods used in engineering investigations are discussed. In addition, brief case histories from the literature are illustrated.

NDT methods can be divided into following main categories: ultrasonic, magnetic-particle, liquid penetrant, radiographic, remote visual inspection (RVI), radar-based non-contact applications, eddy-current testing, and low-coherence Interferometry. Methods such as ultrasound, radiography, impact echo, rebound hammer, photogrammetry, and crack detection with help of very fine ferromagnetic particles are also widely adopted by industry and engineers. Steel industry, for instance, use these methods for testing on welding, homogeneity of material, and so on, and these testing methods are also described in the handbooks.

1.3.7.1 Noncontact 3D Laser Scanning Noncontact three-dimensional laser scanners are a tool for capturing geometrical information of the objects (Feng, 2001). This technique that was initially developed for car manufacturing analyzes objects or environment to collect data on its shape and possibly its appearance (i.e., color). It is widely used in industrial applications as well as in rock and bridge engineering. Use of three-dimensional lasers has increased in the untraditional fields in recent decades, and modern three-dimensional laser scanners provide improved resolution, high-measurement accuracy, high scanning speed as well as lower cost. They can also accommodate integrated camera and laser plummet. Adapted software converts the stored data to useful information such as digital, three-dimensional models. Several companies worldwide provide this technique in various performances. These existing systems in the market are based on three scanning principles, for example, triangulation, pulse-based, and phase-based techniques.

A high speed phase-based three-dimensional laser scanner consists of two major components: the single point laser measuring system and the mechanical beam reflection system. A scan takes just few minutes as the system is developed for high-speed, high-performance, and eye-safe scanning tasks. Sampling rate up to hundreds of thousands of points per second can be achieved and the system works both in indoor and outdoor environments. Scanning ranges are from around 0.1 m to about 50 m in average lasers and up to few 100 m for the latest technology. The achieved measurement accuracy is in millimeter range and can also be performed in darkness. An interesting study of development of a prototype system that combines the noncontact measurement technologies of photogrammetric imaging and three-dimensional laser scanning to create dimensionally accurate and pictorially correct three-dimensional models and orthoimages of a rock slope can be seen in Kwong et al. (2007).

Optical technologies encounter many difficulties with shiny, mirroring, or transparent objects. The reflectivity of an object is based on the object's color or reflecting power of a surface. Transparent objects such as glass will only refract the light and give false three-dimensional information. Shiny objects can be scanned by covering them with a thin layer of white powder. A white surface reflects a lot of light and more light photons will reflect back to the scanner.

1.3.7.2 Infrared Thermography Infrared thermography or thermal imaging is example of infrared imaging science. Thermal images are visual displays of the amount of infrared energy emitted, transmitted, and reflected by an object. Thermography allows fast scanning of objects and produces immediate images in real time. It is a noncontact and remote measurement that can be used on both still and moving objects.

Thermography is used in many different areas as construction industry, condition monitoring and predictive maintenance industry. It is a safe and convenient method that allows large areas of structures to be surveyed quickly, remotely, and cost effectively. Improved camera and software technology have supported the use in many various applications within the construction industry. Detection of hidden structures, deterioration, moisture, and heat losses can also be performed.

A thermal imaging camera detects and measures invisible infrared energy being emitted from an object. Data are processed and images of that radiation, called thermograms with variations in temperature can be produced and plotted. It is very easy to produce these thermograms, but the interpretation of the information gathered takes both education and experience in order to perform proper analysis.

This noncontact method technique is very interesting and promising. Improved manufacturing efficiencies and product quality emerge new applications for Infrared Thermography. More information can be seen in the website of the Institute of Infrared Thermography (<http://www.infraredinstitute.co.uk/index.html>).²

1.3.7.3 Acoustic Emission A structure starts to deform elastically when it is applied to a load; either by internal pressure or by external mechanical loading. Thereby, the stress distribution and storage of elastic strain energy in the structure changes. Acoustic emission (AE) (Jaffrey, 1982) is a naturally occurring phenomenon that takes place and generates elastic waves with these before mentioned loading conditions that relate to rapid release of energy. It detects ultrahigh frequency sound that stressed materials release. Acoustic emission monitoring is classified as a passive nondestructive testing method and AE tests can be used to evaluate the structural integrity of a component or a structure, structural damage diagnosis, lifetime assessment and SHM.

In AE monitoring, a transient elastic wave generated within a material by rapid release of energy is electronically monitored. Defects are detected and located in real time while the phenomena are taking place and instant action can be taken in order to save resources and provide safety.

A lot of development took place in the past decades. This technique is reliable and there is genuine long-term practice (Miller and McIntire, 1987) to monitor material flaws, corrosion, leakage in tanks, pressure vessels, piping systems, and steam generators. Anyhow, AE monitoring have entered civil engineering field; and bridges, offshore structures, heritage structures, dams, and many other structures are monitored continuously. Phenomenon that is studied nowadays with AE monitoring is corrosion, occurrence, and extension of fatigue cracks, fiber breakages in composite materials or fiber breakages in bridge main cables, stay cables or pre-stressed cables as well as cracking in concrete or reinforce concrete members. This is also a perfect method to verify post-tensioning in a structure.

1.3.7.4 Ground-Penetrating Radar GPR is an accurate geophysical method. It uses electromagnetic waves to map the spatial extent of near-surface objects, interfaces, or

²Accessed March 1, 2011.

changes in soil media and produce images of those features. Radar waves are propagated in distinct pulses from a surface antenna, reflected off buried objects, features or bedding contacts in the ground, and detected back at the source by a receiving antenna. As radar pulses are being transmitted through various materials on their way to the buried target feature, their velocity changes, depending on the physical and chemical properties of the material through which they are traveling. When the travel times of the energy pulses are measured and velocity through the ground is known, distance (or depth in the ground) can be accurately measured. A three-dimensional data set is then produced. In the GPR method, radar antennas are moved along the ground in transects, and two-dimensional profiles of a large number of periodic reflections are created. There are now a number of commercially available equipments for civil engineering purposes (Conyers, 2002).

1.3.7.5 Remote Sensing Remote sensing is technology of obtaining reliable information on a given object or area either wireless, or not in physical or intimate contact with the object. Any form of noncontact observation can be regarded as remote sensing. Microwave Interferometry and Photogrammetry are good examples of remote sensing and presented latter.

1.3.8 Interferometric Radar

Interferometric radar is a pioneering revolutionary technology in the domain of geodetic measurements that is now spreading out to other areas such as civil engineering. The measurement device is coherent radar generating, transmitting, and receiving the electromagnetic signals to be processed in order to provide movement and deformation measurements (Gentile, 2010). Both static and dynamic measurements of structures can be performed. This noncontact method to measure objects distances up to kilometers is very convenient for many applications such as stay cables and main cables in bridges. No instrumentation is needed, traffic can continue and the method saves time, money, and resources.

1.3.9 Photogrammetry

Geometric properties of object can be determined from photographic images; this practice is called photogrammetry (Mikhail et al., 2001). The American Society for Photogrammetry and Remote Sensing (ASPRS) founded in 1934 is a scientific association. Their mission is to advance knowledge and improve understanding of mapping sciences to promote the responsible applications of photogrammetry, remote sensing, geographic information systems (GIS), and supporting technologies. They do define photogrammetry as follows (<http://www.asprs.org/>)

Photogrammetry is the art, science, and technology of obtaining reliable information about physical objects and the environment, through processes of recording, measuring, and interpreting images and patterns of electromagnetic radiant energy and other phenomena.

Photogrammetry is used in different fields: topographic mapping, architecture, engineering, manufacturing, quality control, archeology, meteorology, and geology; and it enables producing plans of large or complex sites very effectively. It can be divided to aerial photogrammetry, close-range photogrammetry or Stereophotogrammetry.

In aerial photogrammetry, a camera is installed on an aircraft and multiple overlapping photos of the ground are taken in order to create two-dimensional or three-dimensional models from aerial photographs. Close-range photogrammetry cameras are used to model buildings, engineering structures, vehicles, forensic, and accident scenes. The camera is normally set close to the subject and is typically hand held or on a tripod and the produced output is three-dimensional model or a drawing. In Stereophotogrammetry three-dimensional coordinates of points on an object are estimated. Two or more photographic images taken from different positions are required. Common points are identified on each image and a line of sight can be constructed from the camera location to these points on the object. Triangulation is used to establish three-dimensional locations of the points (Ackermann, 1984). A lot of information such as publications, and so on, can also be found on the web of the International Society of Photogrammetry and Remote Sensing (ISPRS) (<http://www.isprs.org/>).³

Monitoring of crack origin and evolution with photogrammetry can be seen in Benning et al. (2004).

1.3.10 Smart Technical Textiles

Technical textiles are frequently used in civil engineering and geotechnical applications for reinforcing, repairing, or retrofitting purposes (Veldhuijzen Van Zanten, 1986). Typical applications in civil engineering domain include repair of damaged parts of structures (e.g., cracking of the bridge deck), retrofitting of seismically weak structure (e.g., old masonry structure). Typical geotechnical applications include reinforcing bearing capacity of soils beneath foundations (e.g., dams, dikes, tunnels) and stabilization of landmasses prone to subsidence or sliding (e.g., to prevent land sliding, or creation of sinkholes).

Once the technical textile is applied to the host structure, there is a need to evaluate both its performance and the performance of the host structure in long term, in order to assess effectiveness of the technical textile application and the improvement made to the host structure. It is important to detect any deterioration in the performances, since it may lead to failure of the structure. Two parameters that are of particular interest for assessment the condition of civil structures are strain and temperature. In geotechnical applications, besides these two parameters, monitoring water pressure and leakage is important for assessment of condition of reinforced soils and foundations.

By embedding a monitoring system in the technical textile, the latter is transformed into an innovative intelligent multifunctional material—smart textile—that simultaneously provides both reinforcing and monitoring capabilities. An integration of sensors into the technical textile is functionally beneficial for both parties. The sensors provide with assessment of performances of the technical textile, whereas the latter provides for protection and an easy and practically inexpensive installation of the sensors, because they were integrated in the technical textile during the production. Thus, research is being performed in order to create a multifunctional technical textile with monitoring capabilities (e.g., Messervey et al., 2010).

Various sensing technologies can be embedded in the technical textile; however, the fiber-optic sensors seem to yield the most promising results. Sensors based fiber Bragg gratings (FBG) are particularly suitable for embedding in layers of technical textiles used to repair and retrofit civil structures such as bridges and buildings

³ Accessed March 1, 2011.

(Messervey et al., 2010), owing to their small size and both serial and parallel multiplexing capability. Distributed sensing technologies are particularly suitable for embedding in technical textiles used in geotechnical applications, since they provide with coverage of long lengths (up to several kilometers), which are characteristic for geotechnical structures (Belli et al., 2009).

Besides the developments in domain of traditional, glass fiber-based sensors, research is ongoing in domain of plastic optical fiber based sensors too (Liehr et al., 2009). Although the plastic fiber features significantly higher losses, and consequently can be applied to cover limited length (few hundreds of meters), they are highly deformable (few tens of percents of the original length), which makes them particularly suitable for monitoring large deformations such as found in geotechnical applications.

The first smart technical textile based on Brillouin scattering in glass optical fibers appeared on the market and they are commercially available. The research is ongoing, and various new products are expected emerge in the next decade.

1.3.11 Specific Issues Around Usage of New Technologies

Structures such as wind turbines are increasing, they are often located in remote areas with difficult or no access at all. They do require new kind of solutions in order to be monitored. Lot of research is ongoing in the field and solutions can be adapted from other areas like from offshore structures that also have no easy accessibility.

Other important structures and structural components difficult to access are the insides of main cables and stay cables in bridges, heritage structures in poor condition, residential areas of high-rise buildings, surfaces of tunnel structures, and so on. Sensors can be required implemented by manufacturers when producing components, as installation is difficult or impossible afterwards.

New technologies are merging the field and techniques from other engineering fields as well as monitoring methods are adapted to civil engineering purposes. These applications might though lack long-term experience; therefore, it is good to perform proper investigations when choosing the technology so that capital is not invested in nonproven technology. Small-scale test in the field is sometimes appropriate to prove, if the technique is feasible in the given circumstances. It is also very important that the installation is done in a proper way; otherwise, there is a risk to jeopardize the function of the whole system.

1.3.12 Chosen Technologies and Motivation

Many large construction projects were instrumented with thousands of sensors in the last decades. New technologies entered the field and a lot of heuristic knowledge was gained when working with new technologies, both in theory and in practice.

FOS appears to have a bright future, and a lot of research has been going on presently. Corrosion is present in reinforced concrete and steel structures; therefore, better methods for corrosion monitoring need to be found in order to provide long lasting structures and to save capital. New NDE techniques offer for straightforward monitoring and testing of structures. True information about old structures can be recorded in order to avoid uncertainties and malfunctions.

First, the chosen technologies and areas of interests are FOS, acoustic emission, radar technology, WIM applications, and GPS, as they have shown their adaptability to civil engineering structures in recent decades.

And second, corrosion monitoring as this issue is present in nearly every structure and huge amounts of capital can be saved if corrosion problems can be solved. New developments and the chosen technologies that have potential for SHM of civil structures are discussed below.

This chapter does not discuss wireless sensing technologies as wireless structural monitoring systems are still in their infancy. A detailed overview in designing wireless sensing units for the health monitoring of civil structures can be seen in Lynch (2007). The chapter has reviewed the design of a number of different wireless sensing unit prototypes that have been designed explicitly for structural monitoring applications. The firmware required to operate the units and to locally interrogate structural response data and a case study is presented, and a novel wireless active sensing unit design is proposed.

1.4 FIBER-OPTIC TECHNOLOGY

1.4.1 General

An optical fiber is a thin, transparent fiber, usually made of fused silica for transmitting light over large distances with very little loss. The diameter of the optic fiber is similar to that of a human hair and the core of it serves to guide the light along the length of the optical fiber. There are both single mode and multimode fibers: the core of the single mode fiber is very small, 5–10 μm , whereas core of the multimode fiber is around 50 μm . The core is surrounded by cladding with slightly lower index of refraction than the core. The purpose of the cladding is to minimize the losses and also physically to support the core region as the light propagates in the fiber. Optical fibers operate over a range of wavelengths; 1310 and 1550 nm is common for single mode fibers with minimal losses and 850 and 1300 nm for multi mode fibers.

Development and research is ongoing; existing technology is improved and new products appear on the market continuously. Clear and detailed descriptions over the different fiber-optic technologies can be seen in Measures (2001). The book is highly relevant still today and a perfect introduction into fiber-optic sensors, interrogators, and related aspects.

Several companies working with fiber-optic sensors were founded in the 1990s in collaboration with universities. Several doctoral theses, as well as books were published about various kinds of fiber-optic systems and SHM related topics. Fiber-optic sensors, smart materials, and structural technology were developed, and examples can be seen in Udd (1991, 1995), Inaudi (1997), Vurpillot (1999), Glisic (2000), Clark et al. (2001), Glisic and Inaudi (2007), and Imai et al. (2009).

The high performances of the fiber-optic sensors (FOS) are intrinsically linked to the optical fiber itself. The optical fiber can be used for both sensing and signal transmission purposes. The silica of which the optical fiber is composed is an inert material, which is resistant to most chemicals in wide range of temperatures and is, therefore, suitable for applications in harsh chemical environments (Udd, 2006). Various packaging especially designed for field applications made fiber-optic sensors robust and safe to use even in very demanding environments (Udd, 2006; Glisic and Inaudi, 2007).

The light used for sensing purposes in the core of the optical fiber does not interact with any surrounding electromagnetic (EM) field. Consequently, the fiber-optic sensors are intrinsically immune to any EM interference (EMI), which contributes significantly to their long-term stability and reliability. The ability to measure over distances of several

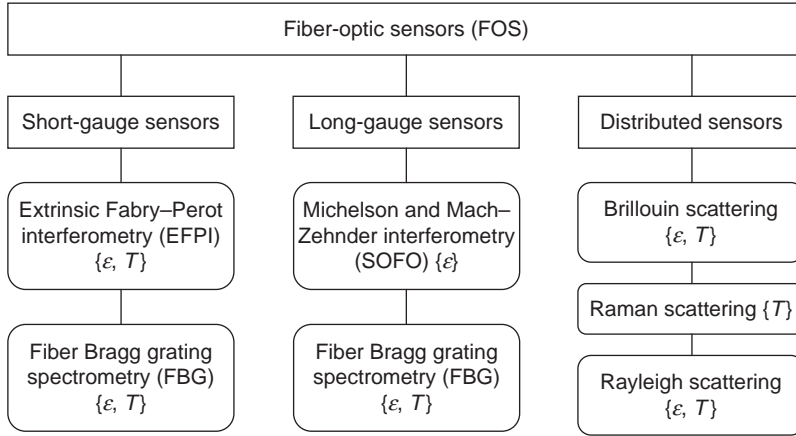

FIGURE 1.1 Division of FOS based on gauge length and functional principle.

tens of kilometers without the need for any electrically active component is an important feature when monitoring large and remote structures, such as landmark bridges, dams, tunnels, and pipelines (Udd, 2006).

Fiber-optic sensors cover large spectrum of parameters that can be monitored (e.g., strain, inclination, temperature, humidity); thus, multiple parameters can be combined on the same network (e.g., Del Grosso et al., 2005). Compared with conventional electrical sensors, fiber-optic sensors offer two new and unique sensing tools: long-gauge strain sensors and truly distributed strain and/or temperature sensors. The former can be combined in topologies that allow for global structural monitoring while latter allows for one-dimensional strain field and integrity monitoring.

As the area of fiber-optic sensors is really wide, it is not possible to present every single technique. Sensors that are generally used in civil engineering applications and their division based on gauge length and the functional principle are presented in Figure 1.1.

Recent significant developments in the optical telecommunications market helped reduce the cost of the FOS, which is still higher compared with conventional sensors, but, however, affordable and justified by superior long-term performance of the FOS. In this section, several FOS techniques are presented, along with their typical applications and summaries of the best performances. Many sensors like the ones based on fluorescence are mostly used for medical and chemical applications and are beyond the scope of this chapter.

1.4.2 Sensors Based on Sagnac, Michelson, and Mach–Zehnder Interferometers

Sagnac interferometer, also called as a fiber-optic gyroscope (FOG) is a gyroscope that uses the interference of light to detect mechanical rotation. This is very developed sensor and principally used for rotation rate measurements as well as in aerospace engineering. Two counter propagating light beams travel along the fiber inside an interferometer in opposite directions. As the path is closed and same for both beams, the beam traveling against the rotation experiences a slightly shorter path than the other beam. This is called Sagnac effect. This sensor can also be used in dynamic measurements but is not well known in commercial civil engineering applications.

FIGURE 1.2 Schematic representation of standard SOFO sensor.

Both Michelson and Mach–Zehnder interferometers are easy to understand and manufacture. They are pretty similar in appearance: two fiber beams are inserted with light and then a relative phase shift between these beams is measured in order to measure eventual length difference. In the Michelson interferometer, the end of the fiber paths includes chemical mirrors that reflect the light back to the photo detector. Mach–Zehnder interferometer has two outputs instead of the mirrors and the light passes the fiber paths and is then measured by a photo detector. Michelson interferometer-based decoder allows for very stable, long-term static measurements, whereas Mach–Zehnder interferometer allows for very sensitive short-term dynamic measurements. A detailed description of Michelson Interferometer that is commercially available is given in the following subchapter.

1.4.2.1 SOFO Michelson interferometer that is proven in large number of projects (Glisic et al., 2010a) is called SOFO (French acronym for Structural Monitoring using FOS, Inaudi, 1997). The standard SOFO sensor comprised two zones: the active zone that measures the deformations, and the passive zone that serves as the carrier of information between the active zone and the reading unit. The sensor is schematically represented in Figure 1.2.

The active zone is limited by two anchor pieces and consists of two optical fibers placed in a protection tube. The anchor pieces have a double role: to attach the sensor to the monitored structure and to transmit the deformation from the structure to the sensing fiber. The measurement fiber is pretensioned between the anchor pieces in order to measure the shortening of the structure as well as its elongation. The reference fiber is independent of both the measurement fiber and the deformation of the structure, and its purpose is to compensate for temperature changes. Both fibers have mirrors silvered at their extremities.

The passive zone transmits the information from the active zone to the reading unit. It comprised one single-mode fiber, connector, and coupler, which are all protected by a plastic tube. The coupler is placed in the passive zone of the sensor, close to the anchor piece in order to increase the precision and to facilitate the manipulation during the measurement.

The light inserted in the passive zone is split into two fibers of active zone, travels to the extremities and reflects back off the mirrors. Since two fibers have in general different length, a shift in phase is created between the two reflected lights, and this shift in phase is proportional to the length difference in the optical fibers. The deformation of monitored structure will be transferred only to measurements fiber while the reference fiber remains unchanged. As a consequence, the shift in phase will change. The shift in phase is converted to length difference in the reading unit, which contains decoder in form of Michelson interferometer.

TABLE 1.1 The Best Performances of Discrete FOS

	Interferometric (SOFO)	Fiber Bragg Gratings (FBG)	Fabry–Perot (EFBI)
Gage length	250 mm–20 m	10 mm–2 m	51–70 mm
Multiplexing	Parallel	In-line and parallel	Parallel
Maximum number of sensors in the network	Static: unlimited; dynamic: 8	16 channels 5–10 sensors/channels	32
Stability	Static: long term	Long term	Long term
Resolution	Static: 2 μm ; dynamic: 10 nm	0.2 me	$\pm 0.01\%$ full scale
Repeatability (precision)	Static: <0.2% of measured value	<1 $\mu\epsilon$	N/A
Dynamic range	Static: –5,000 to +10,000 $\mu\epsilon$; dynamic: ± 5 mm	–5,000 to +7,500 $\mu\epsilon$ packaging dependent	$\pm 3,000$ $\mu\epsilon$
Temperature sensitivity	Self-compensated	Compensation needed	Insensitive or packaging dependent
Maximum measure frequency	Static: 0.1 Hz; dynamic: 10 kHz	0.5 MHz	20 Hz

The SOFO sensor is true long-gauge sensor, because the light “integrates” the strain along its gauge length, which is typically limited between 20 cm and 10 m. The best performances of the SOFO system are given in Table 1.1, and applications can be seen in Enckell and Larsson (2005) and Enckell (2006).

1.4.3 Sensor Based on the Fiber Bragg Gratings

Fiber Bragg gratings (FBG) consist of periodical changes created in fiber core by appropriate exposing to ultraviolet light (Dadpay et al., 2008). If the light containing certain range of wavelengths is inserted into the fiber with an FBG, the latter will reflect back one specific wavelength and let pass through all the other wavelengths, as shown in Figure 1.3. The specific wavelength that is reflected depends on optical properties of the FBG that were preimposed by manufacturing process. The optical properties of the FBG depend linearly on strain and temperature. Increase in one or both of these parameters will

**FIGURE 1.3** Principle of FBG sensors.

practically change the wavelength that is reflected back to the light source. By determining the difference from initial wavelength it is possible to determine strain or temperature in the FBG. Since the change in wavelength depends on both strain and temperature simultaneously, strain sensors must be compensated for temperature using an appropriate procedure. The typical length of an FBG is several millimeters, thus, depending on packaging, they can be used either as short-gauge sensors (fiber-optic equivalent for classical strain-gauges) or as long-gauge sensors (e.g., if the fiber with FBG is pretensioned between two anchoring points). There is a large variety of both types of the sensors available on the market.

The source and decoder for FBG-based sensors are usually combined in the same device. The source is able to generate desired range of wavelength, while decoder measures intensity of reflected light and determines reflected wavelength using tunable laser with wavelength filter (e.g., Fabry–Perot cavity) or spectrometer. Both static and dynamic measurements are possible, depending on type of the reading unit.

An important advantage of FBG-based sensors is that several gratings with different specific wavelengths can be placed along a single fiber, allowing an easy multiplexing. Thus, several sensors can be read from a single channel on the reading unit. The total number of sensors that can be placed along single line depends on range of strain and temperature changes in the monitored structure. For typical civil engineering applications, involving steel or concrete structure, this number varies between 5 and 10. The best performances of the FBG sensors are given in Table 1.1.

1.4.4 Sensors Based on Fabry–Perot Interferometry

The previously presented sensors, SOFO and FBG, are called intrinsic sensors, because the optical fiber is used as the sensing body. Fabry–Perot interferometric sensors can be either intrinsic or extrinsic, but latter was proven to be more effective and reached market maturity, and that is why they are presented in this section. Schematic principle of functioning of an extrinsic Fabry–Perot interferometric (EFPI) sensor is shown in Figure 1.4.

The sensor consists of lead fiber and target fiber, both cleaved at 90° and both with partially reflective surfaces. There is a few millimeters air gap between the cleaved surfaces. The broadband light is sent from the source (multimode optical fiber is used as opposed to single-mode used in the case of SOFO and FBG sensors) through lead fiber. When the light reaches the cleaved end of the lead fiber a part of it is reflected back to the reading unit, and the other part passes through the air gap, reflects off the surface of the target fiber, and re-enters in the lead fiber. Two lights are then combined in the lead fiber into an optical signal (constructive or de-constructive interference of several wavelengths)

FIGURE 1.4 Schematic principle of EFPI sensors.

that contains information about the size of the air gap (Krohn, 2000). This information is finally decoded in the reading unit.

The lead fiber is connected to target fiber using a packaging with purpose is to couple the sensor to the structure. Any deformation of the structure will result in the change of the size of the air gap that is sensed by optical signal and determined in the reading unit.

The great advantage of the EPFI principle is its insensitivity to temperature changes. However, depending on the gauge length of the sensor and the position of the anchoring points between the packaging and the optical fibers, sensitivity to temperature is often present due to thermal expansion of the mechanical components of the sensor, and in general the sensors should be compensated for temperature.

Besides the strain, the EFPI sensors can be packaged so that they can sense temperature and pressure. They can be made extremely small (practically the size of optical fiber is the lower size limit) in and they found many applications in biomedical domain.

In civil applications, the EFPI sensors face some limitations regarding multiplexing and remote position of the reading unit; however, the complete system for smaller projects or for manual measurements is less expensive than SOFO and FBG systems. The best performances of EFPI sensors are shown in Table 1.1.

1.4.5 Best Performances of Discrete FOS

The best performances of discrete FOS are for comparison given in Table 1.1. These performances were extracted from commercial data sheets and web page of various companies.

1.4.6 Distributed Sensors

Distributed sensor (or sensing cable) can be represented by a single cable, which is sensitive at every point along its length. Hence, one distributed sensor can replace large number of discrete sensors. A distributed sensor requires single connection cable to transmit the information to the reading unit, instead of a large number of connecting cables required in case of wired discrete sensors. Finally, distributed sensors are less difficult and more economic to install and operate. An illustrative comparison between pipelines equipped with distributed and discrete sensors is shown in Figure 1.5 (this schematic drawing does not refer to real case, e.g., redundancy is not included).

Although a distributed sensor is sensitive to measured parameters (strain and/or temperature) at every point of its length, it delivers measurements at discrete points that are spaced by a constant value, called the sampling interval, and the measured parameter is actually an average strain measured over a certain length, called the spatial resolution (Lanticq et al., 2009). The spatial resolution can be considered as the gauge length over which the measurement is made. Sampling interval and spatial resolution are two parameters characteristic for the distributed systems. They can be set by the user depending on application. However, they are correlated with resolution and precision of measurement, and the time of measurement, and the trade-offs must be made. For example, a measurement that is very precise, and sensitive (small spatial resolution), are slow, while a fast measurement affects one or both other parameters.

There are three main principles for distributed sensing in the domain of FOS: Rayleigh scattering (e.g., Posey et al., 2000), Brillouin scattering (e.g., Karashima et al., 1990), and Raman scattering (e.g., Kikuchi et al., 1988). Each technique is based on the relation

FIGURE 1.5 Distributed versus discrete monitoring; schematic comparison (does not refer to real case).

between the measured parameters, that is, strain and/or temperature, and encoding parameter, that is, changes in optical properties of the scattered light. This is schematically presented in Figure 1.6.

Rayleigh scattering can be used for both strain and temperature monitoring. It is based on the shifts in the local Rayleigh backscatter pattern, which is dependent on the strain and the temperature. Thus, the strain measurements must be compensated for temperature. The main characteristics of this system are high resolution of measured parameters and short spatial resolution, but the maximal length of sensor is limited to 70 m (Lanticq et al., 2009). Thus, this system is suitable for monitoring of localized strain changes over relatively short distances. Best performances achievable in strain monitoring using the Rayleigh scattering are given in Table 1.2.

Brillouin scattering can also be used for both strain and temperature monitoring. It is based on the change in frequency of Brillouin scattered light, which is dependent on the strain and the temperature. Thus, as in case of the Rayleigh scattering, the strain measurements must be compensated for temperature, and temperature measurements are to be performed with sensors containing a loose (strain-free) optical fiber. Both spontaneous (Wait and Hartog, 2001) and stimulated (Nikles et al., 1994, 1997) Brillouin scattering can be used for sensing purposes. Monitoring system

FIGURE 1.6 Scattered light properties as encoding parameter for strain and/or temperature measurements (Glišić and Inaudi, 2007, courtesy of SMARTEC SA).

TABLE 1.2 Comparison of Best Performances Achievable in Strain Monitoring Using Distributed Systems

	Brillouin, Stimulated	Brillouin, spontaneous	Rayleigh
Spatial resolution	0.5–5 m	1 m	10 mm
Sampling interval	100 mm	50 mm	10 mm
Maximum no. of sensing cables in network	16	N/A (1?)	N/A (1?)
Stability	N/A	N/A	N/A
Resolution	2 $\mu\epsilon$	30 $\mu\epsilon$ (“accuracy,” 2 RMS)	1 $\mu\epsilon$
Repeatability	N/A	<0.02%	N/A
Instrument range	$\pm 30,000 \mu\epsilon$	10,000 $\mu\epsilon$	$\pm 7,000 \mu\epsilon$
Maximum length of sensor	250 m to 5 km (up to 20 db)	N/A	70 m
Temperature sensitivity	Compensation needed	Compensation needed	Compensation needed
Measurement speed	10 s–15 min	4–25 min	4 s

based on stimulated Brillouin scattering is less sensitive to cumulated optical losses that may be generated in sensing cable due to manufacturing and installation, and allows for monitoring of exceptionally large lengths (Thevenaz et al., 1998), for example, in the case of strain monitoring, a single reading unit with two channels can operate measurement over lengths of 10 km, while in the case of temperature monitoring, the lengths of 50 km can be reached. Remote modules can be used to triple the monitoring lengths. The measurement specifications of Brillouin-based measurements are not as good as these of Rayleigh-based measurements; however, the great advantage of Brillouin-based systems is significantly longer length of the sensor (several kilometers). Thus, the Brillouin-based systems are better suited for monitoring global strain changes over large distances. Applications and different methods of Brillouin monitoring can be seen in Nikles et al. (2004) and Inaudi and Glisic (2005, 2006). The best performances in strain monitoring achievable with Brillouin-based systems are given in Table 1.2.

Raman scattering is the result of a nonlinear interaction of the light traveling in the silica fiber core and can only be used for temperature monitoring. It is based on the change in amplitude of Raman scattered light, which is dependent on temperature only. The insensitiveness of this parameter to strain is actually an advantage compared with Rayleigh and Brillouin-based temperature monitoring, since no particular packaging of the sensor must be made to make sensing fiber strain-free. Typical spatial resolution of Raman systems is 1 m, and typical resolution is better than 1°C. Since the leakage of pipelines, dykes, dams, and so on, often changes thermal properties of surrounding soil, besides the temperature monitoring; the Raman-based systems are used for leakage monitoring in large structures.

There is a sever tradition of monitoring dam constructions with Raman systems and some examples can be seen in Aufleger (1998).

1.4.6.1 Crack Detection with Distributed Techniques Crack-related parameters: detection, identification, localization, and quantification, can be measured with

distributed fiber-optics techniques. Brillouin-based technology for crack detection and crack width estimation is tested and discussed by Bao et al. (2005), Imai et al. (2009), and Nöther et al. (2009). Shi et al. (2005) and Zhang and Wu (2008) do report about distributed sensing system based on Brillouin scattering for monitoring geotechnical engineering structures and large Earth structures.

Enckell et al. (2011) do report about evaluation of a large-scale bridge strain, temperature and crack monitoring with distributed fiber-optic sensors (Ravet et al., 2009). The main goals of the system are to detect and localize new cracks, measure high strain, and unusual strain behavior. Also new methods and procedures in installing, testing, modifying, and improving a SHMS were developed, tested and proven, both in laboratory and on-site. The system sends warning messages to the bridge authorities with well-specified scenarios (Myrvoll et al., 2009; Enckell et al., 2011). The system is installed over five 1-km long girders of the Gota Bridge, Gothenburg, Sweden (Glisic et al., 2007, 2009) and monitoring is ongoing and intended to the last about 10 more years, to the end of the bridge's lifetime. This is the first application of distributed systems on the bridges at such a large scale.

1.5 ACOUSTIC EMISSION

1.5.1 Theory of Acoustic Emission

When a material deforms and cracks, the subsequent atomic rearrangement produces transient elastic waves, which is known as acoustic emission (AE). Degrading mechanisms within materials, such as cracking, corrosion, and yielding, which produce AE signals, are called sources. AE signals contain information about the nature and the severity of the changes occurring within the material. Signals propagate through the material away from the source. AE technology is a passive technique that detects these signals using surface mounted transducers (sensors). Active defects are point sources, emitting nondirectional AE, which radiate out in a spherical wave front and detection is permitted by sensors placed anywhere on the structure. AE has the ability to locate the position of active defects, using two or more sensors. Location is achieved by identifying the time of arrival of an AE signal at different transducers. AE has progressed greatly over the past 30 years, with the increase in computing power allowing increased accuracy through data filtering and processing, which has seen the establishment of many commercial applications. Advantages of acoustic emission are high sensitivity; early and rapid detection of defects such as corrosion, flaws, wire break, and cracks; real-time monitoring of structures in-service; cost and time reduction; defect localization; global and local monitoring; monitoring of nonaccessible zones; defective area location; repeatable; and the evaluation is comprehensive and source detection; and it is not limited by defects geometry. Disadvantages are complicated signal analysis that requires highly trained and experience personal, low signal to noise separation and difficulty to separate external noise in some applications.

1.5.2 Sources of Acoustic Emission

Sources that emit detectable AE are numerous; in fact most materials emit AE when they are put under load. Common sources include the fracture of ice cubes in a drink or the

crunch of an apple being eaten. Acoustic emission can be generated by many mechanisms, which include

- Fracture of crystallites/inclusions
- Crack nucleation and propagation
- Micro-cracking including fracture of inclusions
- Phase transformations in solids (e.g., martensitic)
- Boiling and electrical discharge (electrical transformers)
- Matrix cracking (fiber-reinforced plastics)
- Delamination (concrete and fiber-reinforced plastics)
- The creation, annihilation of point, line or surface defects

Other forms of acoustic emission mechanisms commonly encountered include

- Mechanical sources, for example, pumps, actuators
- Joints and supports of structures, for example bridge expansion joints and bearings

Practitioners of AE try to differentiate between real damage sources and extraneous noise. Fundamental to the identification of signals of an individual application is the development of a database. A database contains examples of AE data from tests where the origin of the signals was confirmed either through visual inspection or other nondestructive testing. Using source confirmed AE examples, AE data taken in relatively blind conditions can be attributed to a certain type of source and be used to measure the severity/significance of damage.

1.5.3 The Development of Acoustic Emission in Industry and Civil Engineering

The technology was born in the early 1960s when it was recognized that growing cracks and discontinuities in fiber reinforced plastic tanks and pressure vessels could be detected by monitoring their acoustic emission signals. Measuring bridge fatigue crack growth in steel with acoustic emission can be seen as early on as 1972 (Pollock and Smith, 1972), with further fatigue work documented in later in the decade (Sinclair et al., 1977; Lindley et al., 1978). Great advancements were made from the 1990s by Cardiff Universities research into steel bridge fatigue using modern fast DSP AE systems coupled with neural network software (Carter and Davies, 1996; Watson et al., 2001; Pullin et al., 2007). AE studies of concrete structures were predominantly led by research and application in Japan, in particular by professor Ohtsu (1987) and professor Shigish and Dr. Yuyama (Ohtsu and Yuyama, 2000). This Japanese looked at the application of AE on a variety of common concrete construction elements; beams, columns, foundations and slabs. In situ tests were carried out on concrete docks, pylon foundations, bullet train bridges, tunnels, and an arch dam. The ability of acoustic emission to detect wire break has long been recognized (Holford, 1996) and is now commonly employed on both suspension bridges and post-tension concrete ([http://www.ndtnews.org.2008](http://www.ndtnews.org.2008;);⁴ http://www.mistrasgroup.com/news/itn/print/09012010_BDE.pdf).⁵

⁴Accessed February 25, 2011.

⁵Accessed January 27, 2010.

1.5.4 Acoustic Emission Systems

A typical AE system comprises a high speed digital signal processor (DSP), AE processing boards with individual processing channels for each sensor (i.e., a nonmultiplexing system) and the ability to program the settings for signal thresholds and frequency range to enable the AE signal to be filtered. It should also have software for source location in one, two, and three dimensions, feature extraction capability to allow characterization of the signals, and stable software for long-term monitoring. The acquisition of raw RF waveforms is a distinct advantage for source analysis. An AE signal is recorded when the signal reaching the sensor exceeds a threshold value, set by the operator in order to avoid recording unwanted noise (e.g., 30–45 dB is generally satisfactory for most bridges). AE sensors are piezoelectric crystals that convert movement (a variation of pressure) into an electrical voltage. The sensors must all have an identical response and they should be calibrated annually. They are normally held in place using metallic clamps for steel structures or bonded to concrete. These are connected to the AE system using coaxial cables with shielding to prevent electromagnetic interference. There are two types of AE sensor: resonant and broadband. Resonant sensors are more sensitive to sources at particular frequencies—thus, sensor spacing can be maximized—and they help minimize background noise by filtering out unwanted frequencies. Sensors with a low-resonant frequency are more susceptible to noise but high-frequency signals are readily attenuated which limits their use. A resonant frequency of 30–100 kHz is typical for concrete applications; whereas 100 and 200 kHz is used for metallic structures. Higher frequency sensors can be used in high noise environments but only for local monitoring due to the higher attenuation at these frequencies.

1.5.5 Codes, Standards, and Recommended Practice in Acoustic Emission

ISO standards exist for calibration of acoustic emission sensors

- ISO 12713 : 1998 (ISO, 1998)
- ISO 12714 : 1999 (ISO, 1999)

The American Society for Testing and Materials (ASTM) has several standards concerning acoustic emission technology and monitoring⁶

- ASTM E1106-07 (ASTM E1106-07, 2007)
- ASTM E1781-08 (ASTM E1781-08, 2008)

Example of European and British standards for AE can be seen in

- BS EN 1330-9:2009 Nondestructive testing terminology part 9: terms used in acoustic emission testing (British Standard, 2009)
- BS EN 13477-2:2001 Nondestructive testing—acoustic emission—equipment characterization (British Standard, 2001)
- BS EN 13554:2002 Nondestructive testing—acoustic emission—general principles (British Standard, 2002).

⁶Accessed January 27, 2010.

Procedures and recommended practices for steel and concrete structures monitoring by acoustic emission have been developed and can be seen in

- BA86/06 Advice notes on the nondestructive testing of highway structures—Section 3.3—acoustic emission by the UK highways agency defines a wide range of uses of AE and guidance for use on concrete and steel structures. Specific case studies are defined (Highways Agency, UK, 2006).
- Recommended practice for in situ monitoring of concrete structures by acoustic emission, by Ohtsu and Yuyama (2000) reports about AE monitoring for concrete structures.
- A proposed standard for evaluating structural integrity of reinforced concrete beams by acoustic emission by Yuyama et al. (1999) for evaluating structural integrity.
- Acoustic emission for bridge inspection, report no. FHWA-RD-94—prepared for FHWA and U.S. Department of Transportation, June 1995. This defines the use of AE for local area monitoring of steel defects (Physical Acoustics Corporation, 1995).
- Developments for the nondestructive evaluation of highway bridges in the United States (Washer, 1998).
- Development of an advanced structural monitoring system for fracture critical steel bridges (<http://www.lrrb.org/pdf/201039.pdf>).⁷

Golaski from Kielce University of Technology has also published an overview (Golaski et al., 2002) concerning AE monitoring of reinforced concrete bridges. AE studies of other concrete structures can be seen in Ohtsu (1987), Matsuyama et al. (1993), Colombo et al. (2002), and Watson et al. (2002). Publications from American universities around AE testing and monitoring can be seen in Fowler et al. (1998) and Hamstad and McColskey (1999). A study of stress corrosion cracking of high-strength steel used in prestressed concrete structures by AE can be seen in Ramadan et al. (2008).

1.6 RADAR TECHNOLOGY

1.6.1 General

RADAR is an acronym coined in the 1934 for radio detection and ranging (Buderi, 1996). The first ground-penetrating radar survey was performed in Austria in 1929 to sound the depth of a glacier (Stern, 1929, 1930). The technology was largely forgotten until the late 1950s when U.S. Air Force started investigations into the ability of radar to see into the subsurface. A system much like Stern's original glacier sounder was proposed, built, and sent on Apollo 17 to the Moon (Simmons et al., 1972) in 1972 to study the electrical and geological properties of the crust.

1.6.2 Ground-Penetrating Radar

Ground-penetrating radar (GPR) is one of the most inclusive archaeological geophysical methods because it collects large amounts of reflection data and produces massive three-dimensional databases. It can also locate objects and map features without any risk of

⁷Accessed January 27, 2010.

damaging them (Conyers, 2002). GPR is now available for other areas, and it is an effective nondestructive tool for structural analysis. It offers a set of unique solutions featuring dedicated high-frequency antenna configurations and three-dimensional software processing solutions. GPR can be used in various applications: utility detection and mapping, civil engineering, geology, geophysics, geotechnics and environment, archeological and cultural heritage, forensic, and security. Ground-penetrating radars for civil engineering nondestructive surveys of structures and buildings provide valuable information on: concrete thickness and inner rebar structure, presence of wall cavities, presence of water, and reconstruction of wall internal structure.

The principal operation for GPR uses electromagnetic wave propagation and scattering to image, locate and quantitatively identify changes in electrical and to some extent magnetic properties in the object that is under survey. A surface antenna or several antennas produces radar waves that are propagated in distinct pulses in the microwave band of the radio spectrum. These waves are reflected off buried objects and detected back at the source by receiving antenna/antennas. As radar pulses are transmitted through various materials on their way to the buried targets, their velocity changes depending on the physical and chemical properties of the material through which they travel (Conyers, 2004; Conyers and Goodman, 1997). Velocity of energy pulses through the ground is known, and their travel times are measured so can their distance be accurately measured to produce a three-dimensional data set (Conyers and Lucius, 1996). When a radar pulse traverses a material with a different composition or presence of water, the velocity changes and a portion of the radar energy are reflected back to the surface and recorded at the receiving antenna/antennas. Data can be plotted in many different formats, depending what is suitable for the project; it may be plotted as profiles, as plan view maps isolating specific depths, or as three-dimensional models.

Modern GPR also uses high- and low-frequency antennas (dual frequency antennas) that allow for better detection performance; both shallow and deep targets can be detected with a single scan (Simi et al., 2010). Possible errors are reduced and the method saves both time and money. The penetration depth depends on the soil conditions, and these devices can be attached to vehicles, trolleys, or other devices that might be practical in a specific project.

One of the most actual and crucial need in highway engineering is the maintenance and rehabilitation of existing road. There are specialized GPRs for road, railway, and tunnel surveys. Another special application for civil engineering is bridge deck surveying. Deck surveying detects early phase deterioration and current damage to concrete bridge decks. This method can also be used with old structures where drawings are missing in order to locate reinforcement layers and/or prestressing cables, their position and current status. Load capacity of these bridges can, therefore, be calculated.

An example of a novel GPR system for high resolution inspection of walls and structures can be seen in Sarri et al. (2002). This chapter gives an overview, describes the theory, reports measurements and calculations and highlights the field test results. These field test results also confirmed excellent performance of the system.

Use of GPRs in civil engineering structures such as bridge decks, walls, heritage structures, roads, railway beds, and many other applications is innovative and offers real-time information about the real condition of the structure. These are very promising techniques and their use can save a lot of money and time as well as provide safe structures without hidden malfunctions. Two different setups can be seen in Figure 1.7.

FIGURE 1.7 (a) Setups for bridge pavement measurements. (b) Setup for soil measurement with several units connected together (Courtesy of IDS).

1.6.3 Interferometric Radar

Instruments based on radar Interferometry for the measurement of displacements and vibrations were developed in last decades (Farrar et al., 1999; Tarchi et al., 2003) and are now commercially available. For example, landslides, mine slopes, volcanoes, glaciers, dams, bridges, towers, and buildings can be monitored with submillimeter accuracy.

Ground-based radar interferometry is a pioneering revolutionary technology in the domain of geodetic measurements that is now spreading out to other areas such as civil engineering. The measurement device is coherent radar generating, transmitting, and receiving the electromagnetic signals to be processed in order to provide movement and deformation measurements (Gentile, 2010). This new technology allows also dynamic measurements of structural vibrations such as resonance frequencies and vibration modes up to 100 Hz. The method is based on the detection of amplitude and phase of an electromagnetic wave transmitted by the instrument and reflected back from the object to be measured. Each submillimetric displacement gives rise to a phase difference of the reflected wave that is detectable by the radar. More comprehensive introduction to theory of the radar Interferometry can be seen in Rödelsperger et al. (2010).

The instrument is installed on a tripod that allows the movement in the desired area or direction. The complete equipment consists of a radar instrument, a control PC with adequate software in order to store, process, and view the data. The high-resolution capacity over distance provided by the radar produces a displacement map showing the displacement of many points across the entire target. The radar samples that target about every 0.5 m, which correspond as if the target was applied with large amount of sensors. Normally, every structure has reflective points in itself and does not need any additional equipment. Anyhow, there is a possibility to apply passive radar reflectors to the points of interest if needed.

These systems are excellent early warning system. The great benefit with radar interferometry radar compared with current technology is remote operation. No contact whatsoever with the target to be monitored and no complicated or time consuming installation is required. The system is able to supply continuous deformation maps with an extraordinary measurement speed as well as accuracy. Simultaneous displacement of the entire scenario can be remotely measured to distances up to kilometers. Wide area monitoring of landslides provides up to several square kilometer monitoring at once. The measurement is not dependent on weather conditions and high accuracy of 0.01–1 mm can be

reached. Rödelberger et al. (2010) also list advantages and disadvantages of the radar technology compared with various common monitoring techniques as follows

Advantages:

- Remote sensing instrument
- Simultaneous monitoring of all targets within the beam
- Independence of daylight and weather
- High accuracy and spatial resolution

Disadvantages:

- High dependence on atmospheric effects
- Relative displacements in line of sight (LOS) only
- Difficult point localization (georeferencing of target points)

Gentile and Bernardini (2009) also discusses advantages, limitation as well as possible applications of the radar based measurements. He also reminds about following issues that are good to keep in mind when handling with radar techniques to bridges and large structures:

As a consequence of the one-dimensional imaging capabilities of the radar sensor, measurement errors may arise when different points of the structure are place at the same distance to the radar

The radar provides a measurement of the variation of the target position along the sensor's line of sight (i.e., the radial displacement); hence, the evaluation of the actual displacement requires the prior knowledge of the direction of motion.

Manhattan Bridge from 1909 suffered of fatigue cracks and was stiffened under several contracts after 1980. Mayer et al. (2010) describes monitoring of the vertical and torsional displacements of the midspan of the Manhattan Bridge using Interferometric Radar and Global Positioning Systems (GPS). Figure 1.8 shows the Interferometric Radar equipment

FIGURE 1.8 Interferometric radar equipment in front of the Manhattan Bridge (Courtesy of IDS).

in front of the Manhattan Bridge. The bridge testing provided valuable information about the dynamic characteristics of the structure, effects of the stiffening and also verified that the deflections and resonant frequencies measured with these different technologies compared well with one another.

1.7 GLOBAL POSITIONING SYSTEM

The global positioning system (GPS) systems are space-based global navigation satellite systems that provide reliable location and time information anywhere on or near the Earth. A comprehensive introduction to global positioning system (GPS) can be seen in El-Rabbany (2002). According to Rizos (2002), relative positioning techniques can be divided into following classes: (1) static and kinematic surveying techniques, (2) differential GPS (DGPS), and (3) real-time kinematics (RTK) techniques. Plentiful applications can be found in land, marine, and air navigation. Nowadays, GPS has also found its way to civil engineering applications. It is weather independent but needs an unobstructed line of sight to five GPS satellites in order to perform SHM of large structures; long-span bridges, high-rise buildings, high industrial chimneys and towers are some of the current targets.

The major distinction between static and kinematic baseline measurements involves the method by which the carrier wave integer cycle ambiguities are resolved. A network or multiple baseline approach for positioning is normally used in static applications. Static GPS system can also have multiple receivers, multiple baselines, multiple observational redundancies, as well as multiple sessions. Adjustment of observations is performed by least squares; therefore, the system is very accurate. The disadvantage is that the observation time is also longer: around an hour to several hours.

Real-time kinematic (RTK) positioning requires two receivers that record observations simultaneously. Postprocessing of the data to obtain a position solution is not required and real-time surveying in the field can be performed. Advantage is that the measured data can be checked directly. Modern GPS systems use real-time kinematic surveying; direct and absolute measurements in real-time are achieved.

Improvement to GPS is called differential global positioning system and it uses a network of fixed, ground-based reference stations to broadcast the difference between the positions indicated by the satellite systems and the known fixed positions. DGPS needs to receive a correction signal using a separate radio receiver in order to perform. A “base station” antenna is placed near to the target on a stable reference place with line of sight to at least five orbiting GPS satellites so no signals are reflected. Antennas that are placed on the structure in monitoring points are called rover antennas. The base station receiver calculates its position based on satellite signals and compares this location to the known location. The difference is applied to the GPS data recorded by the roving GPS receiver. When the base station calculates and broadcasts corrections for each satellite as it receives the data, it becomes a real-time application.

Accuracy of the order of 1 mm can be obtained using GPS, although not necessarily with real-time systems. The alternative to the real-time mode is the processing of data saved by separate receivers.

Brownjohn et al. (2004) reports about testing the feasibility of GPS for building performance monitoring for Republic Plaza high-rise building in Singapore with a dual-rover RTK GPS system in order to provide ultralow frequency response data. This chapter

describes the system integration for the present monitoring system and presents some results on performance of the building and the GPS system.

Roberts et al. (2010) do report about monitoring bridges by Global Navigation Satellite Systems (GNSS). The work reported investigates the use of kinematic GPS and compares results to the FE modeling. Seven different bridges, of various sizes and types are investigated, and the results show that GNSS is valuable tool to monitor the movements, and the characteristics of the movements of bridges.

Example of monitoring earthquakes by GPS monitoring systems is the instrumentation of the medium span cable-stayed Naini Bridge in India. GPS rovers have been installed at the pylon tops (see Figure 1.9) of the bridge in order to monitor for settlements of the pylons as these have been constructed by use of an unusual foundation method based on thinking wells. By using the advanced GPS monitoring program DEMON by Eiva, Denmark, it has been possible to carry out very accurate RTK GPS measurements with accuracy down to 2 mm lateral and 5 mm vertical by postprocessing data based on special algorithms. These include computation of absolute positions from pseudorange (code) observations, preliminary validation of single difference baseline observations, the computation of relative positions using code and carrier or carrier only observations and the computation of the GPS satellite orbit repeatability period, which is used to reduce or eliminate effects due to multipath in the baseline results (Bhanushali et al., 2006). The Kashmir Earthquake October 8, 2005 was recorded with this system, even though the earthquake occurred 800 km from the bridge. Figure 1.10 shows output from the bridge SHMS with lateral pylon vibrations with amplitudes up to 50 mm.

Modern GPS provides high performance and real-time measurements, they are easy to install and have shown to be suitable for measurement and SHM purposes for various civil engineering structures.

FIGURE 1.9 GPS at pylon top of Naini Bridge, India (Courtesy of COWI).

FIGURE 1.10 The Kashmir earthquake that occurred 800 km away was recorded on the Naini Bridge by the COWI operated SHMS; Figure 1 shows output from the bridge SHMS with lateral pylon vibrations with amplitudes up to 50 mm.

1.8 CORROSION MONITORING SYSTEMS

Corrosion is a huge problem and causes damage, failure, and uncertainty in structures. The loss of capital caused by premature deterioration in structures is large. Undetected corrosion may also cause collapse of the structure and thereby lost of human lives. Corrosion is present in aggressive environments and structures in these environments should be provided with adequate SHMSs for corrosion monitoring. “Techniques for corrosion monitoring” (Yang, 2008) gives a review of corrosion fundamentals and provides a four-part comprehensive analysis of a wide range of methods for corrosion monitoring, including practical applications and case studies. The book reviews electrochemical techniques for corrosion monitoring, such as polarization techniques, potentiometric methods, electrochemical noise and harmonic analyses, and galvanic sensors, differential flow through cells and multielectrode systems. In addition, the physical or chemical methods of corrosion monitoring such as gravimetric, radioactive tracer, hydrogen permeation, electrical resistance, and rotating cage techniques are then presented.

As part of a durability strategy for reinforced concrete (RC) structures in aggressive environments (marine or polluted) corrosion monitoring sensors can be installed. Sensors can be embedded in concrete from the first beginning so that the moisture content and temperature of the structure can be monitored during the curing process to ensure maximum strength of the concrete. Once construction is complete, the instrumentation can be used to conduct long-term monitoring of corrosion conditions over time (Dunn et al., 2010). Another issue with reinforced concrete infrastructure in order to prevent deterioration is cathodic protection. It controls the corrosion of a metal surface by making it the cathode of an electrochemical cell. It is important to know the timing for applying the cathodic protection and there are various measuring devices for that purpose. Many electrochemical measurements only record the corrosiveness of the environment at the time of taking the reading. In order to evaluate the effectiveness of the cathodic protection, it is common to use devices that measure cumulative metal losses. The whole corrosion profile

FIGURE 1.11 Electrodes placed at successive depths can sequentially be measured to locate the depth to which the chloride had ingressed into the reinforcement and thereby the corrosion front can be established (Buhr et al., 2010) (Courtesy of COWI).

in time is recorded by the probe and more accurate decisions in maintenance planning can be taken.

Traditional corrosion monitoring sensors for RC are typically a set of carbon steel electrodes A1–A4, which are small pieces of reinforcement with a specified concrete cover placed within the structural steel cover. The carbon steel electrodes are intended to be used as anodes. They are galvanically discontinuous, that is, they are not in electrical contact with the structural reinforcement.

These embeddable probes monitor ingress of aggressive substances, particularly chlorides. Figure 1.11 illustrates the depth to which the chloride had ingressed into the reinforcement and thereby the corrosion front can be established.

An interesting study of corrosion monitoring in concrete structures of Copenhagen Metro can be seen in Buhr et al. (2010). In all 170 sets of corrosion probes were installed to have a prewarning system for corrosion in the concrete cover. The article describes the monitoring system and highlights the results from the pilot installation. Another study (Dunn et al., 2010) presents a reinforced concrete corrosivity monitor including linear polarization resistance, open circuit potential resistivity, temperature, and a potential related to chloride ion concentration.

There is a wide variety of fiber-optic sensors for corrosion and humidity measuring purposes. Many of these sensors are aimed at reinforced concrete measurement and a lot of research in ongoing (Srinivasan et al., 2009).

Corrosion problem also occurs in steel constructions and the most common methods to protect the steel are coating, painting, and weathering steel. The coating/paint must be robust and properly applied in order to provide protection in the existing environment. Monitoring corrosion of the external surface of steel structures using potential or voltage techniques is also common. Weathering steel is steel with special chemical constellation that forms a protective layer on its surface under the influence of the weather. The surface of the steel corrodes by forming a dense and tightly adherent oxide barrier that seals out the atmosphere and retards further corrosion

(Roberge, 2006). Weathering steel is commonly used in sculptures, marine transportation, chimneys, and buildings.

Monitoring corrosion of some delicate structures such as steel oil pipelines to determine the state of corrosion is required by law in the United States. Many bridge structures also do suffer of combined corrosion and fatigue effects and do require monitoring for safety and maintenance reasons. The Silver Bridge over the Ohio River failed from the corrosion cracks in an eyebar killed 46 people in 1967 (Kulicki et al., 1990), and Oakland Bay Bridge in San Francisco also had problem with cracks that may have been caused by vibrations from wind and rumbling traffic united with corrosion.

Acoustic Emission methods can also be used for corrosion monitoring. The emission from corrosion usually releases much less energy than emission from crack growth and the sensor frequencies used to detect these signals are determined more on the basis of the environmental noise under test conditions than on the frequency spectrum of the emission (Cole and Watson, 2005).

Newer structures use optimized steels and coating materials that can provide much longer service lives to improve the performance of the structures and hopefully more reliable structures can be offered in the future while capital is also saved.

1.9 WEIGH-IN-MOTION (WIM) SYSTEMS

1.9.1 Weigh-in-Motion

Weigh-in-motion is a technology for measuring the weight of moving vehicles, and it is commonly used for trucking terminals, seaports, toll roads and bridges, and border crossing. Many heavy vehicles are weighty and do also exceed legal limits and can cause severe damage to roads and bridges. Accurate information about vehicle axle loads is important in order to make prognoses for traffic development as well as in construction and maintenance planning (Quilligan, 2003). Seaports and trucking terminal do acquire exact weight of cargos for loading purposes.

Various WIM systems have been developed around various technologies. Emerging WIM systems are being developed around new technologies such as fiber optics.

The most common weigh-in-motion systems include

1. Load cell
2. Bending plate
3. Piezoelectric
4. Fiber optic

Load Cell WIM systems use a single load cell with two scales to detect an axle and a weigh both the right and the left side of the axle at the same time. The system records the weights measured by each scale and summarizes them in order to count the axle weight while the vehicle passes over the load cell. Bending Plate WIM systems use with strain gauges bonded to the underside of the plates. The system records the strain measured by the strain gauge and calculates the dynamic load while a vehicle passes over. Piezoelectric WIM systems use piezoelectric sensors to detect the voltage change caused by the pressure exerted on the sensor by an axle while passing over. The system records the electrical charge created by the sensor and calculates the dynamic load.

Several WIM solutions with fiber-optic sensors have been presented in recent years. The advantage of these sensors is that they can be embedded deeper in the road surface that provides highly protective environment. These sensors are also simple to install and maintain and their lifetime is equal or better compared with conventional sensors (Kunzler et al., 2003). Also, the cost of fiber-optic sensors is competitive nowadays and as the new technology will improve, it might eventually replace the ones currently in use.

Bending-plate and piezoelectric WIM systems work to reasonable accuracies for traffic moving at motorway speeds. These technologies provide sufficiently accurate data for the statistical review of traffic and the development of structure specific assessment live loading. These sensors will detect vehicles without disrupting traffic flow. These sensors are ideal for installation on main thorough-fares such as motorways or dual-carriageways.

High-precision weight measurement for law enforcement is achieved well with weigh-bridges based on load cells. However, weigh-bridges tend to require slow transition by the vehicle being weighed in order to achieve high accuracy. Clearly, the installation of such a device for the measurement of all vehicles would require all vehicles to slow down in order to be weighed. This is only feasible at gated toll stations and would also require a large number of devices to cover the entire toll lanes provided.

For structures as very large bridges, it is important to track the total traffic load on the bridge. An accurate assessment of total traffic load is best achieved by the measurement of weight of all vehicles. A WIM system that can operate without interfering traffic flow is therefore also appropriate. With the weighing of all vehicles, accuracy on measurement of $\pm 10\text{--}15\%$ would be sufficient for determining the total traffic load on a bridge, and would also be sufficient for the purposes of poststatistical review for the development of bridge specific assessment live loading.

Typical WIM systems will be designed in accordance with the design requirements as presented in ASTM Standards (ASTM E1318-09). Other considerations to the choice of WIM system include maintenance requirements and system lifetime.

1.9.2 Railway Weigh-in-Motion

As for the WIM systems, the railway weigh-in-motion (R-WIM) market is under development. Old systems that are available frequently require the slow passage of trains by the measurement of loads transferred from the rails to the sleepers, or from the sleepers to support structures. Emerging in-line wheel load weighing systems are now available and can detect overloaded wagons as well as damaged wheels and flat spots. These systems are now used by railroad companies to check the operational safety and to identify possible unsafe wagons. It is not suitable for trains to be slowed down for weighing prior to crossing any structures to be monitored. Therefore, a system that has minimal impact on the railways shall be selected. Kistler Rail WIM based on quartz sensor technology is currently providing such a system (see Figure 1.12).

1.9.3 Bridge Weigh-in-Motion

Bridge weigh-in-Motion (B-WIM) was first developed in the late 1970s (Moses, 1979). A lot of development took place in the latest decade (Quilligan, 2003; Leming and Stalford, 2003), and there is also a commercial system on the market. B-WIM is the process by which axle and gross vehicle weights of trucks traveling at highway speeds can be

FIGURE 1.12 KISTLER—Rail WiM (using quartz sensor technology) (Courtesy of Kistler).

determined from instrumented bridges. B-WIM systems involve attaching strain sensors to the soffit of a bridge and placing sensors for detecting axles in order to provide information on vehicle velocity, axle spacing's and position of each vehicle. This is done either with axle detectors on the road surface axle detectors or by placing additional strain sensors under the bridge. Obrien et al. (2008) do give a comprehensive overview about latest development as well as applications in Europe and Japan.

1.10 COMPONENTS OF STRUCTURAL HEALTH MONITORING SYSTEM

It is important to have an appropriate comprehension of the structure and elements of a SHMS. In order to be able to design sustainable SHMS solutions as well as to integrate the advantages offered by a SHMS into structural design and operation, a short introduction to SHMS components is given.

Following common outline highlights the elements integrated in the SHMS solution

- Sensory system located on the structure; It consists of various types of sensors depending on the nature of the structure; Signal collection, synchronization, conditioning, and digitization units may also be included;
- Data acquisition systems to execute preprocessing and local buffering for sensors distributed in a limited geographical area on the structure; Portable and/or fixed systems are possible;
- Data communication system for the transfer of the collected data to a remote computer;
- Data processing and control system with database application that collects, stores, and processes the raw data in real time;
- User interface;
- Maintenance tools;
- Interfaces to external systems.

The task of the SHMS is to monitor the in situ behavior of a structure accurately and efficiently, to assess its performance under various service loads and environmental conditions, to detect damage or deterioration, and to help determining the health or condition of the structure. The SHMS system should be able to provide reliable information regarding safety and integrity of a structure. This information can be incorporated into maintenance and management strategies of the structure, as well as in improved design guidelines.

1.10.1 Sensory System

A sensor is a type of transducer that converts a physical property into a corresponding electrical or optical signal. As the number of various sensing technologies is large, it is important to have a sound general knowledge about them, in order to select the most suitable for a specific structure. It is favorable to choose commercially available sensors that are well proven in similar circumstances as the intended structure.

On the other hand, emerging technologies do lack that experience in many cases. The recommendation is to establish a thorough testing schedule and procedure that will proof the feasibility, functionality, installation issues as well as the long-term function of the complete sensory system, hardware, software, and other data acquisition equipment for the completed installation. Qualified, experienced, and competent testing team with representatives from stakeholders is to be established. External experts with both long-term theoretical knowledge and practical experience need to be part of the testing team. Testing starts with a focused technical specification: measurement parameters and prospective measuring techniques are specified. The results shall be verified against the technical specification and the testing aims. It is complimentary to start in small scale if anything unexpected would happen so no unnecessary capital is wasted.

The sensory system will include the sensors and their corresponding interfacing units for input signals gathered from various monitoring equipments and sensors. Detailed guidelines about SHM issues are given in Aktan et al. (2001). This report is directed to bridges but gives also general appropriate knowledge about sensor performance characteristics and helps the reader with sensor selection criteria.

1.10.2 Data Acquisition System

Data acquisition system converts the physical phenomenon measured by sensors into digital numeric values that can be operated by a computer. Modern monitoring systems have a tendency to grow rather large and over-instrumentation is common (Brownjohn, 2007). All data acquisition modules need also to be synchronized and preferable a fiber-optic network is used for communication. A local area network (LAN) is commonly used in SHMSs. The network connects computers and devices and ensures a high level of redundancy. Communication protocol is also specified.

Data acquisition system consists of hardware, software, and secondary equipment such as connectors, cables, and cabinets. Many SHMS have need for unique solutions and the data acquisition system can be adapted for these special needs, that is, so-called tailored solution can be offered.

1.10.3 Data Processing and Control System

Data Processing encompasses automatic conversion of the raw data into useable information. It consists of data collection, transmission, preprocessing, analysis, postprocessing, and storage of the data in a format that is easy to access and present.

Larger SHMSs do have a control room where supervisory control and data acquisition (SCADA) are normally located. The master screen in a control room can be either a desktop display with the ability to transfer data between different functions quickly and easily, or a large display wall. This wall can be divided into various monitoring areas with different functions.

Various operators will work with the SHMS either permanently or at chosen intervals. The man-machine interface may be established for the SCADA and will be used for display of general interest's views from the SHMS monitored systems. The system will visualize in real time all collected information, in the most suitable way for an immediate and efficient representation (graphs, tables, videos), and will allow the search, visualization, and elaboration related to user specified periods. Example of the control room design with SCADA can be seen in Figure 1.13.

1.10.4 User Interface

The conventional SHMS solutions have been forced to use local, workstation based user interfaces due to various limitations. The modern solutions though, do use a universal and standard based web interface. Generally, the goal is to create a user interface that makes it

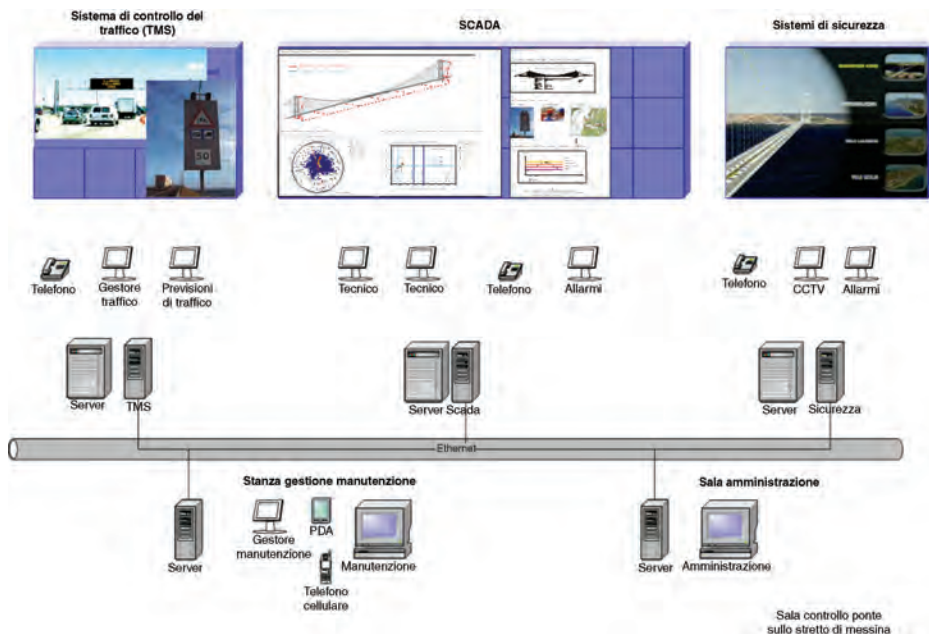

FIGURE 1.13 Example of control room design with Traffic Control, SCADA and Security Control (Courtesy Stretto di Messina).

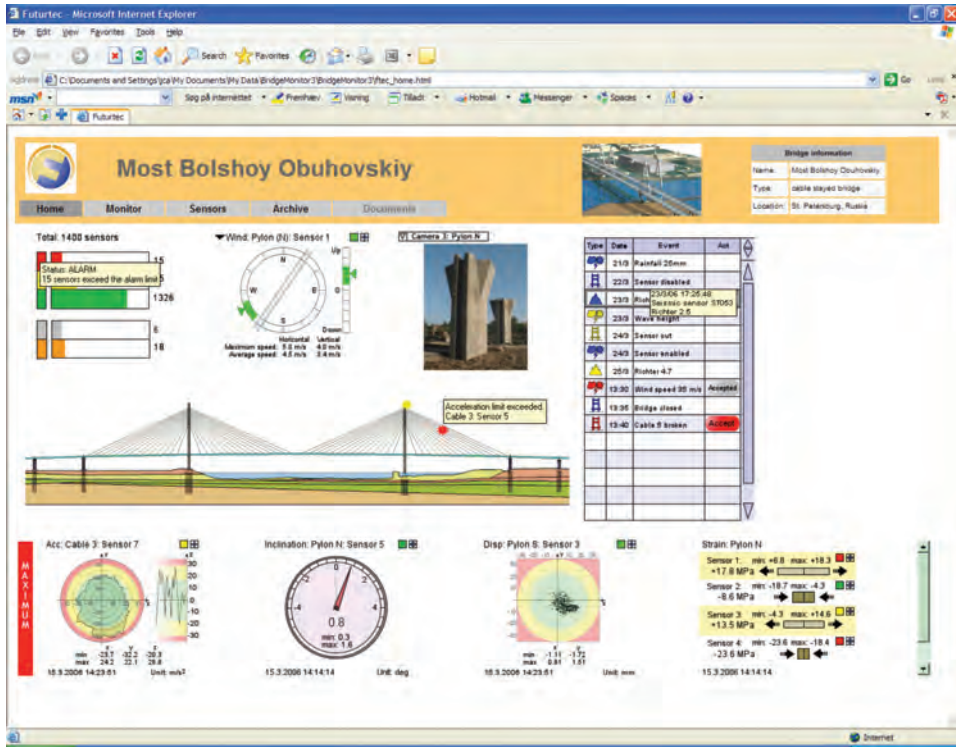

FIGURE 1.14 Optimized Internet user interface at the Neva Bridge (Courtesy of Futuretec OY, Finland 2006).

easy, efficient, and pleasant to operate a system while producing the desired results. The user interface has to be optimized to the different phases of the lifetime of the structure; construction, testing, operation, and extreme (unplanned) events. The measurement system should be redundant and indeed error resistant.

The role of the user interface might change over the years. The user interface should be as simple as possible as even small user interface problems when repeated day after day get to be intolerable in long term. The interface must be planned to give the minimized output and modifications to the monitoring system or to the user interface should be few and cautiously considered to minimize the need for personnel retraining. The management system of the structure must work so that it enables operators to understand and trust the information provided by the system and rapidly act on it regardless of tools, time and space. See Figure 1.14 for an example of the optimized Internet user interface.

1.10.5 Maintenance Tools

Maintenance tools are required for the inspection and maintenance purposes of the whole SHMS. A Portable inspection and maintenance system is located on the structure and can be used if problems should occur. Many emerging technologies do need some special tooling and furthermore training in problem finding and solving.

1.11 STRUCTURAL HEALTH MONITORING SYSTEM DESIGN

An appropriate SHMS for a structure should be able to provide, on demand, reliable information pertaining to the safety and integrity of a structure. Critical parameters, load conditions, and environmental circumstances are monitored, preferably with the minimum amount of sensors. The more straightforward the system is the simpler it is to perform data processing and reliable information about the real structural conditions of the structure in real time can be extracted and presented.

1.11.1 Structural Analysis for New Structure

The structural analysis is a preliminary task and the core of a favorable monitoring. Identification of the structure and the parameters that are to be monitored is done cautiously in order to choose the most important features to be monitored. Feature identification concludes a review of drawings and any relevant information about design uncertainties, special care is given to new complicated design as well as new material constellations.

A complex structure often requires a complex SHMS. Measurements need to be comparable with the calculations, analytical models and FEM in order to allow for calibration. Technical requirements for desired sensors are established.

1.11.2 Structural Analysis for Existing Structure

Existing structures do provide a lot more information; drawings, inspection protocols, maintenance actions, retrofitting/strengthening of the structure, noted problems, test sample results, measuring data, concerns, or verified structural weakness. It is also possible to visit the structure and perform a visual inspection. The structure can also be tested and classified in order to find the most relevant features for monitoring.

Technical requirements for desired sensors are established.

1.11.3 Sensor Selection

Sensors that will fulfill the technical requirements established in the structural identification are chosen with care. The chosen sensors need to be commercially available and proven technology and installation procedure for all chosen sensors are studied in detail. The choice of sensors may involve collaboration with various experts in several fields of engineering depending on project complexity. If dealing with emerging technologies where experience lacks, and some uncertainties do exist, a small structural test or test installation can be performed in order to clear these uncertainties.

Locations of the sensors, cables, connection boxes, data loggers, central units, and communication systems are decided and drawings are established. If temporary monitoring devices under the construction are needed, they are also listed in detail and the list of equipment and the schedule of temporary monitoring is established.

1.11.4 Data Acquisition Issues

Data acquisition components that are compatible with selected sensors and which will fulfill the technical requirements established in the structural analysis are chosen. Measurements schedule for every sensor is established. Output signal of a

sensor is either analogue or digital. The conversion of an analogue to a digital signal is performed by an analogue-to-digital converter (ADC). Many electrical sensors need signal conditioning and filtering in order to allow for transmission and postprocessing of the signal. In general, methods for data quality assurance, analysis, and processing are invented for all types of sensors. Civil engineering SHMSs tend to be large in size and signals need to be transmitted over long distances, many times up to few kilometers. Therefore, the data transmission needs to be well planned, to prevent data corruption or any loss of data.

Many projects are unique with unique needs: if the commercial software for the sensors is not adequate, it has to be calibrated and tested. System servicing and troubleshooting procedures after the installation are also described and planned in detail. The criterion for the database is established.

If the safety purposes are included in the designed monitoring system, the warning and alarm subsystem is designed and created. Criteria for decision making with alarm or warning, reporting schedule, and the form of documentation are established.

1.11.4.1 Data Analysis and Data Mining Comprehensive data analysis is a key issue to successful application of a SHM. Data mining is the process of extracting patterns from large data sets by combining methods from statistics (statistical pattern recognition) and artificial intelligence. Data analysis may allow for damage location and quantification as well as for condition assessment. Comparison between the measured values and FEM is also part of the scope and allows for model calibration and updating, and maintenance planning. Different approaches such as frequency and time domain analysis for evaluation and interpretation of measurement data can be found in FIB Guidelines (<http://www.ishmii.org/wp-content/uploads/2010/07/FIB-Task-Group-Europe.pdf>).⁸

The SHMS will collect synchronized measurement data, status of sensors and fault notice generated by the individual subsystems and equipment. The on-site operator shall have the possibility to request displays of all current measured points, values or status, initiate logs and reports on events, notice and confirm alert, and alarm description. The SHMS shall also be designed to be as user friendly as possible: information that is available need to be straightforward as the operators may lack the ability to understand and judge procedures behind the analysis. Emerging technologies do set new requirements for operators and education is needed in order to avoid mistakes and malfunctions. Requirements for training and education should be presented and scheduled.

1.11.4.2 Data Access Accessibility and easy localization of measured point, time and data is an important challenge in large projects, because the size of the collected raw data can be up to terabytes. The access requirements differ for various stakeholders. The designer desires to find data that can be compared to his original design calculations. The construction engineer desires values that describe what is happening in the structure at the moment of construction and testing. The operator's desires values that describe how the structure is operating under load during the operation and the unit responsible for maintenance planning desires values that describe how the structural behavior changes in the long term.

In order to design an efficient platform for all stakeholders, all specific needs are collected and evaluated. Technical requirements are established and procedures for different groups are defined. The key point about access to the data archive is that all access

⁸Accessed January 27, 2010.

methods have to use open protocols and to have a documented key feature with “ease of access” in mind, then just documenting the data access protocols is not sufficient.

1.11.4.3 Data Storage and Data Archival If possible, all raw data are stored and later archived as it is uncertain what types of information will be needed or useful in the future, during the expected lifetime that could be up to 200 years. Data storage consideration will reflect the model for data organization. Depending on the extent and purpose of data storage, the monitoring system can be structured to fulfill the specified requirements as follows:

- None
- Ad hoc reports at random/selected periods
- Statistic
- All raw data
- Processed data

For small monitoring systems designed to support the user safety of the bridge, one can choose only to save alarms and warning events when these are exceeding preset trigger values; consequently, storage of any other measured data will not take place. Limited data saving can also be the strategy for those monitoring systems based on ad hoc, random or selected period reports, thereby reflecting the periods when the monitoring system is in operation.

Ad hoc measurement based on portable SHMS is often subject to discard many measured data and archive only those that are needed for the analysis work, as the measurement points of these systems are often mobile and the measurement from the sensors can differ from time to time.

Data archival is essential in large projects and inactive or noncritical data will be transferred to a particular type of long-term storage media. Archived data generally consist of primary copies of the data being stored.

1.11.5 Responsibilities and Installation Planning

Responsibilities for the incorporated partners are well defined in order to avoid malfunction, inaccuracy, and delays. All deliveries, installation, and testing are planned in detail, and timetables and schedules are established. The opportunity to highlight requirements, standpoints and expectations for the system is given to all incorporated partners so that changes can be made upon request.

After the final decision is taken about the SHMS components, it is necessary to make a detailed installation plan. It is recommended to pay a visit to the existing structure on-site in order to make a visual inspection and recognition. Attention is paid for accessibility to the structure from the installation point of view. The condition of surfaces, need for fixing the concrete surface, grinding the steel surface free from corrosion and paint, need for scaffolding for installation to be able to reach the installation points and be able to fasten the sensors in a proper and safe way to the structure, possible position for equipment and cables, access to electricity and any other concern is carefully investigated onsite. For structures under construction, the timetable of the construction steps is studied carefully, and a timetable for the installation of the sensors is established. A visit is paid to the construction site if possible, and all insecure installations are considered once more and

tested if needed. If any divergence from the planning is noted, all the partners are to be contacted in order to find a new solution. In complicated concrete constructions, the timetable for reinforcement need to be studied carefully for easy and rapid installation if the sensors are to be fixed on the reinforcement.

The complete installation plan is distributed to the owner, contractor, installation team, and any other part that is involved in the process so that they are able to request changes. If required, the installation plan is revised until all parts have approved it (Enckell, 2006).

1.12 SYSTEM PROCUREMENT AND INSTALLATION

1.12.1 System Procurement

Construction lead times for minor and portable systems are typically calculated in weeks or months and most of their components are available immediately. Mid to large size system engineering and construction can take from a few months to several years including a number of complete subdeliveries from the construction period to the operation phase.

Following tasks are recommended

- Application development has to be carried out under a verified quality system.
- All hardware components need to undergo component level testing prior to integration.
- All application modules have to undergo component level testing prior to application testing and resulting into the actual SHMS hardware.
- Integration and testing of all required specifications are performed prior to the final factory acceptance test that is a requirement for shipping authorization. A client representative is typically present at FAT that generally takes a few days to complete.

1.12.2 Commissioning

Commissioning assures that all subsystems and components of a SHMS are designed, installed, tested, operated, and maintained in accordance to the technical requirements of the owner. Various techniques and procedures to check, inspect, and test all components from individual sensors to data analysis subsystems are used in order to allow quality assurance.

The SHMS manufacturer is also responsible for all other supplies such as installations performed by local subcontractors. Sensor and processor installations, component connections, and testing are always the responsibility of the SHMS supplier's specialist personnel.

Significant part of the commissioning is the operator and maintenance training. Written user instructions such as Operation and Maintenance manuals in local language as well as clear and fast on-line search and help functions are required. On the large and long-term projects lasting for years or even decades, it is challenging to ensure integrity of the system due to additions and changes to the initial scope during the project. The possibility for modification of the existing technology and integration of the new technology is a requirement. The SHMS supplier should be capable to offer remote service for software maintenance, updates and debugging and these requirements have to be part of the initial operating system and application design.

1.12.2.1 Factory Acceptance Tests (FAT) A factory acceptance test demonstrates that the sensors and related hardware and software operate in accordance to technical specifications. FAT is documented and does test functionality, communications, support systems, error management, and interface requirements.

The client is generally present and shall approve FAT. Any unapproved equipment shall be rejected or subject to repair. FAT is especially important for emerging technologies due to the uncertainty of the potential issues that may exist.

1.12.2.2 Site Acceptance Test (SAT) The site acceptance test is an important verification of the SHMS and important test for manufacturer. This test shall be performed after the installation and will guarantee that the system works in accordance to the design parameters and technical requirements. It is advisable that the SAT is done in three phases:

1. Functional test of the whole system (no loading on structure).
2. Calibration of the system parameters during the load tests of the structure.
3. Verification of the calibrated parameters during the operation.

Unapproved sensors shall be rejected or subject to repair. If installed sensors are rejected, alternative measurement techniques shall be established.

1.12.3 Installation

Installation procedures that are described in the literature seem often to point out that the installation is an easy process. Anyhow, in the practical case it is often the opposite. This misleading information is causing a lot of expectations and may cause malfunction and might decrease the quality of the system. Installation is a complex matter and related issues are highlighted in this section.

A good collaboration with the contractor is vital as it is important to get information about delays and changes in construction or schedule rapidly. The workers on the construction site must be informed about the sensor installation so that a positive attitude is created in order not to damage the sensors. Need for the necessary equipment and personal is controlled.

Installation of the sensors and devices is performed following the installation plan and with the presence of experienced personal.

The works to be done before actual installation are the following (Enckell, 2006):

- The sensors and devices to be installed are delivered, checked, and quality controlled.
- The personnel installing the sensors are well informed about the installation procedure and trained so it has a good understanding of the sensor devices. When installing novel sensors, it is necessary to give personnel additional education about the sensors and installation procedure.
- The necessary equipment is procured and if necessary tested.
- Data acquisition systems are calibrated and the software is programmed and tested in the office.
- A lot of practical details often delay the project; therefore, it is good to check the following: access to the construction site, safety regulations, other activities that

might collide with the installation at the building site, access to electricity and facilities for the personnel, and so on.

- Passages for the cables, and so on, are realized in advance if possible. This is especially important in new concrete structures where the plastic pipes or similar facilities need to be cast in advance.

The works to be done in actual installation are the following ones (Enckell, 2006):

- The sensors and devices are installed in accordance to the installation plan and drawings.
- If any changes are made, they must be noted so that the drawings can be revised and updated.
- The installation, as performed, is described in detail in a diary and documented with photographs.
- The sensors are tested, measured, and calibrated if possible or necessary.
- If there is a risk for damages, the sensors are protected or marked.
- The sensors are connected to the data logger for temporary or permanent measurement, or if they are not to be used directly, they are protected or set in a safe place.
- If temporary measurements are performed during some stage of the construction the measurement equipment is protected against damage and marked clearly.
- In the case of a new concrete construction and sensors are to be embedded, it is recommended that the responsible engineer is present during the casting in order to supervise the casting and ensure the survival of the sensors.

The works to be done after installation of the sensors and cables are the following ones (Enckell, 2006):

- The sensors and devices are connected to connection boxes, data acquisition systems main units, and so on, according to installation plan and drawings.
- The communication system is established.
- The cables are fixed temporarily or permanently on the cable rack.
- If any changes are made, they must be noted so that the drawings can be revised and updated.
- The installation as realized is described in detail in a diary and documented with photographs.
- The system is tested.
- The system and monitoring results are verified by other systems, models, or calculations.

Correct installation procedure in the field is highly important for trustworthy results and for the long-term quality of the monitoring system, especially with the installation of the new and emerging technologies. Many projects have unique requirements; therefore, it is not possible to describe a general procedure that covers all details for all the projects. Good and detailed planning saves time and thereby the costs for the installation and ensures qualified installation.

1.12.4 Lifetime Support

The SHMS component availability is typically guaranteed for 10–30 years. Operating system, user interface and application support services in the future could be highly variable, depending on the supplier and can pose a serious risk to the stakeholder if an improper choice is made.

As the lifetime expectation for the solutions in question is over a decade and potentially it should last for several decades, the safest choice is to require the system to be based on an open source operating system such as Linux, user interface to be built into a standard web browser and internal communications utilizing extensible markup language (XML). Ensuring support for the application itself can only be achieved by requiring a third party software escrow arrangement as even the largest vendors cannot provide guarantees for the required competence availability after several years. SHMS should be as flexible as possible in order to guarantee the long-term function and upgrades.

1.12.5 System Efficiency and Redundancy

The system has to provide full and detailed information storage under disaster conditions to enable fast recovery and postdisaster off-line analyses. In fact, the most critical usage pattern for the monitoring system is during disaster recovery. This dictates the requirements for user interface simplicity and intuitiveness as well as a remote data storage service at the supplier's server.

1.12.6 Dismantling Environmental Issues

A plan for dismantling and waste collection needs also has to be established. The materials used should be environment friendly and chemicals used in the installation procedures as well. Safety instructions need to be clearly stated if any risks are present.

1.13 APPLICATION OF STRUCTURAL HEALTH MONITORING SYSTEMS

Authors of this chapter have been working with emerging technologies: both in theory and in practice. Several both small-scale and large-scale installations and measuring campaigns are completed and SHMSs are designed, mostly for international major bridges but also for other structures such as high-rise buildings and heritage structures.

In the 1970s, the first structural monitoring was mainly based on simple instrumental loops for automatic data acquisition from some critical points of the structure. This trend has slowly been developed from relatively small systems logging only semi-static parameters to today's modern turnkey SHMS distributed data acquisition systems with a high degree of build-in structural evaluation and decisional support.

Some SHM projects are presented here. These projects give an image of SHM projects with advantages, disadvantages, malfunctions, and uncertainties through the past decades.

1.13.1 High-Rise Building, Singapore—2001

Singapore is a cosmopolitan city-state often described as a gateway to Asia with a city landscape of tall buildings. The Housing and Development Board (HDB), as Singapore's public housing authority, has an impressive record of providing a high standard of public

housing for Singaporeans through a comprehensive building program. As part of quality assurance of new HDB tall buildings, it was decided to perform long-term structural monitoring of a new building of a project at Punggol East Contract 26 (Glisic et al., 2003).

1.13.1.1 Quick Facts

Name and Location: Punggol East Contract 26, Block 166A, Singapore

Owner: Multiple

Structure Category: High-rise building

Start of SHMS: 2001 (during construction)

Number of Sensors Installed: 10 discrete long-gauge strain sensors

Instrumentation Design by: SMARTEC and HDB

1.13.1.2 Description of the Structure The Punggol EC26 project consists of six blocks with pile foundations; each block is a 19-storey building, with six units supported on more than 50 columns at ground level. The block called 166A was selected for monitoring. The photographs taken during construction and upon completion are shown in Figure 1.15.

This monitoring project is considered as a pilot project with two aims: to develop a monitoring strategy for column-supported structures such as buildings, and to collect data related to the behavior of this particular building providing rich information concerning their behavior and health conditions. The monitoring is to be performed during whole life span of the building, from construction to the in use. Thus, for the first time; the sensors are used in a large-scale life cycle monitoring of high-rise buildings.

1.13.1.3 Purpose of the Instrumentation The monitoring strategy was developed based on the different criteria presented in detail in the literature (Glisic et al., 2003). The main requirements were to perform long-term SHM of a representative number of critical structural members, and that is why fiber-optic sensors were selected. Ten ground floor columns were selected as being the most critical elements in the building, whereas the

FIGURE 1.15 Building at Punggol EC26: (a) during construction and (b) upon completion (Courtesy of SMARTEC, HDB, and Sofotec).

number of sensors was adapted to the available budget. The identification of columns was based on numerical modeling. The dominant load in each column is an axial compression force; therefore, it is supposed that the influence of bending on deformation can be neglected. Consequently, a single sensor per column was installed parallel to the column axis. The gauge length of the sensors was determined with respect to the available height of the column (3.5 m) and on-site conditions; hence, 2 m long sensors were used.

Several columns at the same level (storey) in a building of simple topology create a so-called scattered simple topology (Glisic and Inaudi, 2007). The analysis of a scattered topology consists of several algorithms that are to be applied in order to assess the global structural behavior. Supposing the floor slab to have high stiffness, the columns supporting the slab are expected to deform by similar absolute values and the total strains in different columns are expected to be in mutual linear correlation. The column with foundation subject to settlement will elongate while the neighboring columns will shorten. In this case, the linear correlation between the elastic strains of the columns is lost.

1.13.1.4 Examples of Outcomes Average strain evolution is for 10 monitored columns presented in Figure 1.16. A period of 9 years is presented in the figure and several events are highlighted. Three periods in strain evolution can be identified in Figure 1.16: (1) May 2001–July 2002 is construction period and all the factors: load, creep, shrinkage, and temperature variations have visible influence to total strain; (2) July 2002–January 2005, creep and shrinkage have dominant influence to total strain (temperature influence is minimized by reduced exposure of columns to direct sun); (3) January 2005–May 2010, rheologic strain components stabilize slowly and the daily thermal strain fluctuations become more visible.

Detailed data analysis is presented in literature Glisic and Inaudi (2007) and Glisic et al. 2010b, and here only the summary of main findings is presented.

FIGURE 1.16 Nine-year record of strain evolution in the building (Courtesy of HDB, SMARTEC, and Sofotec).

During construction, Column C9 had the strain that is significantly lower than other columns, though its change is proportional to other columns in the period of construction. The explanation for this behavior is found in lower load level at this location.

In Singapore, the temperature is very stable over the year, and only small fluctuations of strain are registered on a daily and yearly basis.

Earthquake in neighboring Indonesia in 2005 generated a tremor that was felt by inhabitants of the building. A measurement session was performed immediately, and as the strain change measured after the tremor was within the ranges measured before and after the tremor, the conclusion was that the tremor did not affect the structural behavior of the columns.

Differential settlement of foundation is detected in column C3. The strain in this column had significantly lower increase in compression than the other columns, and in the past few years even decrease of compression is noticed. The evaluated differential settlement of the column is in range of 1 mm, and thus it is inoffensive for the building performance.

1.13.1.5 Benefits of Using SHMS Technologies in the Project Monitoring strategy has been developed and monitoring system applied for the first time in long term in high-rise buildings. The monitoring helped (1) to understand the real structural behavior of the building columns, (2) to evaluate creep and shrinkage, (3) to determine underloading (over-dimensioning) of columns C9 and improve structural design for the future, (4) to immediately evaluate the impact of tremor to the building, and (5) to detect differential settlement in column C3. The employed monitoring system performed very well and all the sensors function properly more than 9 years after embedding in concrete. Unusual behaviors were detected at early stage demonstrating high sensitivity of sensors and suitability of monitoring strategy.

1.13.2 The New Årsta Railway Bridge, Sweden—2005

The New Årsta Railway Bridge in Stockholm is an optimized, very slender and complex 11-span prestressed concrete structure. It is located to the west of the Old Årsta Bridge crossing the bay Årstaviken. The bridge was built as part of an upgrading from two tracks to four between Stockholm South and Årstaberg further south. The bridge accommodates two tracks for railway traffic, a service road and a pedestrian and cycle road. The slender design of the bridge and complicated construction methods were reason that initiated The Swedish National Railway Administration (Trafikverket, former Banverket) to install a monitoring system on the bridge. The bridge was opened for traffic on 2005 (Enckell, 2006; Wiberg, 2006).

1.13.2.1 Quick Facts

Name and Location: The New Årsta Railway Bridge, Sweden

Owner: Swedish National Railway Administration (Trafikverket, former Banverket)

Structure Category: Continuous prestressed concrete girder bridge

Spans: 11 spans: 1×65 m, 9×78 m, 1×48 , 15 m

Structural System: Prestressed concrete

Start of SHMS: 2003 during construction

FIGURE 1.17 The New Årsta Railway Bridge during construction.

Number of Sensors Installed: 56 sensors

Instrumentation Design by: Collaboration between Royal Institute of Technology (KTH), BBK AB, SMARTEC SA, and BEMEK AB.

1.13.2.2 Description of the Structure The new Årsta Railway Bridge is very complex 11-span prestressed concrete girder structure (Figure 1.17). The bridge is 833 m long and 19.5 m wide. The headroom under the bridge is 26 m. The trains are running on two unballasted tracks and the bridge accommodates a pedestrian track on the west side and a service road in the east side of the bridge.

The cross-section has a very soft form: the design is very slender with a superstructure that is thickest above each pier and then gets thinner toward each mid span where it is as narrow as possible according to design calculations. Every pier has a 2-m thick transversal beam and manholes are located on the bridge deck in every span, between the rails.

Concrete is of red color as it was desired that the new bridge design would fit the old bridge design and the surrounding landscape. The slender design of the bridge required a high amount of reinforcement and in order to satisfy the needs for bearing capacity concrete of the quality class K60 was used. The total cost of the bridge is calculated to about SEK1.2 billion.

1.13.2.3 Purpose of the Instrumentation The Swedish National Railway Administration (Trafikverket, former Banverket) ordered a SHMS consisting of fiber-optic long-gauge sensors, thermocouples, strain transducers and accelerometers. A research project was connected to the project in order to study and understand the dynamic and the static behavior of the bridge. The main objectives were to monitor a chosen characteristic span of the bridge during 10 years including the construction phase and the testing phase in order to

- Verify that design assumptions concur with reality
- Improve knowledge of traffic and temperature effects
- Document changes in static strain and dynamic properties

- Ensure that elements have not been subjected to excessive loading
- Obtain information concerning the condition of the structure that has consequences for maintenance and repair operations
- Learn about SHM and related issues.

1.13.2.4 Examples of Outcomes As handling with emerging technologies in the field without previous experience, some problems occurred, especially during the construction period. Some sensors stopped working after installation or casting and were probably broken by reinforcement workers or vibrating during casting. Two sensors are not in pretension and therefore unable to measure: these sensors are not damaged but were either gliding after the installation or were not pretensioned enough during the installation procedure. Some cables were also damaged by workers after installation.

On the other hand, the measured results confirmed the behavior of the concrete from the casting to the operation: initial swelling, drying shrinkage, creep, shrinkage, loading, unloading, and prestressing are verified. Sudden strain level changes were also noted and changes in daily variations revealed cracking in the structure.

Figure 1.18 illustrates the prestressing steps from 5 to 8 of May 2003. Figure also shows when sensor AS4, that was either gliding or not prestressed enough in the installation phase, stops measuring after the last prestressing stage. Taking off the formwork; 12 of May 2003 can also be seen in the figure.

Figure 1.19 shows the results for sensor AS1 during a load test. Measure is taken about every 7 min that is the time to measure the whole system of 40 fiber-optic sensors and thermocouples. The measured strain is expressed as microstrain, meaning strain of 1×10^{-6} .

More results for early age, construction, long term, temperature, and cracking can be seen in Enckell (2006, 2007).

FIGURE 1.18 The figure illustrates measured results for the New Årsta Railway Bridge: the prestressing of the cross-section, the lowering down the formwork and the failure of the sensor function.

FIGURE 1.19 The figure illustrates measured results for the New Årsta Railway Bridge during a load test: the maximum strains that occurred for sensor AS1 during the train on the bridge were 20×10^{-6} in elongation.

1.13.2.5 Benefits of Using SHMS Technologies in the Project As the monitoring has carried out during several years, project has produced material and a lot of results are available. Two licentiate thesis, one doctoral thesis, conference papers, and few technical reports are published (Enckell et al., 2003a, 2003b; Enckell and Wiberg, 2005; Enckell, 2006; Wiberg, 2006; Wiberg and Enckell, 2008).

Installation, measurements, and data analysis has been done and a lot of heuristic knowledge has been learned. Significant phases of bridge life were registered including early age deformation, prestressing, removal of the forms, and long-term creeping and shrinkage. Unusual behaviors that revealed cracking were detected and can be used in maintenance planning. Comparison between fiber-optic sensors and strain transducers were also made and proofed the superior quality of the static fiber-optic measurements in long term.

1.13.3 Stonecutters Bridge, Hong Kong—2010

The Stonecutters Bridge is a cable-stayed bridge with a main span of 1018 m (see figure 1.20). The main span is supported from two single central towers both placed on land providing a clear entrance to the container port with a vertical clearance of minimum 73.5 m.

1.13.3.1 Quick Facts

Name and Location: Stonecutters Bridge, Hong Kong, SAR, China

Owner: Highways Department

Main Consultant: Ove Arup & Partners Hong Kong Limited

Structure Category: Main bridge: Cable-stayed bridge, double cable plane, and two girders.

Spans: Main span 1018 m.

FIGURE 1.20 Stonecutters Bridge, Hong Kong, SAR, China (Courtesy of COWI).

Structural System: Composite steel—reinforced concrete towers and steel box girders inter connected with cross girders. Back span as concrete girder

Start of SHM: 2010

Number of Sensors: 1420 sensors

System Concept and Functions Initiated by: Bridges and Structures Division of Highways Department, the Government of HKSAR.

Instrumentation Design by: COWI (as subconsultant to Arup).

System Operation by: Bridges and Structures Division of Highways Department, the Government of HKSAR.

1.13.3.2 Description of the Structure The 53.5 m wide bridge deck consists of twin box girders connected by cross girders. The stay cables connect to the outside edges of the deck only. The deck is in steel in the main span and 50 m into the first back span while the rest of the back spans are in concrete.

1.13.3.3 Purpose of the Instrumentation The Stonecutters Bridge Structural Health Monitoring System is an example of a distributed monitoring system with the provisions for all the aspects of health evaluation based on automatically processing of data.

In designing, the Structural Health Monitoring Systems for Stonecutters Bridge, COWI and Highways Department took full account of the valuable experience gained in operating the Wind and Structural Health Monitoring System (WASHMS) for Tsing Ma Bridge, Kap Shui Mun Bridge, Ting Kau Bridge and the cable-stayed bridge (Hong Kong Side) in Hong Kong—Shenzhen Western Corridor. In order to obtain a whole life health record of Stonecutters Bridge, a construction stage structural health monitoring system will be implemented in addition to a more conventional operation stage structural health monitoring system.

The design challenges for the WASHMS was primarily to monitor the aerodynamic loads free of the turbulence generated by the bridge, temperature loads and responses, stress monitoring of cable stays with record length over 500 m and advanced deformation monitoring based on GPS and accelerometer readings analyzed by operational model analysis.

Also, the great design effort was put into the user interface and data management system in order to prevent users of the system to be drowned by data overload from the +1500 sensors installed on the bridge.

1.13.3.4 Planned Outcomes of the SHMS In order to establish a link between the events logged by the WASHMS on the bridge and the Bridge Management System and Bridge Rating system for the structural, electrical and mechanical components of the bridge was defined, to give a clear and common basis for observations either logged by the WASHMS.

The bridge rating is based on a point ranking concept. The ranking is general which means that the method can be used on both structural components and installations. For maintenance management of structural components, it is necessary to consider the risk imposed by the possible failure modes of the individual component. For that purpose, the point ranking method has been used.

The bridge rating system will provide rational basis for prioritization of inspections and maintenance on primary and secondary structural components. The categories, primary and secondary components, are related to the load capacity analysis model. The system will be based on the results from the principal inspection and the WASHMS. By using these two in combination the additional inspections and maintenance work can be initiated in a proactive manner.

The rating system will ensure that the needed actions to be taken in order to keep structures safe will be taken in time. Such actions include structural repair and strengthening as well as protection against environmental actions.

The WASHMS has been designed divided into three subsystems, namely, the On-Structure Instrumentation System (OSIS), the Portable Data Acquisition System (PDAS), and the Computer System for Operation and Control (CSOC). Furthermore, the WASHMS includes a system for monitoring of traffic by digital video cameras, the DVC monitoring system.

The OSIS is based on a number of data acquisition units (DAQ units) that acquire data on the bridge and transmit these data to the OSIS Controlling Computer through a fiber-optic data network.

The PDAS equipment is compatible with the OSIS network architecture, ensuring that the PDAS can be connected to the OSIS system at the bridge for on-line or batch transfer of data to the central computer.

The CSOC is used for monitoring and analysis of the data acquired by OSIS. This includes alarms generated by OSIS when preset limit values for traffic, wind or structural loads are exceeded. Alarms can be used as inputs to the Bridge Rating system, and they can be transferred to the traffic police.

A bridge rating system is established to be used in the systematic approach described in the inspection and maintenance concept in the maintenance and management system (MMS).

The functioning of the bridge rating system is based on the results from the principal inspection and data from WASHMS. By using these data in combination, it shall be possible to initiate the additional inspections and maintenance works in a proactive manner.

In praxis, the bridge rating system will receive structural events from the monitoring system. This can either be events measured by the WASHMS or events logged manually in the event database based on visual inspections. By the properties of the event, the system will automatically update a bridge inventory according to the principals for the point

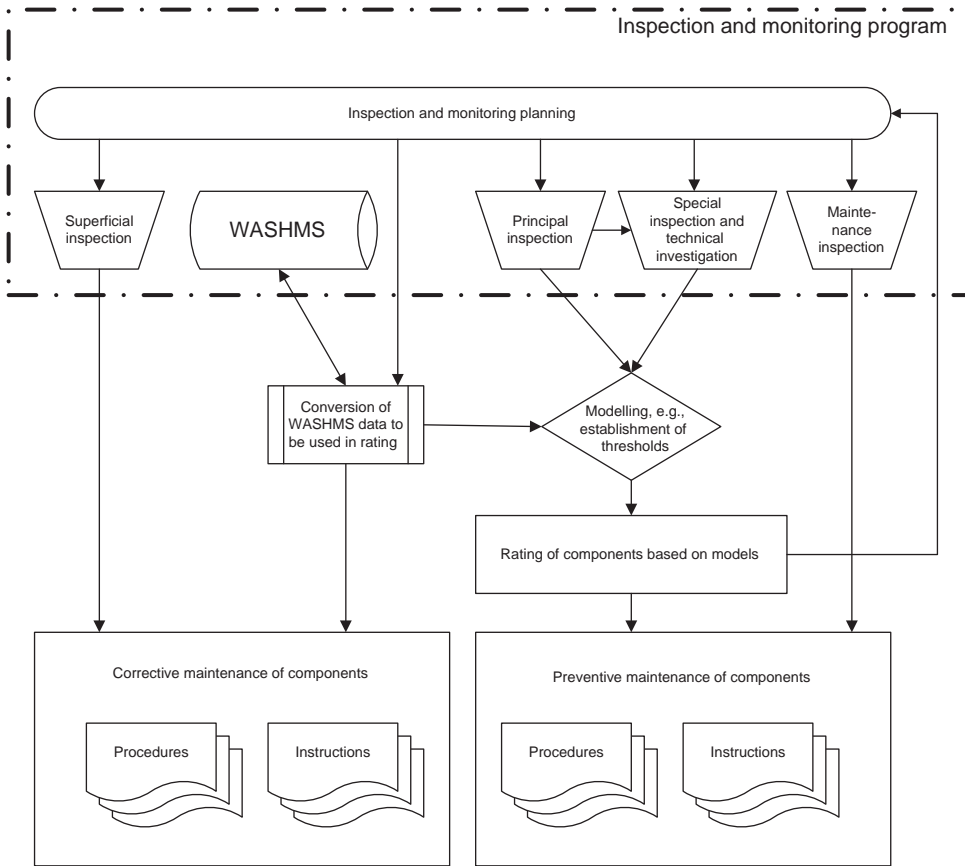

FIGURE 1.21 WASHMS as an integrated part of the management system.

ranking. This can be the planning tool for the maintenance managers in order to evaluate what work orders for maintenance inspections shall be issued; to optimize the works and to track and plan maintenance budgets.

Figure 1.21 shows WASHMS as an integrated part of the management system similar to the inspections. This means that the management may benefit from WASHMS in the long-term planning of preventive maintenance and in the day-to-day corrective maintenance. Both superficial and maintenance inspections are routine inspections that creates no information to be included in a rating process. It shall be emphasized that one should not rely fully on the data and results from WASHMS but on a combination of monitoring and inspections done by experts.

1.13.4 Severn River Crossing, UK—2010

Severn Suspension Bridge, which links England to South Wales in the United Kingdom is a conventional suspension bridge. It was opened to traffic in 1966. The total length of the bridge is 1597 m, and it accommodates also cycle tracks and footway. Traffic flows increased by 63% between 1980 and 1990, and further increases were expected in the years ahead. Therefore, the Severn Bridge crossing was strengthened and resurfaced in

the late 1980s. As there were severe congestion problems in the summer and at peak times each day, a Second Severn Crossing construction was started in 1992 and the second bridge was opened to traffic in 1996.

1.13.4.1 Quick Facts

Name and Location: Severn River Crossing, United Kingdom

Owner: Severn River Crossing for the UK Highway Agency

Structure Category: Suspension Bridge

Spans: Main span 9876 m, side spans 3048 m each; total length approximately 1597 m

Structural System: A suspension bridge with the orthotropic steel box girder deck supported by two main cables slung between two steel towers

Start of SHMS: 2008

Number of Sensors Installed: 90 passive acoustic emission sensors

Instrumentation Design and Supplied by: Physical Acoustics Limited (PAL).

1.13.4.2 Description of the Structure The Severn Bridge was opened in 1966 to replace the ferry service crossing from Aust to Beachley. The new bridge provided a direct link for the M4 motorway into Wales (<http://www.severnbridge.co.uk/>).⁹ Length of the main span is 9876 m and lengths of the side spans are 3048 m each. The high tensile steel towers rise to 136 m above mean high-water level and are of hollow box construction. The deck is an orthotropic steel box girder of aerofoil shape with cantilevered cycle tracks and a footway. Suspension cables carrying the deck are not vertical as in most suspension bridges, but rather arranged in a zigzag style in order to reduce vibration.

1.13.4.3 Purpose of the Instrumentation The Severn Bridge has carried more than 300,000,000 vehicles since it was opened in 1966. In 2008, Severn Suspension Bridge underwent invasive investigation of the main cable that revealed corrosion in the individual steel wires and also a small number of broken wires. A dehumidification system and a full AE wire break detection system for long-term evaluation of suspension bridge (see Figure 1.22). Main cables over the whole 1673 m of each cable were installed in order to ensure the continued integrity and safety of the structure (<http://www.ndtnews.org/> 2008). The AE monitoring system monitors continuously sounds for individual wires breakages within the main cable in order to keep track of the rate and location of any further wire breaks. The system enables evaluating the health of the structure and can also to identify regions that might require further cable investigation. The monitoring system consists of 90 passive acoustic emission sensors as well as six local data interrogators that are distributed along the bridge on an optic fiber network. Sensors are attached to cable clamps every 36 m along the whole cable. Signals from the main cable are detected, automatically processed by local interrogator and reported to a “base-station” on the network. There the data is processed and potential wire breaks are automatically reported via a secure website by e-mail.

1.13.4.4 Examples of Outcomes The wire break system has been successfully proven to detect artificial wire break sources at all points of the cable during the commissioning to

⁹Accessed February 25, 2011.

FIGURE 1.22 (a) Sensor installation. (b) Acoustic emission sensor mounted on cable band (Courtesy of Physical Acoustics Ltd.)

within 0.5 m or less. Unusually in this type of monitoring as the wire break is hidden from view, there has also been a third party verification of a real wire break. This took place in 1 m section of unwrapped cable and was witnessed by the maintenance engineers working on the bridge. The system identified, analyzed, and reported the wire break event automatically and calculated the location within 0.08 m of the actual observed break.

1.13.4.5 Benefits of Using SHMS Technologies in the Project The wire break monitoring system is capable of detecting and locating wire breaks between the cable saddles at either end of the main cable. The monitoring system offers valuable information regarding wire breakage where no other technology can. In comparison, opening of cable by wedging limited to a small percentage of the overall cable length, with the visual inspection at that point showing approximately 5% of wire. The data from the system would allow identification of any points of interest on the main cable, allowing focused inspection at that point. The system also acts as a safety system, monitoring overall cable integrity which would alert the bridge owners if wire break occurs and also if there was a change or significant increase in the number of wire breaks. After the initial installation costs, the long-term monitoring and maintenance is low and automated, this is needed for long-term monitoring.

1.13.5 A4 Hammersmith Flyover, UK—2010

Hammersmith Flyover, constructed in 1961, is 630 m long bridge with 16 spans varying between 33 and 47 m. It is one of the earliest examples of a post-tensioned segmental viaduct in the United Kingdom. Managed by Transport for London, it carries a high volume of traffic, including a large percentage of heavy goods vehicles, on the A4 over the

intersection of four major routes. Post-tensioned concrete has been an economically competitive form of construction for medium to long span structures over the past 50 years. During the 1980s, however, a number of defects were discovered in this form of construction around the world. Corrosion can remain hidden until the loss of strength is sufficient to cause failure without warning, such as in the case of Yns-y-Gwas bridge in Wales in 1985.

1.13.5.1 Quick Facts

Name and Location: Hammersmith Flyover, West London, England

Owner: Transport for London

Structure Category: Post-tension concrete bridge

Spans: 33–47 m spans with total length approximately 630 m

Structural System: Precast, segmental concrete box girder with post-tensioning.

Start of SHMS: 2010

Number of Sensors Installed: Approximately 300 passive acoustic emission sensors

Instrumentation Design and Supplied by: Physical Acoustics Limited (PAL).

1.13.5.2 Description of the Structure Hammersmith Flyover is an elevated roadway in west London. The superstructure of bridge consists of a series of 3 m long triple-cell spine box beam units with 75 mm in situ concrete joints to 300 mm cantilever diaphragm units. The longitudinal post-tensioning consisted of 2 sets of 4 tendons of 16, 19-wire strands either side of the two internal webs encased in in situ grout “boxes.”

Hammersmith Flyover was one of the first examples of an elevated road employing reinforced concrete balanced cantilever beam supports with a single central column.

1.13.5.3 Purpose of the Instrumentation A detailed special inspection was carried out on the Hammersmith Flyover by exposing the tendons at critical locations. Found section losses were used in a three-dimensional finite element load assessment model to determine the flyover’s current live load capacity. The results showed that despite the evident corrosion, the structure passed full 40t highway loading in accordance with BD21/01. While this gave reassurance that the structure was safe and “fit-for-purpose,” visual inspection at a limited number of locations was not considered to be sufficient by Transport for London. To manage the structure effectively, transport for London needed to know whether the post-tension cable deterioration was continuing and if so, at what rate and where wire breaks were occurring. Acoustic wire break monitoring is deployed over the east side of the flyover (nine spans) to detect and triangulate wire breaks linearly along the structure and define the location to specific tendon groups.

The specified accuracy of the system required a high-frequency acoustic emission sensor in each 3 m segment. Sensors are bonded to the surface of the concrete with structural adhesive and cabled back to the monitoring system in the instrument cabinet.

Detection of the wire breaks uses the signature data collected during third party Japanese Public Highways Corporation trials and those detected on other structures. The distinct signature and signal transmission from breaks allows automatic detection and instant wire break alerts. Signal location uses time of arrival of the energy wave (released during wire break) at acoustic sensors. These data are cross correlated with an acoustic map of the structure developed during the commissioning of the system that confirms the exact location, even where tendon groups are in close proximity. This method takes into

FIGURE 1.23 Blind wire break trials during system commissioning (Courtesy of Physical Acoustics Ltd.)

account complex wave paths caused by mortar condition and variable contraction (Bridge Design and Engineering Autumn 2010).

In addition to the acoustic emission system, a strain, displacement and rotational structural monitoring system and a total station system was also installed.

1.13.5.4 Examples of Outcomes Once installed, the wire break system operation was verified by cutting a single exposed wire in a blind test, see Figure 1.23. This was done by incrementally reducing the section of a single wire over a period of time using a grinder until the wire yielded and broke. The break was remotely detected and triangulated to within 100 mm of the physical break and to the correct tendon group. The system will operate for at least 5 years monitoring any change in the condition of the post-tensioning, highlighting any specific areas of concern and any significant increase in wire break activity.

1.13.5.5 Benefits of Using SHMS Technologies in the Project The system was operational from the end July 2010 to present and no results have been publicized. However, generally, acoustic emission monitoring of post-tension structures is widely acknowledged to be the only way to detect and locate wire breaks, which occur hidden inside ducts. The technique is nondestructive so it does not require any disturbance of ducts which, through the refreshing of oxygen, can reinitiate the corrosion process. The system once set up runs and reports automatically so costs are low. With historical sudden failures of post-tension structures, such as Yns-y-Gwas Bridge in Wales, monitoring of any post-tension bridge with a suspected problem is recommended.

1.13.6 Streicker Bridge, United States—2010

The Streicker Bridge is a new pedestrian bridge at Princeton University campus. Funded by Princeton alumnus John Streicker (class of 1964), the bridge was designed by renown Swiss engineer Christian Menn in collaboration with the HNTB architecture and engineering firm, whose lead engineers for the project were Princeton alumni Theodore Zoli

FIGURE 1.24 Rendering (a) and photograph (b) of Streicker Bridge.

(class of 1988) and Ryan Woodward (class of 2002). The rendering and the photograph of the bridge are shown in Figure 1.24.

Besides its primary aim, to provide and facilitate safe pedestrian crossing-over the Washington Road, the bridge has strong symbolic and aesthetic significance. Taking into account its scientific, social, and symbolic measures (Billington, 1983), the Streicker Bridge can be considered as a piece of structural art. Created as a part of Princeton University's Natural Sciences neighborhood, the bridge connects the Icahn Laboratory (Lewis-Sigler Institute for Integrative Genomics) and new neuroscience and psychology building (under construction) on the west with Jadwin Hall (physics), Fine Hall (mathematics), new Chemistry building, and Lewis library on the east. The bridge will "stand as a tangible symbol of the cross-disciplinary collaborations that are central to scientific research and teaching today" (President Tilghman in News at Princeton 2006). The bridge's "X" shape in plane symbolizes these cross-disciplinary collaborations, and the arch itself represents the south entrance gate to Campus.

1.13.6.1 Quick Facts

- *Name and Location:* Streicker Bridge, Princeton University, NJ, United States
- *Owner:* Princeton University
- *Structure Category:* Pedestrian bridge, deck stiffened arch, curved continuous girders ("legs")
- *Spans:* Main span 34.75 m, total length approximately 104 m, maximum "leg" length 40 m (maximum "leg" span 19 m)
- *Structural System:* Post-tensioned concrete deck and weathering steel arch and columns
- *Start of SHMS:* 2009 (during construction)
- *Number of Sensors Installed:* 53 discrete long-gauge strain sensors, 47 temperature sensors, 40 m of distributed strain sensor
- *Instrumentation Design by:* SHM lab at Princeton University.

1.13.6.2 Description of the Structure The Streicker Bridge has a main span and four approaching legs. Structurally, the main span is a deck-stiffened arch and the legs are curved continuous girders supported by steel columns. The legs are horizontally curved and the shape of the main span follows this curvature. The arch and columns are weathering steel while the main deck and legs are reinforced post-tensioned concrete. The slender and elegant deck-stiffened arch represents an efficient solution to bridge the span of 34.75 m (114 ft) keeping the deck thickness of only 578 mm (22.75 in.) and arch diameter of 324 mm (12.75 in.). The slender cross-section is maintained in all four legs. Each leg had different length and different span length that were imposed by the surrounding roads and the landscape. The longest is the 40-m long south-east leg, and it contains the longest span of approximately 19 m. Turner Construction Company was the main contractor and university's Office of Design and Construction was the supervisor.

1.13.6.3 Purpose of the Instrumentation SHM Lab at Princeton University instrumented the bridge with various SHM systems, with aim to transforming it into an on-site laboratory for various short- and long-term research and educational purposes (Glisic, 2011). The research will focus on addressing general SHM challenges such as bridging education gap between research and practice, collecting real structural behavior data sets, identifying changes in strain patterns caused by unusual behaviors, and characterizing the SHM contribution to sustainability of built environment. Research in domain of monitoring approaches, methods and instrumentation, and evaluation of lifecycle cost benefits in function of the long-term SHM approaches is planned as well (Glisic and Adriaenssens, 2010). A long-term objective of this project is to develop a holistic framework that will transform the current inefficient fragmented approach to SHM and eventually lead to the widespread, comprehensive, and beneficial application of SHM as a tool for optimized bridge management. The SHM of Streicker Bridge serves as a support to university courses on SHM and several other courses related to structural analysis and design. The bridge represents tangible demonstrator for students and practitioners, and it is open for visits of community members.

At the present stage, the bridge instrumentation is based on two monitoring approaches: global structural monitoring using long-gauge FBG strain sensors, and integrity monitoring using distributed fiber-optic sensing based on stimulated Brillouin scattering (Brillouin Optical Time Domain Analysis or BOTDA). Taking into account that the main aims of monitoring are related to research and education, not all the components of the bridge were instrumented. Assuming symmetry and similarity in structural performance, it was decided to equip only half of the main span and only one approaching leg, that is, south-east leg with sensors.

The fiber-optic technologies were used in this initial project phase because they have proven durability and feature very good long-term stability and insensitiveness to external environmental and man-made influences. In the future, the other monitoring systems and other approaches will be applied. The sensor network design is based on fiber-optic methods using loose structural analysis approach (Glisic and Inaudi, 2007). The total number of the sensors was determined as a trade-off between the performance and the cost. Installation was performed by undergraduate and graduate students of Princeton University (see Figure 1.25). The sensors were embedded in concrete during the construction. The sensors attached to rebars before pouring are shown in Figure 1.25.

FIGURE 1.25 Photograph taken during the installation (from upper-left clockwise): student installing the sensors, parallel discrete and distributed sensors installed onto the rebar, crossed sensors, package of three sensors with different gauge lengths, and students installing extension cable.

1.13.6.4 Examples of Outcomes Static monitoring started for the main span approximately 6 h after the pouring of concrete, while for the south-east leg it started immediately after the pouring. The data were registered with the pace varying from 5 to 15 min for discrete FBG sensors, and approximately 1 h for distributed BOTDA sensor. Full presentation of results would exceed the contents of this chapter, which is why only the most illustrative findings are presented. Since the project is still in its initial stage, the analysis of the presented results is to be considered as preliminary.

The first month of measurement performed on the middle segment of the main span is given in Figure 1.26a. Various works and events were successfully detected and they are indicated in Figure 1.26a: thermal contraction due to hydration process (swelling was not registered since the monitoring started 6 h after the pouring), post-tensioning, de-centering, and removal of the forms. No unusual behaviors were detected in this period.

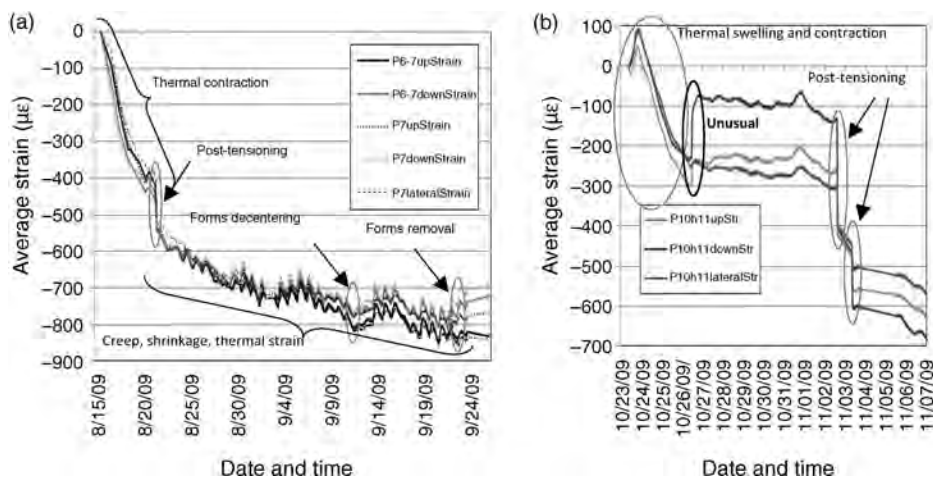

FIGURE 1.26 Early age measurement in the main span (a) and the south-east leg (b).

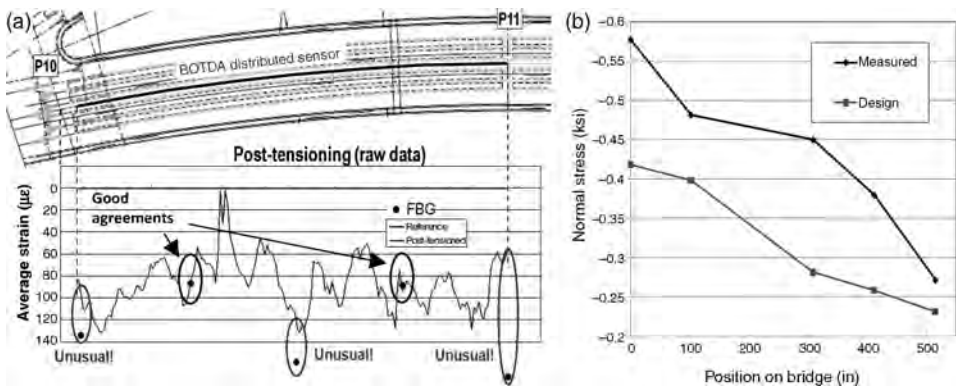

FIGURE 1.27 Comparison between distributed and long-gauge sensor measurements (a) and comparison between design and measured stresses in the cross-sections centroids of the main span (b) (Liew 2010).

The early age measurements for middle of the longest span the south-east leg are presented in Figure 1.26b. Thermal swelling and contraction due to hydration process and the post-tensioning of the deck were detected and indicated in the figure. However, besides these usual behaviors, an unusual event is detected—increase in strain—by all the three sensors. Similar unusual behaviors were noticed in some other sections of the south-east leg. The nature of this event is still under investigation, but preliminary study indicates the early age cracking as the cause. The unusual strain was rectified in all the sections by the post-tensioning. Further analysis of the detected event represents the topic of a graduate student master thesis.

Post-tensioning as measured with distributed sensor is given in Figure 1.27a. The comparison with long-gauge FBG sensors is shown in the same figure. Two monitoring systems have good agreement in quarter span sections where no unusual behavior occurred. Discrepancy is noticed in the section where the unusual behaviors were detected. This discrepancy is a consequence of 1-m spatial resolution of distributed system, which makes it impossible to accurately detect strain concentrations, unless a special software module is enabled. Comparison of two systems is the topic of an undergraduate student senior thesis.

Based on measurements, the actual post-tensioning stresses are calculated and compared with design as shown in Figure 1.27b. The measurements show that in reality, post-tensioning losses are likely to be smaller than expected (Liew, 2010).

1.13.6.5 Benefits of Using SHMS Technologies in the Project Important phases of bridge life were registered including early age deformation, prestressing, and removal of the forms. Unusual behaviors were detected in several sections of the south-east leg, and based on preliminary analysis they are attributed to the early age cracking. Post-tensioning closed the cracks successfully. The post-tensioning stresses in concrete were evaluated based on measurements and compared with design. The comparison shows higher stresses than designed, indicating smaller post-tensioned losses and better performance of the bridge (Figure 1.27).

Comparison between two monitoring systems was successful and at locations where no unusual behaviors were detected the agreement between the systems was within the error of measurements. At locations where unusual behaviors occurred a discrepancy

between the systems were observed due to 1-m spatial resolution of distributed monitoring system.

Undergraduate and graduate students were involved in various phases of the project including installation, measurements, and data analysis. Project generates material for an undergraduate and a graduate course at Princeton University and for several senior, master, and Ph.D. theses.

1.13.7 Messina Bridge, Italy—2018

The planned Messina Strait Bridge will connect the coasts of Sicilia and Calabria in southern Italy. It is planned to carry a four-lane highway with emergency lanes and a dual railway line. The bridge is a suspension bridge with a world record breaking 3300 m main span. The design life of the bridge is 200 years (Figure 1.28).

1.13.7.1 Quick Facts

- *Name and Location:* Messina Bridge, Strait of Messina, Italy
- *Owner:* Stretto di Messina Spa.
- *Structure Category:* Main bridge, suspension bridge, double main cables and three girders, two for road and one for rail traffic
- *Spans:* Main span 3300 m, total length 3666 m, span lengths 333 m–3300 m–333 m
- *Structural System:* Steel towers and steel girders
- *Planned Start of SHMS:* 2014, during construction
- *Number of Sensors Planned to be Installed:* 3500 sensors
- *Instrumentation Detailed Design by:* COWI A/S for Eurolink Spa.

1.13.7.2 Description of the Structure The suspended deck is arranged with the cross girders spaced at 30 m as the main elements whereas the two roadway girders and the central railway girder are taken as secondary elements spanning between the cross girders. Thereby, the Messina Strait Bridge will be the first bridge in the World to adopt the triple box concept for the deck, which is 68 m wide. The main cables consist of twin

FIGURE 1.28 Messina Bridge, Italy (Courtesy Stretto di Messina).

cables spaced 1.75 m—that is, a total of four cables are required for the bridge. The sag to span ratio of the cables is fixed as 1:11.

The towers are frame structures with slightly inclined legs (inclination of $\sim 2^\circ$) and three connecting cross-beams. They are constructed in steel. The tower top level is at 382.6 m.

1.13.7.3 Purpose of the Instrumentation The SHMS has been developed in parallel to the design of the bridge. The SHMS will facilitate various tasks including construction monitoring, operation monitoring, design validation, and maintenance planning. The SHMS will be integrated into a sophisticated management and control system for the bridge and approach (road and rail) networks. A key function of the SHMS will be to provide information that will support decisions for both operational and maintenance tasks. Operation monitoring will be performed through continuous real-time monitoring of environmental conditions, traffic (road and rail) loads, as well as structural response, providing real-time assessment of the status of the structure for the protection of user safety. A facility for extrapolating data and simulating predictions of future loading conditions will be provided to enable improved bridge operation capability. Data that are recorded by the SHMS will also be used to update service life calculation and point ranking assessment of structural components of the bridge to assist with long-term maintenance planning.

The detailed arrangement of sensors has been developed in collaboration with the structural designers to produce a monitoring plan that will focus on relevant critical areas of the bridge. The layout of sensors and the structure of the SHMS are also sympathetic to installation of the sensors during fabrication of the structure as well as progressive activation for effective construction monitoring. The SHMS will consist of approximately 3000 measurement locations and portable sensors, of which 90% will be integrated into the permanent SHMS data-stream.

The Messina Bridge SHMS has been engineered for the following objectives:

- to provide data for design, construction, and performance verification
- to provide data for review of design loading and development of assessment loading
- to provide current information on load conditions for effective bridge operation
- to provide current information on the condition of structural components
- to provide data for maintenance planning
- to provide data for troubleshooting unforeseen structural problems.

1.13.7.4 Examples of Planned Outcomes The Messina Bridge is a structure that will push the boundaries of engineering knowledge and experience. The significant increase in scale of the whole structure pushes all elements to their physical and dynamic limits. All aspects of the design have been reviewed and scrutinized by leading researchers and engineers, tested in the wind tunnel, and analyzed with Finite Element modeling. A detailed understanding of the structural behavior has been developed through significant research. The Messina Bridge SHMS has been strategically engineered to provide data for design, construction and performance verification. If unforeseen structural problems develop, important data for troubleshooting will be provided. The Messina Bridge SHMS will also provide live information on load and environmental conditions as well as deflections for effective bridge operation. Data recorded by the SHMS will be used to prepare and update simulations of load conditions expected in the subsequent hours, which will

further enhance the effectiveness of bridge operation and in particular traffic management. Data will be stored in accordance with data management protocols, which are designed to optimize data storage while retaining important information. This data will not only allow for the review of events and structural performance, but it will also allow for the future review of design loading and development of assessment loading.

1.13.7.5 Benefits of Using SHMS Technologies in the Project The objectives of the SHMS are not only limited to structural performance; the SHMS has also been engineered to provide data for monitoring the internal environmental conditions, condition of structural components as well as to provide data for maintenance planning. The Messina Bridge will be provided with an extensive dehumidification system to control the internal environment of the bridge boxes, towers as well as main-cables. The SHMS will provide monitoring of the internal environment and therefore function of the dehumidification system. Maintenance associated with fatigue can become costly to repair, particularly if cracks propagate extensively following crack initiation. Significant efficiency in maintenance can be achieved if the fatigue life of components is known. The monitoring of stress cycles and the development of fatigue utilizations is an integral part of the SHMS. The monitoring of the mechanical devices as well as elements that are prone to wear is particularly important to the effective maintenance of the structure. Buffers have been provided at the towers to control the deck movement relative to the tower, while allowing an important change in articulation under seismic conditions. The maintained function of these buffers is important to the success of the design. Expansion joints and bearings are the components of bridges that are most commonly subject to repair and replacement at intervals throughout the life of the structure. The excessive wear of the expansion joints and bearings may also lead to deterioration of other components that are not straightforward to maintain and can be expensive to repair, whether by direct association to the relevant component or by modifying structural behavior.

1.14 DISCUSSION

1.14.1 Development of New and Emerging Technologies

Tremendous development took place in emerging technologies in recent decades and it is still ongoing. A consequence of the process is that a new sensory technology with advance data acquisitions tools is now available. Completely new advantages and challenges were presented to the civil engineering society working with these emerging technologies.

Many sensors are accurate and reliable and also easy to comprehend and work with if some education is given. Fiber-optic sensor technology provides us with precise, sensitive equipment with well-established data acquisition facilities. Some fiber-optic technologies are already well recognized with long-term experience while others just entered the market and are still under development. Many commercial products exist in applications measuring discrete and distributed strain, temperature, and pressure, but more development is needed in the areas of monitoring humidity, corrosion, crack detection, and combination of parameters in the same sensor.

Noncontact NDE techniques such as interferometric radars, photogrammetry, and thermography open new areas and show potential. They do provide various advantages: no need to stop traffic, no need to install sensors, portable equipment, and easy setup.

Data interpretation is an important issue as it is not always delivered with the sensory system. Data interpretation is also almost unique for every single structure as even two similar structures could have different problems if built in problems arose during the construction period. Some time after installation is normally needed to learn about the structural behavior related to daily and annual variations, loading conditions and environmental effects. After that trial period, it is easier to calibrate the SHMS to fit the defined requirements.

1.14.2 Obstacles

By experience, a proper understanding is only gained with long-term experience and several obstacles have been observed while working with new and emerging technologies. The following ideas are identified as the most important and should be further investigated in order to find solutions and encourage the use of emerging technologies as they can bring to SHM numerous benefits.

When planning projects, the lack of understanding from different stakeholders can sometimes be a hinder for emerging technologies. The experts in different areas that do have proper understanding for the specific technology are hindered by decision makers that are conservative and do prefer to stuck to old, conventional techniques. And not only that, new and emerging technologies are also rejected by civil engineers as some civil engineers do lack understanding of variability and advantages that these techniques can offer. Economical limitations are also a problem as they set limit for authorities when choosing the systems. Authorities, in their turn, also have to deal with political decisions that do control projects and influence its pace.

The quantity of collected data must be adapted to the needs of the project. Capital is wasted with too complicates systems with either sensor and/or data overload. No proper analysis of the results can be performed if the amount of data is huge and the time of interpretation is limited. These kinds of projects contribute to bad status and give negative picture of chosen technologies. Therefore, it is important to give general and simple information to all parts so that the field becomes more adaptive. To demonstrate performed projects and achieved goals is a good way to highlight the advantages.

1.14.3 Need for Education and Collaboration

As the subject is large and development ongoing, there is also need for education. The people involved (engineers, owners, financiers, and researchers) working and making decisions concerning advanced fiber optic, laser, and other techniques need to be skilled to be able to judge the reliability of these systems. Engineers working with these techniques should also be unassuming and take their time to learn and understand and thereby be able to use these techniques properly and efficiently.

Special needs emerge if any deviation is notified when working with installations of emerging technologies. Multiple skills including the ability to solve practical problems are required in harsh environment in the field. Capability to judge problems, find solutions and see consequences of decisions made is most favorable. Complexity of existing problems is not easy to understand if the heuristics lacks. The systems need also to be flexible so that modifications can be made during the process. Universities are providing courses in various different technologies but as the subject is large, it is not easy to distinguish what is most preferable. An expert working with emerging technologies does need a wide

education, understanding and experience for various techniques and needs also be continuously updated in relevant subjects as development is ongoing.

Emerging techniques are many times characterized by their advantages and the disadvantages, and challenges are totally left out. The importance of international collaboration cannot be neglected: advantages, disadvantages, and challenges need to be discussed to save resources and capital. Mistakes and malfunctions are also to be reported in order not to be repeated.

1.14.4 Future Use and Development

It is good to keep in mind that very high quality is needed in sensory technology. In order to reach good results, sensor production must be optimized and the sensors have to be quality controlled, preferable in a standardized way. Some standards do exist for a few technologies like for example acoustic emission that does have a long-term experience in other engineering applications and testing procedures.

Less established technologies need to be tested and go through defined procedures as FAT, SAT, or any other required testing if implemented in real structures as they do lack long-term function verification. Implementing emerging techniques also includes taking a certain risk, and these projects should therefore be performed initially in smaller scale so in case of malfunction the loss of capital is kept in acceptable frames. With gained experience larger projects can be gradually realized. Also, the documentation and presentation need to become more generalized so that the different stakeholders have easier to understand and compare the products that are available on the market.

New challenges for fiber-optic sensors lie on cable applications such as prestressed or poststressed cables in various applications; stay cable and main cable applications in bridges. It would be convenient to install these cables with embedded sensors; either discrete or distributed sensors that do measure humidity, strain, and temperature as the inspection of these cables afterwards are indeed complicated. Distributed strain sensors need packaging improvements that will make them easier to install on the surfaces of large structures.

Many of the technologies aforementioned also compete with each other, and it is many times difficult to tell which one is the most suitable for a specific application. Our experience is also that complex structures do require the combination of several of these technologies in order to meet all technical requirements and provide a SHMS with functionality, quality as well as redundancy.

1.15 CONCLUSION

This chapter is based on research, literature surveys, design work on major international bridges and long-term experience of practical use of emerging technologies in SHM on various bridges as well as on other structures. Major conclusions are presented here in order to point the direction for future focus and development.

Emerging technologies do provide high precision, high accuracy, stability, and redundancy. They perform real-time monitoring that saves capital and improves the safety of the structure. Possible problems are faced at the beginning and an instant measure can be taken in order to correct the malfunction in monitored structures.

Emerging technologies together with adequate data acquisition contribute to accurate SHM methods in harsh environments. Nevertheless, emerging technologies do require a new kind of philosophy as they are characterized with certain uncertainty and intricacy. Interpretation of results is not always as easy as described in literature and experienced staff is essential for successful SHM. Need for wider understanding for relevant stakeholders is also significant. Necessity for new education is thereby emerged: engineers with practical skills are needed when working in the field with emerging technologies.

Experienced experts need to evaluate FATs, SATs, various installation issues and other related issues in order to judge the reliability and thereby provide high-quality systems that fulfill the initial technical requirement. A simple system consisting of smaller amount of sensors with proper data analysis is better than a complicated system with numerous sensors but with poor analysis. SHMS for complicated structures also requires combination of several techniques in order to be able to measure all desired parameters. As the development is ongoing, continuous update and education for people working with emerging technologies are required.

International collaboration and openness are needed for faster development: both advantages and disadvantages are presented and highlighted in truthful manner to avoid repetition of mistakes. Sensor production and especially quality insurance issues need to be optimized in order to provide high quality sensors.

Standardization of vocabulary and methods of a bit more established techniques need to get started so that it will be easier for new stakeholders to judge the function and reliability of these systems. General development in various areas of science and technology combined with the use of novel construction materials and structural systems will certainly bring both needs for further developments new SHM technologies, and knowledge and resources for their successful developments. The world is full of deteriorated, malfunctioning structures and as our infrastructures are aging there is an accelerating need for emerging technologies from that point of view too. Thus, we are confident that the future for the new and emerging technologies is bright.

ACKNOWLEDGMENTS

We would like to thank all the participants in Punggol EC26 project and also thank them for their kind collaboration and making available the data presented in this book: Er. Lau Joo Ming, Er. Fong Chor Cheong, and their crews in the Housing and Development Board (HDB), Singapore—the pioneer of large-scale implementation in long-term structural health monitoring for residential buildings; Nicoletta Casanova, Daniele Inaudi, and their teams in SMARTEC SA, Switzerland, and Rocrest Ltd., Canada; Mr K.P. Kwan, Mr Jeffery Low, and Sofotec Singapore Pte Ltd, Singapore.

The Strecker bridge project has been realized with great help, and kind collaboration of several professionals and companies. We would like to thank Steve Hancock and Turner Construction Company; Ryan Woodward and Ted Zoli, HNTB Corporation; Dong Lee and A.G. Construction Corporation; Steven Mancini and Timothy R. Wintermute, Vollers Excavating SMARTEC SA, Switzerland; Micron Optics, Inc., Atlanta, GA. In addition the following personnel, departments, and offices from Princeton University supported and helped realization of the project: Geoffrey Gettelfinger, James P. Wallace, Miles Hersey, Paul Prucnal, Yanhua Deng, Mable Fok; faculty and staff of Department of Civil and Environmental Engineering and our students: Maryanne Wachter, Jessica Hsu, George

Lederman, Jeremy Chen, Kenneth Liew, Chienchuan Chen, Allison Halpern, David Hubbell, Morgan Neal, Daniel Reynolds, Konstantinos Bakis, and Daniel Schiffner.

Concerning the Stonecutters Bridge, Hong Kong, great thanks for the input received by K. Y. Wong at Bridges & Structures Division of Highways Department, the Government of Hong Kong S.A.R. P.R. China. For the Messina Straight Bridge, thanks for kind help and fruitful discussions provided by the owner, Stretto di Messina represented by Eng. Enzo Vullo, the Contractor Eurolink SpA and COWI's designer group with help from Simon de Neumann from Flint & Neil Ltd.

Great thanks go also for: Paolo Papeschi and Paolo Farina from IDS Ingegneria Dei Sistemi S.p.A (Italy) and Kevin Banks from IDS Ingegneria Dei Sistemi (UK) Ltd; Leif Norman (Sweden) and Jon Watson (UK) from Physical Acoustics Ltd and Birit Buhr Jensen from COWI A/S, Denmark for their valuable help in the areas where author's did lack in experience.

We would also like to humbly thank all involved people in projects, measuring campaigns, and testing that are not mentioned above. Working with new and emerging technologies has been exciting, demanding, and enlightening and we are extremely satisfied over the goals we have reached so far and would like to continue together against new challenges.

2.1 INTRODUCTION

The concepts that drive geographic information systems (GIS) have become commonplace in today's everyday activities—witness the use of guidance systems in our cars, our use of online mapping programs (such as Google maps, Yahoo maps, etc.) to explore destinations. All of these are based upon basic GIS functions, namely, linking data to maps. The use of geographic information systems has consequently become widespread in the past 20 years or so. All 50 states have institutionalized their GIS activities and 45 of them provide clearinghouses for their geospatial data (AASHTO, 2008). For a full list of

GIS acronyms and jargons visit the National Center for Geographic Information and Analysis web site (Padmanabhan et al., 1992), and download report number 92-13.

GIS offers a data management and modeling platform capable of integrating a vast array of data from various sources, captured at different resolutions, and on seemingly unrelated themes. The objectives for this chapter are to define and describe the basic elements of GIS, explore its application to engineering measurements (in the context of surveying and geodesy), provide some example applications for the technology, and present issues involved in implementing these systems. The discussion begins with some background on GIS providing definitions and some discussion regarding the “why” of using them.

2.2 BACKGROUND

The GIS is a computerized database management system that provides graphic access (capture, storage retrieval, analysis, and display) to spatial data. GIS software provides a map display that allows thematic mapping of data and its graphic output overlain onto a map image. Figure 2.1 depicts the generic framework used by virtually all-current GIS software packages.

The key element that distinguishes GIS from other data systems is the manner in which geographic data are stored and accessed. GIS packages used for engineering measurements applications store geographic data using topological data structures (objects’ locations relative to other objects are explicitly stored and therefore are accessible) that allow analyses to be performed that are impossible using traditional data structures. The addition of this spatial dimension to the database system is, of course, the source of power of GIS. Without this dimension, the GIS is merely a database management engine. Linked with the spatial dimension, its database management features enable GIS to capture spatial and topological relationships among geo-referenced entities even when these relationships are not predefined. Standard GIS functions include thematic mapping, statistics, charting, matrix manipulation, decision support systems, modeling algorithms, and simultaneous access to several databases.

FIGURE 2.1 Generic framework GIS.

2.2.1 Measurement-Based GIS

In 1999, Goodchild proposed a new and expanded focus area for GIS software, namely, one whose geometry is based upon measurements rather than coordinates. The traditional approach to storing geographic information is with coordinate data. Mapping has not, normally, been considered a measurement science. Instead, information that links GIS layers to original measurements is commonly removed, making conventional error analysis, within the GIS, impossible. The data-based nature of GIS, however, allows this information to be included.

Sadiq and Duckham (2009) examined a technique for storing and retrieving spatially varying data quality information in a relational spatial database. Rather than storing global data quality statements, the system enables data quality information to be referenced to a spatial framework, individual spatial objects, or even parts of spatial objects. Their relational model allows flexible storage of spatially varying data quality information, and seamless querying irrespective of the underlying storage model. They found that this system is practical and efficient for a wide range of queries, and outlined the performance trade-offs associated with different data quality storage models. Kuhn (2009) proposed a taxonomy of measurements that allows for data integration and the application of computational techniques, such as least squares, to measurements. Positions and their uncertainties, for example, could more reliably be determined if original measurement data were maintained in a system.

2.3 BASIC PRINCIPLES OF GIS

2.3.1 GIS Data

Data and the modeling of those data are crucial elements of a successful system. The GIS derives information from raw data—one of its primary strengths. Although data and information are often used interchangeably, they can be quite different. Data consist of facts or numbers representing facts whereas information derives from data and gives meaning to those facts. This section describes the nature, types and sources of data, and the modeling techniques and data models which are used to convert the raw data to information.

2.3.1.1 The Nature of Data There are two types of data in general—spatial data and attribute data. The former describes the physical geography represented in a database whereas the latter, attribute data, linked to the spatial data, describe the “attributes” of the spatial objects. For example, a point could represent a tree location and its attributes might be species, diameter, or height. If a line feature represents a road segment, attributes might include pavement type, number of lanes, or speed limit. Apropos to measurement-based GIS, attributes may also include survey measurement information. Area attributes might include soil type, vegetation cover, or land use. An attribute is the generic descriptor for a feature, while each feature has a specific value. In the point example above, likely values for the species attribute would be Pine, Fir, and Aspen. Attributes may be described as the questions that would be asked and values as the answers. Attributes to be collected would be determined in the software planning process, while their specific values would be entered in the field. Again, these may include survey measurements and/or their history.

The two most common ways of representing spatial data are the raster and vector formats. A familiar analogy for these formats is bit-mapped photos (such as jpeg) corresponding to the raster format and vector-based ones (such as tiff) representing the vector format. Each of these approaches offers advantages and disadvantages based on the application for which the data are to be used. Data structure, that is choice between raster and vector, is in general one of the first major decisions to be made in establishing a GIS. With regard to measurement-based GIS, this decision is fairly straightforward. Field measurements are typically concerned with measuring and locating features and artifacts rather than processing images, for example. These are all well-defined lines and shapes lending themselves better to the vector data structure. This notwithstanding, there are situations in which the raster format may apply and, so, the next few paragraphs provide a description of both structures including some discussion of their relative advantages and disadvantages.

The Raster Data Structure Raster data consist of rows of uniform cells coded according to data values. For example, a landscape scene would be gridded, and each cell in the grid would be given a single landscape identity, usually a code number that refers to a specific attribute measure (e.g., a particular land use or type of land cover). The number might also be an actual measurement value, such as an amount of rainfall. These cells are akin to pixels on a computer monitor. Indeed, carrying the analogy further, pixels have values associated with them as well—color, hue, and shades of gray—and the degree of resolution provided relates to the size of the pixel. Similarly, the degree of approximation in a landscape relates to the size of the raster cell. A grid comprised of small cells will follow the true location of a boundary line more closely, for example. However, as with photo resolution, there is an overhead cost, namely, the size of the raster file containing the data will increase as cell size decreases. In general, raster provides a simple data model and fast processing speed at the expense of the excellent precision provided by the vector model with its higher data needs. The nature of raster data lends itself to natural resources applications whose data elements tend to be continuous in nature—such as soil type.

The Vector Data Structure Vector data consist of points, lines, and closed polygons or areas, much the same as the drawing elements in computer-aided drafting (CAD) programs. The lines are continuous and are not broken into a grid structure. In the vector model, information about points, lines, and polygons is encoded and stored as a collection of x - y coordinates. The location of a point feature, such as a manhole, is described by a single x - y coordinate. Linear features, such as roads, are stored as a string of point coordinates. Area features, such as census tracts or traffic analysis zones, are stored as a closed loop set of coordinates. The vector model represents discrete features such as buildings better than continuous features such as soil type. The vector format, in general, provides a more precise description of the location of map features, eliminates the redundancy afforded by the raster model and therefore reduces mass storage needs, and allows for network-based models. Vector models are, however, often computationally intensive—much more so than their raster counterparts.

Topology describes how graphical objects connect to one another by defining relative positions of points, lines, and areas. For example, topology allows queries about which street lines are adjacent to a census tract area, or what intersection node points form the end points of a street segment (link), for example. The latter information is essential for

routing applications. Only vector-based data include topological information which is in part why these data may have higher costs associated with them—the presence of topology implies the maintenance of additional databases whose purpose is to store information on the connectedness of points, lines, and areas in the database.

Scale and Accuracy Scale and accuracy are important data considerations, especially when using more than one data source, and is at the heart of any discussion involving measurement-based GIS.

Historically, a main indicator of accuracy and precision is the scale used to describe the data. Simply defined, scale is the relationship between distance on the map and distance on the ground. A map scale usually is given as a fraction or a ratio—1/10,000 or 1:10,000. These “representative fraction” scales mean that 1 unit of measurement on the map—1 inch or 1 centimeter—represents 10,000 of the same units on the ground. Small-scale maps have smaller representative fractions than large-scale maps; for example, 1 in 500,000 versus 1 in 24,000, respectively, that is, large is small. As scale size increases, the ability to depict detail also increases. For example, a map with scale 1 in 500,000 would necessarily represent only main roads and only by centerline whereas with a scale of 1 in 20,000, details such as ramps, collectors, and direction of travel could be shown as well. See Figure 2.2 for examples. On much larger scales, such as 1 in 600 (1 in = 50 ft), features such as pavement markings, actual lane designations, and specific design elements can be depicted. The latter scale is the level of resolution often used in roadway design work.

GIS employs a wide range of data sources reflecting the varied goals of the systems themselves. Since GIS may involve applications as varied as archeological analysis,

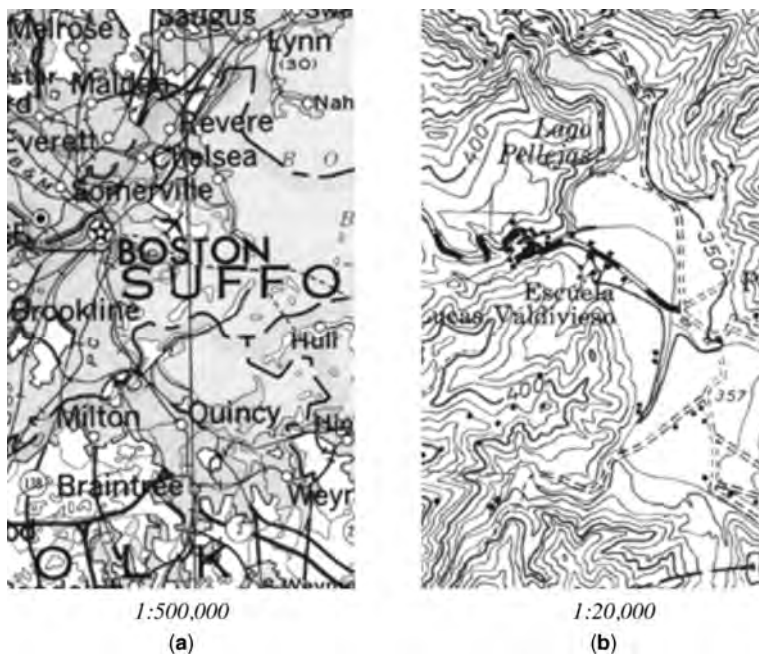

FIGURE 2.2 Effects of scale.

marketing research, and urban planning; the source materials can be difficult to inventory and classify comprehensively. The fact that many different scales may be encountered adds to the complexity of the problem. Even within a single GIS project, the range of materials employed can be daunting. If multiple datasets are contemplated, and they do not have common scales, the process of conflation (the fusion or marrying together of data) may be used in some cases to spatially integrate the datasets to create a new master coverage with the best spatial and attribute qualities. In situations such as this, the analyst should use extreme care in the use of these conflated data.

Uncertainty and Errors Goodchild (1998) described uncertainty as the Achilles' heel of GIS: "the dark secret once exposed, perhaps through the arguments of clever lawyers, will bring down the entire house of cards." Although this may seem extreme, he points out that GIS analysis results are often presented as more accurate than they really are.

In the fields of surveying and geodesy, error analysis based on known measurement error distributions is routine, are based on well-developed theory. For example, errors resulting from individual measurements that are combined arithmetically may be predicted based largely on knowledge of the error distributions of the measurements.

As stated earlier, GIS data normally separate original measurement information from geographic layers. Error modeling for these data has developed rapidly over the past 15 years (see, e.g., Zhang and Goodchild, 2002), but the exclusion of data about measurements constrains its development; error models are "retrofitted" to data, and key information such as error covariance structure often goes missing. In contrast, the fields of surveying and geodesy, as described above, where error analysis based on known measurement error distributions is routine, based on well-developed theory.

A stochastic view of the world, such as that taken by surveyors, assumes that it is not possible to know location on the Earth's surface perfectly (no measurement of a continuous quantity can ever be exact). Herein lies a major advantage of the measurement-based GIS for engineering measurement applications: they adopt a very different approach to GIS architecture, where positions are established not in some absolute Earth coordinate system, but by a hierarchy of relative measurements, anchored to the Earth only at well-defined points (Goodchild, 1999). Preserving the measurements, and the transformations that convert them to positions (and the inverses of such transformations), solves several longstanding GIS-related problems. For example, it is possible to do partial updates, for example, where positions of some features can be made more accurate without at the same time replacing the entire database. It is also possible to perform comprehensive analysis of the propagation of error, and thus of the errors in results of GIS analysis.

2.3.1.2 Geocoding The linkage between attribute data and spatial data as stated previously is the key advantage of using GIS. The process by which this is accomplished is called geocoding. There exist a great many tools to accomplish this process. Some involve matching a nonmap-based database, such as a list of names and addresses, with a map-based database, such as one containing zip code centroids. Using a common field, and the relational model (described in the next section), coordinate information is attached to the name and address.

Other common geocoding tools involve the use of distances along reference lines and offsets from these lines to place objects on a map, thus requiring some sort of linear referencing system. For example, going back to the nonmap-based names and addresses database, one could use a street centerline file which includes address ranges on its links

FIGURE 2.3 Geocoding using address ranges.

to geocode addresses by estimating the address locations based on the length of the segment and the address range assigned to the segment. For example, an address of 41 Elm Street would plot as shown in Figure 2.3.

2.3.1.3 Data Processing For the processing and management of data, the two paradigms most commonly used are the relational and object-oriented models. It should be noted that the database is the operation center of the GIS where much of the primary work is done. Graphics may or may not be necessary for an application but, almost without exception, the database is a key part of any analysis.

Relational database management systems (RDBMS) are well suited for ad hoc user queries—an important aspect of GIS analysis. The relational model uses tables of data arranged as columns (categories of data) and rows (each observation entry). Columns are called fields and rows are called records—as shown in Figure 2.4. Consider, for example, the table of courses shown in Figure 2.6. Note that each course’s attributes are read across, on a row. Queries may be made from these tables by specifying the table name, the fields of interest and conditions (e.g., course credit hours greater than 3). The rows that meet those conditions are returned for display and analysis. The power of RDBMS lies in its ability to link tables together via a “unique identifier” that is simply a field

FIGURE 2.4 DBMS—The relational model.

Professor	Course	Hours	Course ID
Adams	CE341	3	44356
Burken	CE441	3	77877
Nanni	CE223	4	33645
Spring	CE210	3	65645
Zhang	CE446	4	48655

FIGURE 2.5 Table in the RDBMS.

common to both tables and whose values appear only once. Thus, using the current example, one could, in addition to querying about courses from Figure 2.5, query about which students take courses from which professor, number of students in each class who hail from Missouri, geographic distribution of students, and so on. This is done via the common field, student ID, which links the two data tables, as shown in Figure 2.6. Within GIS, this capability to link tables is used to link spatial objects with tables containing information relating to those objects—as shown in Figure 2.7.

These systems may also be used within the GIS to manage survey measurement data. They make it possible to store these data explicitly as an integral part of the geodatabase.

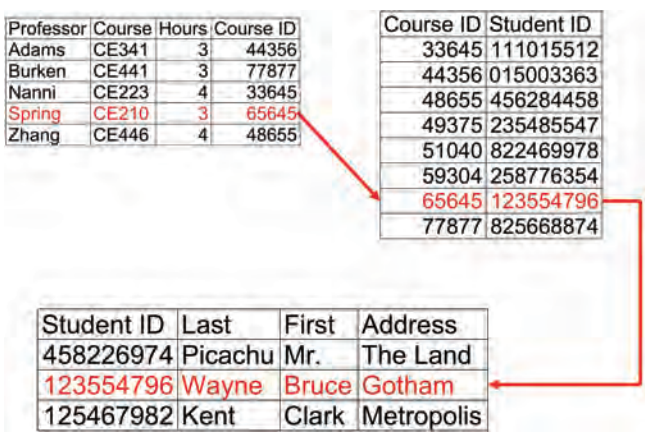

FIGURE 2.6 Linking tables in the RDBMS.

FIGURE 2.7 RDBMS in GIS.

FIGURE 2.8 Survey data in the GeoDatabase.

An ESRI technical paper (ESRI, 2002) describes the data model used to solve problems related to the processing of survey data. Figure 2.8 depicts the conceptual framework.

Object-oriented database management systems (ODBMS) offer the ability to integrate the GIS database with object-oriented programming languages such as Java and C++. Martin and Odell (1992) state that the object-oriented approach “models the world in terms of objects that have properties and behaviors, and events that trigger the operations that change the state of the objects. Objects interact formally with other objects.” In short, the database has a set of objects with attached attributes. At this simplest level, ODBMS is analogous to the RDBMS model in that its objects represent the latter’s “rows” in tables, and its attributes the RDBMS fields. The ODBMS model is much more powerful than this simple definition implies, however. Three concepts are crucial to understanding the ODBMS: abstraction, encapsulation, and inheritance.

Data abstraction is the process of distilling data down to its essentials. The level of abstraction indicates what level of detail is needed to accomplish a purpose. For example, on a small scale, a road network may be presented as a series of line segments, but on a large scale, the road network could include medians, edges of roadways, and roadway fixtures (Rumbaugh et al., 1991). Encapsulation includes procedures with the object data. In other words, code and data are packaged together. The code performs some behavior that an object can exhibit; for example, calculating the present serviceability index of a section of road. Thus, encapsulation allows the representation of an object to be changed without affecting the applications that use it. Modern software programming provides a familiar example of this concept. The application Excel may be called as an object in a Visual Basic routine. The routine would then have access to the application’s full functionality through its attributes (built-in functions).

Finally, inheritance provides a means to define one class of object in terms of another. An object class represents a group of objects with common operations, attributes, and relationships (Fletcher et al., 1995). An object is a specific instance of a class. Each object can have attributes and operations (or code, as explained above). For example, a conifer is a type of tree. There are certain characteristics that are true for all trees, yet there are

specific characteristics for conifers. An attribute is a data value held by objects in a class (Rumbaugh et al., 1991), for example, for the attribute “tree color” the value might be “green.” An operation is a function that may be applied to or by objects in a class. Objects and classes of objects may be connected to other objects. That is, they may have a structural relationship called an association with these other objects. The primary purpose for inheritance is software reuse and consistency (Lewis and Loftus, 1998).

ODBMS hold great promise as GIS tools. Their power, with respect to their abilities to interface with object-oriented programming languages and to provide “smart” data, and their utility when applied to extremely complex databases all support their eventual pre-eminence in the GIS industry. Indeed, in the late 1980s most GIS vendors were moving from RDBMS to ODBMS models (Sutton, 1996). However, today most states continue to use the RDBMS models to manage their geospatial data.

2.3.1.4 Data Sources Digital data may be obtained in a variety of ways and from a large number of sources, all of which fall into one of the five categories listed below. The data sources of interest for measurement-based GIS are those that involve direct measurement of geographic information, such as remote sensing, GPS, and survey data. However, it is often the case that other sources of data are used as the basis for, or supplement to directly measured data, and are therefore included in this discussion.

- Digitizing source materials
- Remote sensing
- GPS for road centerline data
- Existing digital sources
- Survey data

Digitizing Source Materials Digitizing source materials involve digitizing data elements from aerial photographs (considered to be primary source material) or from hardcopy maps (considered to be secondary source material). The process involves collecting the x - y coordinate values of the line features by tracing over each one using a digitizing tablet with a cursor or puck as the input device to locate and input map features into the computer from a paper map. This may also be done using a mouse with a digital raster image map. This latter approach is called “heads up” digitizing. This type of manual production requires planning, source material preparation, and production setup, in addition to postprocessing of data (Davis, 1996). The costs for this type of data acquisition often represent the majority of system startup costs. Semiautomated methods using map scanning and line-tracing technologies are sometimes used to lower the cost and improve the accuracy of the digitizing process.

Remote Sensing Remote sensing is the science (and to some extent, art) of acquiring information about the Earth’s surface without actually being in contact with it. This is done by sensing and recording reflected or emitted energy and processing, analyzing, and applying that information. Remote sensing provides a convenient and efficient means of identifying and presenting planimetric data. Imagery is available in varying scales to meet the requirements of many different users. In general, there are two sources for remotely sensed data: photogrammetry, which uses cameras on-board airplanes, and satellite imagery. The former produces photographs that may either be in paper form, in which case

they must be digitized, as was described in the previous section, or in digital form, which may then be used directly as raster images. Cameras and their use for aerial photography are the simplest and oldest of sensors used for remote sensing of the Earth's surface. Cameras are framing systems that acquire a near-instantaneous "snapshot" of an area of the surface. Camera systems are passive optical sensors that use a lens (or system of lenses collectively referred to as the optics) to form an image at the focal plane, the plane at which an image is sharply defined. Aerial photographs are most useful when fine spatial detail is more critical than spectral information, as their spectral resolution is generally coarse when compared to data captured with electronic sensing devices. The geometry of vertical photographs is well understood and it is possible to make very accurate measurements from them, for a variety of different applications (geology, forestry, mapping, etc.). The use of satellites involves an interaction between incident radiation and the targets of interest. Note, however that remote sensing also involves the sensing of emitted energy and the use of nonimaging sensors. With the advent of online mapping software (as mentioned before, such as Google and Yahoo provide), satellite imagery for the entire United States and most countries around the world is available. These maps are fairly small scale and are therefore are mainly useful for planning purposes only.

Global Positioning Systems These systems use a constellation of 31 actively broadcasting satellites and spherical geometry calculations to determine geo-positions (Wikipedia, 2009). These data, in the form of coordinates, are transformed into path-oriented or linear locations. These measurements are referenced to a standard ellipsoid model instead of base maps or linear field monuments. This allows for new economies in the field and the continued use of existing legacy, and it supports path and network models, applications, and displays.

Existing Digital Data from Other Sources A cost-effective alternative to digitizing is to acquire digital data from a third-party source, such as those described below.

In the recent past, most GIS projects have had to rely almost exclusively upon data available only in printed or "paper" form. Much of these data are now available in digital form while continuing to be published on paper. The ever-increasing pace of this transformation from paper to digital sources has many repercussions for GIS. Inexpensive, and in many cases free, access to high-quality data will enhance the use of GIS in the coming years. The Internet and Worldwide Web are being used more and more to distribute data and information, thus requiring users to know where to look and how to search networks.

All data sources have strengths and limitations. Digital sources are no different. It is important to understand their characteristics, costs, and benefits before using them. Learning a little about commonly employed digital formats will save much work in the long run. Although the types of materials will vary greatly from project to project, GIS practitioners know something of the characteristics and limitations of the most commonly available data sources. These are materials collected and published by a variety of government agencies and commercial interests and are used quite widely.

Local, state, and federal government agencies are major suppliers of digital data. Better than 90% of states maintain databases with state and county route centerlines, and 98% of these also maintain other geospatial databases, as well. The majority of the states (62%) distribute these data free of charge and the others have policies in place that allow data to be shared with other public agencies. Finding the data appropriate for a given system may often require significant online research. This is perhaps less the case at the

federal level mainly because certain key agencies such as the Bureau of the Census, United State Geological Survey, Soil Conservation Service, National Aeronautics and Space Administration (NASA), and Federal Emergency Management Agency, provide standard sorts of information for the entire nation.

Key federal data sources and helpful indexes to those sources include the following.

The Bureau of Transportation Statistics (BTS,) provides links to state GIS resources, national transportation atlas data files, which consist of transportation facilities, networks and services of national significance throughout the United States. The files are in shape-file format, which is the proprietary format for ESRI data. There are also links to Dyna-Map/1000 files which contain centerline data and features for nearly every street in the Nation as well as the National Highway Planning Network which is a comprehensive network database of the nation's major highway system. It consists of over 400,000 miles of the nation's highways comprised of Rural Arterials, Urban Principal Arterials, and all National Highway System routes. The dataset covers the 48 contiguous States plus the District of Columbia, Alaska, Hawaii, and Puerto Rico. The nominal scale of the dataset is 1:100,000 with a maximal positional error of ± 80 m. The network was developed for national level planning and analysis of the U.S. highway network. It is now used to keep a map-based record of the National Highway System and the Strategic Highway Corridor Network.

The United States Geological Survey (USGS, 2010) produces topographic maps for the nation, as well as land use and land cover maps, which include information about ownership and political boundaries, transportation, and hydrography. For access to these data as well as an extensive index of other federal online data sources see the USGS publications web site. The index includes links to the Global Land Information System and tends to concentrate on data created through the USGS.

The Bureau of the Census (Census, 2010) provides socioeconomic and demographic data, census tract boundary files, and street centerline networks (TIGER files) for the entire nation. TIGER comes from the acronym Topologically Integrated Geographic Encoding and Referencing and was developed by the U.S. Census Bureau to support its mapping needs for the Decennial Census and other Bureau programs. The topological structure of the TIGER database defines the location and relationship of streets, rivers, railroads, and other features to each other and to the numerous geographic entities for which the Census Bureau tabulates data from its censuses and sample surveys. It has a scale of approximately 1 in equals 100 ft and is designed to assure no duplication of these features or areas.

The National Aeronautics and Space Administration (NASA, 2010) provides remotely sensed data from all over the world. These data are typically in raster format and are 30 m resolution.

The Federal Geographic Data Committee (FGDC, 2010), established by the Office of Management and Budget, is a clearinghouse for digital data, which is an excellent resource for online federal information of any kind.

As mentioned above, 45 states provide clearinghouses for their geospatial data, significantly easing the task of finding the data desired. Additionally, every state now has a contact person who takes responsibility for the state's GIS. Most data of this type are now available in standard formats, come with adequate documentation and data quality reports, and but still may need to be checked as to origin and quality. Furthermore, the spatial data holdings themselves have limitations. As mentioned earlier different data sources may have different scales associated with them and require conflation to integrate

them. Conflation, however, may not yield the information required. For example, the most widely held data, the USGS 7.5 min quadrangle data (1:24,000 scale), are increasingly becoming unsuitable for the uses of a transportation agency. For example, when collecting driveway data with a GPS unit at 1 m accuracy, centerlines based on 40 ft accuracy do not work well. Updating base maps with greater accuracy has the potential to be an expensive issue.

A primary advantage offered by government datasets is that most are in the public record and can be used for free or for a small processing fee. Some of the agencies that do not provide their data free of charge have found that this practice seriously impedes data sharing.

There also exist many private sources of information. Commercial mapmaking firms are among the largest providers, but other firms have for years supplied detailed demographic and economic information, such as data on retail trade and marketing trends. Some of this information can be quite expensive to purchase. Also, it is important to check on restrictions that might apply to the use of commercially provided data.

Many software vendors repackage and sell data in proprietary formats as well. These data are usually checked and corrected during the repackaging process. The use of these converted datasets can save time. Some firms will also build datasets to a user's specifications. These are often termed "conversion" firms. They are usually contracted to build special purpose datasets for utility companies and some government agencies. These datasets are often of such special purpose that they cannot be assembled from existing publicly available sources, say when an electric utility wishes to digitize its maps of its service area.

Survey Data Ground survey datasets have been developed over a long period of time. Some cadastral datasets, for example, were first created as many as 200 years ago. Given the dramatic improvements in the quality of measurement equipment over the years, integration of modern measurements into geodetic networks presents problems. Storage of coordinates only, as is done in conventional GIS packages, means that adding new, higher quality, measurements to datasets from ground surveys does not improve the quality of the dataset. Indeed, it is necessary to "fit" the results of the new measurements into the old dataset, resulting in a loss of quality. Several authors have described measurement-based systems (Buyong and Frank, 1989; Buyong et al., 1991; Hintz et al., 1996; Goodchild, 1999). According to Joffe (2003) the search for software is over and the ArcGIS extension Survey Analyst is exactly what we need: with ArcGIS Survey Analyst, the quest is over; these tools are now available to surveyors and GIS analysts alike. As a result, a government agency's GIS map base can now be built as a measurement-based multipurpose cadastre, and existing GIS map bases can gradually be transformed into this much desired data model (Joffe, 2003). Navratil et al. () explored the use of this tool with a small test dataset and found that it performs as claimed.

Data Quality It has been said that an undocumented dataset is a worthless dataset. If a dataset's pedigree and quality are unknown, for example, the user must spend time and resources checking the data. Vendors should provide a data dictionary that provides a description of exactly what is in the file (data types and formats), how the information was compiled (and from what sources), and how the data were checked. The documentation for some products is quite extensive and much of the detailed information may be published separately, as it is for USGS digital products.

Some characteristics to consider when evaluating datasets are as follows:

- Age
- Origin
- Areal coverage
- Map scale to which the data were digitized
- Projection, coordinate system, and datum used
- Accuracy of positional and attribute information
- Logic and consistency
- Format
- Reliability of the provider

In summary, sometimes the costs of using and converting publicly and commercially available digital files outweigh their value. No matter how much data becomes available publicly, there is no guarantee that it will contain exactly the sorts of information necessary for specific projects.

2.3.1.5 Data Standards For a variety of reasons, GIS users often want to share or exchange data, usually having to do with overlapping geographic interests. For example, a municipality may want to share data with local utility companies and vice versa. GIS software developed by commercial companies store spatial data in a proprietary format protected by copyright laws. Although vendors often attempt to provide converters, in general, one company's product may not read the data stored in another's format. Applications of digital geospatial data vary greatly, but generally users have a recurring need for a few common themes of data. These themes include transportation, hydrography (rivers and lakes), geodetic control, digital imagery, government boundaries, elevation and bathymetry, and land ownership (or cadastral) information. A lack of investment, common standards, and coordination has created many situations in which these needs are not being met. As a result in some cases, important information may not be available and in others, datasets may be duplicated. A means to maintain and manage the common information being collected by the public and private sector does not exist. This results in increased costs and reduced efficiency for all involved.

Thus, data standardization is a fundamental consideration in developing GIS for integration with existing databases. All users of GIS data depend upon the establishment of standards that should address simple integration and processing of data within the GIS. Standards should include spatial data modeling and scale, accuracy, resolution, and generalization, and datum and projection mapping. As illustrated by the Internet and its interoperability, hardware platforms, operating systems, network environments, database systems, and applications software are generally *not* an issue. The standards for data definitions are much more important than these latter items for providing reliable and portable systems and applications. The GIS software standards, however, can add to the complexity of sharing datasets, since not all GIS share a common route system that is easily transferred from one vendor-specific application to another.

During the 1980s the USGS worked with academic, industrial, and federal, state, and local government users of computer mapping and GIS to develop a standard for transfer and exchange of spatial data. In 1992, after 12 years of developing, reviewing, revising,

and testing, the resulting standard—SDTS—was approved as Federal Information Processing Standard (FIPS) Publication 173-1 (NIST, 1994). The SDTS requires a two-step process for transferring data from one platform to another. The source data are exported by the first GIS to the SDTS format, then the second GIS imports the transfer file, creating a target dataset in its own file format. This approach, while extremely useful in enabling data sharing, is cumbersome at best. Recognizing the criticality of data sharing The National Spatial Data Infrastructure (NSDI) was established by President Clinton's Executive Order 12906 on April 11, 1994 to implement the recommendations of the National Performance Review published by his Administration in the Fall of 1993 [superseded in 1998 by ANSI NCITS 320-1998 (ANSI, 1998)].

The Order states that

Geographic Information is critical to promote economic development, improve our stewardship of natural resources, and protect the environment. . . . National Performance Review has recommended that the Executive Branch develop, in cooperation with state, local, tribal governments, and the private sector, a coordinated National Spatial Data Infrastructure to support public and private sector applications of geospatial data . . .

The concept of this infrastructure was developed by representatives of county, regional, State, Federal, and other organizations under the auspices of the Federal Geographic Data Committee (FGDC, 2010). Rechartered in August 2002, the Committee, an interagency committee, promotes the coordinated development, use, sharing, and dissemination of geospatial data on a national basis. This nationwide data publishing effort is known as the National Spatial Data Infrastructure (NSDI).

The private sector is also actively engaged in building the “National Spatial Data Infrastructure” to meet market place needs defined as business opportunities.

The Open GIS Consortium of 388 private sector, public sector, universities, and not-for-profit organizations representing technology users and providers is addressing the issue of easy access to spatial information in mainstream computing. OGC is working to develop open software approaches that facilitate the development and use of location-dependent software applications using spatial data to increase farm productivity, identify disease and health threats, assist police and law enforcement in identifying crime patterns and many more. In other words, GIS users will be able to access one another's spatial data across a network even if they are using different GIS software programs (OGC, 2009). The International Standards Organization adopted its standard for geospatial metadata, ISO 19115, in 2003, with the intention that standards in member states would eventually be brought into compliance (ISO, 2003).

2.3.2 Spatial Modeling

The benefits of GIS are well established. It provides

- The capability of storing and maintaining large datasets of spatial and tabular information
- Display and analytical capabilities that model the physical proximity of spatial features
- Flexibility in modeling spatial objects to suit the particular needs of the user or application

- Database integration
- Image overlay capabilities
- Network analyses (e.g., shortest path routing).

These capabilities have developed as the technology has matured. In addition, GIS provides a programming environment that allows users to develop specific analysis programs or customize existing programs. All functions for display and analysis can be employed in a single-system design using common programming languages, such as Visual Basic, C++, and Java (Smith et al., 2001). With the advent of object-oriented programming, GIS can be integrated into more mainstream enterprise applications, as well as web-based client applications. GIS provides abilities broader than simply mapping data and includes several types of analytical capabilities that may be broadly categorized into five groups:

- Display/query analysis
- Spatial analysis
- Network analysis
- Cell-based modeling
- Dynamic segmentation

2.3.2.1 Display/Query Analysis The primary appeal of GIS to many is its graphical capabilities as the adage “a picture is worth a thousand words” bespeaks. Maps are the pictures GIS uses to communicate complex spatial relationships that the human eye and mind are capable of understanding. The computer makes this possible, but still, it is the GIS user that determines what data and spatial relationships will be analyzed and portrayed, or how the data will be thematically presented to its intended audience. In short, the GIS allows analyses at a higher level of abstraction than do standard database tools. Using the database capabilities of GIS, the analyst can query the database and have the results displayed graphically. This query analysis, when spoken in everyday conversation, takes on the form of a “show me” question, such as “Can you show me sections of road that are in poor condition?” However, query analysis in GIS can also be used for other purposes, such as database automation, which might be used for error checking and quality control of coded data. As an example, the GIS roadway database could be queried automatically during the crash data entry process to verify the accuracy of speed limit and other crash report variables coded by an officer.

2.3.2.2 Spatial Analysis Several analytical techniques, grouped under the general heading “overlay analysis,” are available in GIS for spatial analysis and data integration. GIS provides tools to combine data, identify overlaps across data, and join the attributes of datasets using feature location and extent as the selection criteria. For example, the number of acres of wetlands impacted by a proposed highway corridor could be obtained by this overlay process. Overlay techniques may also be used in combining data features by adding (or by applying some other function) one dataset to another, or by updating or replacing portions of one dataset with another—thus, creating a new spatial dataset. For example, the analyst could use these techniques to combine number of households and the average number of school age children with pedestrian-related crashes, in order to derive risk factors for the total number of pedestrian-related crashes relative to the total number of school age children per road segment, for pedestrian-to-school safety analysis.

Proximity analysis represents the fundamental difference of GIS from all other information systems. Buffering is a means of performing this practical spatial query to determine the proximity of neighboring features. It is used to locate all features within a prescribed distance from a point, line, or area, such as determining the number of road crashes occurring within one-half mile from an intersection, or, the number of households that fall within 100 ft of a wetland boundary.

2.3.2.3 Network Analysis Unlike proximity analysis that searches in all directions from a point, line, or area, network analysis is restricted to searching along a line, such as a route, or throughout a network of linear features, such as the road network. Network analysis can be used to define or identify route corridors and determine travel paths, travel distances, and response times. For example, network analysis may be used to assess the traffic volume impact of a road closure on adjacent roadways. GIS networking capabilities can also be used for the selection of optimal paths or routes; for example, finding shortest paths between zonal centroids. The network may include turning points, avoid improper turns onto one-way streets, represent posted traffic control restrictions, and include impedance factors to travel (such as mean travel speeds, number of travel lanes, and traffic volumes) to enhance the network analysis. It is this capability that one sees in the on-board navigation tools currently available in some models of automobile.

2.3.2.4 Cell-Based Modeling Cell-based modeling, also referred to as “grid-based” analysis, uses a grid or cells to aggregate spatial data for discrete distribution. Although similar to raster-based systems, these are vector-based. In cell-based modeling, the spatial data are developed as tiles of a given dimension, or points of a uniform distribution, as defined by the user, for display and analysis. Cell-based modeling is effective in displaying patterns over larger areas, such as representing groundwater contamination levels using statistical models as the mathematical base. Since cell-based modeling aggregates data at a specified grid resolution, it *would not* be appropriate for site-specific spatial analysis. In cell-based modeling, special tools are available to merge grid data for overlay analysis. Cell-based overlay analysis is similar to the GIS overlay analysis previously discussed; however, the techniques and functions available in cell-based modeling are somewhat different. When the cells of different datasets have been developed using the same spatial dimensions, they can be merged on a cell-by-cell basis to produce a resulting dataset. The functions and processes used in cell-based modeling to merge grid data are referred to as “map algebra,” because the grid datasets in cell-based modeling are merged using arithmetic and Boolean operators called “spatial operators.”

2.3.2.5 Dynamic Segmentation Dynamic segmentation (dynseg) is a process that allows the association of multiple sets of attributes to a portion of a linear feature without having to modify feature geometry or topology. Although implementation of dynamic segmentation varies by GIS vendor, GIS uses dynamic segmentation to locate and display linear features along a route and/or to segment the route itself. The process consists of interpolating the distance along the measured line of the GIS route from the beginning measure to the ending measure of the line using attributes as the interpolation criteria. In short, the dynseg process allows temporary modification of feature geometry “on the fly” based upon the attribute data being considered. Consider, for example, a vector in a

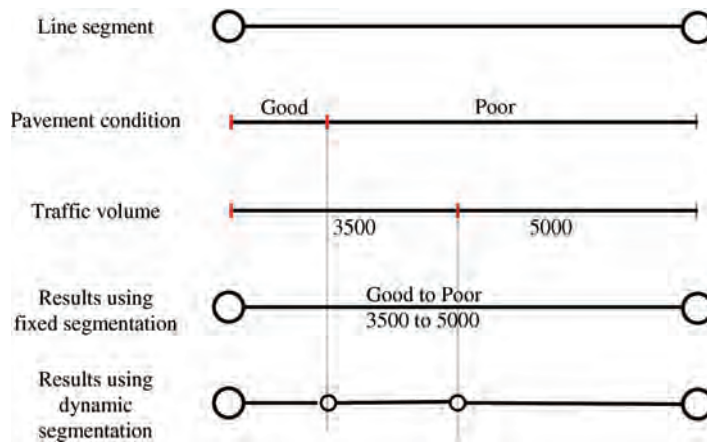

FIGURE 2.9 Dynamic segmentation example.

database representing a segment of road. As explained earlier, this line object is actively linked to a row in a table of attribute data—say road condition. The issue addressed by dynamic segmentation is the inability of the GIS to represent features that do not begin at the beginning of the line and end at its end. In other words, using the road condition example, a road segment's geometry may run from station 0 + 00 to station 5 + 00 but the road condition may (and probably does) change somewhere in between. Figure 2.9 depicts a situation where pavement condition and traffic volume levels are shown along the line segment and demonstrates the difficulty in determining various combinations of pavement condition and traffic volume using fixed segmentation. As the exhibit shows, dynamic segmentation allows representation of these nonuniform attributes without requiring the physical segmentation of the link; that is, no modification of geometry is necessary.

This robust method to represent model links allows the dynamic management of many-to-one relationships between GIS segments attribute features. The method offers several advantages over fixed segmentation. First, the editing of the routes is preferable to editing the underlying base map. Second, the routes may be stored in simple correspondence tables that can be easily read by planning models, for example. Third, depicting the transportation network as linear features (or "linear events") in the GIS means that route tables and associated transit line tables can be managed automatically through dynamic segmentation. Dueker and Vrana (1992) describe dynamic segmentation in great detail.

2.4 MEASUREMENT-BASED GIS APPLICATIONS

Just 10 years ago, GIS was primarily used in single applications. Now it has evolved into serving enterprise wide information through multiplatform applications. Additionally, GIS application development has grown in the past few years significantly. More than one-third of states now spend in excess of a quarter of a million dollars solely on GIS

application development, almost half of which is outsourced. There has been a significant increase in recent years in the number of state departments of transportation developing more accurate road base maps using digital imagery and kinematic GPS. There has also been significant growth in web-based GIS applications and the use of GIS for managing infrastructure inventories (AASHTO, 2009).

Fletcher and Elfick (2009) developed an apparatus that will define a parcel network in a control coordinate system formed from a number of interconnected parcels. This allows automatic creation of GIS databases from existing boundary map data.

Survey Analyst by ESRI integrating survey measurement data into the GIS has been used for a variety of applications to good effect. New South Wales (NSW), Australia, owns and operates the electrified metropolitan railway network throughout Sydney and surrounding commuting areas and is upgrading parts of that system. It used the software to compile survey plans of different ages, dimensions, and orientations resulting in a survey-accurate cadastral database with property attributes to underpin the project GIS database in the ArcGIS environment. The City of Encinitas, CA used Survey Analyst to integrate existing survey documents and records into a new cadastral fabric.

A measurement-based GIS approach is also being used by Encora as part of its European Action Plan for Coastal Management. The software handles data on all spatial scales (entire regional coast vs. a single harbor) and allows comparison of measurements from different years, as well as overlay analysis of measurements and modeling results (Encora, 2007).

Duckham (2002) and Heuvelink (2005) have described efforts to build error-aware systems, and data quality is now an important element of metadata. But, as Goodchild (2008) points out, the mainstream GIS products continue to report the results of calculations to far more decimal places than are justified by any assessment of accuracy, and to draw lines whose positions are uncertain using line widths that are in no way representative of that uncertainty. Indeed, GIS practice seems still to be largely driven by the belief that accuracy is a function of computation, not representation, and that the last uncertainties were removed from maps many decades ago.

2.5 IMPLEMENTATION ISSUES

Implementing GIS is not as simple as merely installing a new piece of software and then operating it. In addition to the information technologies intrinsic to GIS, successful GIS implementation involves elements, such as personnel and their GIS skills, the organizational structure within which they work, and the institutional relationships that govern the management of information flow (Hall, 2006).

GIS is an enabling technology and serves as a platform for integrating various types of data, systems, and technologies. It may be applied to a host of different applications, as demonstrated by the preceding limited review of current applications. Among these are systems that allow for near real-time assessment of conditions, simultaneous sharing of large databases and integration, and enhancement of existing models—all complex and challenging applications. The fact that the adoption rate of GIS technologies has grown exponentially makes successful implementation of these technologies even more challenging. Key areas that must be addressed when implementing GIS include data, people and organizations, and technology.

2.5.1 Data

The collection, maintenance, and use of data are challenging issues that must be addressed early in the implementation process. Who will collect and maintain data, who “owns” the data, and who will serve as its custodian are all questions that must be answered.

The main reason that these questions are important is that they are key in determining if one can take advantage of GIS’s main strength, namely, its ability to share data. That is, as stated previously, GIS serves as a logical and consistent platform in a common location reference system and allows diverse databases to be integrated and shared among different divisions of a department, for example. Integration standards should therefore be established to integrate different databases, some spatial, some not. Answers to the questions also address barriers, such as institutional and organizational arrangements, to the implementation process.

Technical questions, such as what is the nature of the data, how is it to be spatially referenced, and what is its accuracy must be considered—as well as the means by which data from various sources and applications can be integrated. To understand the various data elements in a complex system, metadata (information about data, such as when collected, by whom, scale) should be part of a system. Additionally, spatial data requires establishment of some sort of linear referencing system as was described earlier.

All GIS data, spatial data, and associated attribute data, suffer from inaccuracy, imprecision, and error to some extent. Data quality assurance and quality control rules ensure the delivery of high-quality data. Use of a data steward to collect, maintain, and disseminate GIS data would facilitate this.

2.5.2 Technology

While GIS applications no longer bear the stigma of “new technology” and have been accepted into the mainstream of professional practice, there nevertheless exist technological issues that must be addressed when implementing them. Among these are the identification of critical technologies to be used, and keeping abreast of technological innovations. These include technologies that support interoperability (sharing of data and processes across application/system boundaries), web-based GIS (given its significant growth in the past few years), and a rapidly expanding range of GIS applications. Of course, chosen technologies must match the architecture environment as well. The fact that industry standards are in their infancy exacerbates the problem of choosing the appropriate technologies for a given system. It is crucial to identify limiting technologies, statements by software vendors notwithstanding.

In making this decision one should look to the future, but not too far into the future. One should also keep in mind that there exists an increasing pressure to make geo-referenced data more accessible (and understandable) to the general public.

The introduction of new information technologies is necessarily accompanied by a change in organizational structures and institutional arrangements.

2.5.3 Organizations and People

Organizational and people issues are perhaps the most difficult to address. They continue to be more critical and more difficult to solve than technological issues. Personnel at both management and technical levels must be involved in implementing the system. Yet, this

1. Integration of information for better decisions
2. Decreased risk of poor decisions due to incomplete data
3. Access to more accurate data
4. Reduction of duplicate data
5. Ability to quickly visualize interrelationships of various data and projects
6. Ability to develop public information maps
7. Assist with revenue initiatives
8. Quick response to internal and external queries
9. Easy access to information and maps
10. Significant time savings for information access
11. Unprecedented analysis of information
12. Identification of trends
13. Assist in public relations
14. Better cooperation with regulatory agencies
15. Increased safety for personnel
16. Ability to monitor department commitments

FIGURE 2.10 Intangible benefits of GIS.

has been identified consistently as a problem area—especially maintaining support of upper management. Convincing decision-makers to accept the idea of GIS is key to a system's success. A top-down, rather than bottom-up GIS management strategy should be adopted for GIS planning and implementation.

Of primary interest to decision-makers are two questions: Who pays (for the hardware, software, and personnel required) and from where will the resources be drawn? As with any investment decision, GIS must have economic justification. Hall et al. (2000) conducted a benefit cost analysis of GIS implementation for the state of Illinois. They calculated not only a ratio of slightly less than one but also identified several intangible benefits for GIS project, shown in Figure 2.10, which indicate that GIS benefits outweigh implementation costs.

Champions (at both the management and “grass-roots” levels) are critical to a system's success as well. They can facilitate a positive decision to purchase and enhance the chances for system success.

With regard to the latter, qualified GIS personnel must be available. What training and education are necessary for minimum acceptable qualifications are based upon the level of GIS knowledge needed. There are likely to be three levels of GIS staff and users: local GIS users, local GIS specialists, and a GIS application/data steward. Training for the GIS support personnel is extremely important to the success of GIS.

Early implementation of GIS is often more dependent on vendor supplied training. However, in the long term, the GIS support group should develop specifications for in-house training. Several GIS entities (Zhang et al., 2001) have proposed that a certification for GIS professionals be established to address this important issue. Getting and retaining adequately trained GIS staff continue to be problems. Indeed, there will be increased reliance on outside experts (consultants) for more complex GIS analyses (because of the difficulty in finding and keeping expert staff on internal payroll).

Additional problems of which to be aware relate to the nature of GIS data, namely, that, to be successful, it must be shared. This leads to turf battles and questions about who should have access and how much to the GIS.

2.6 CONCLUSION

Emerging issues and applications at the forefront of current attention include the following:

- Metadata
- Data visualization
- Enterprise GIS

2.6.1 Metadata

Metadata, a description of the contents of a dataset, serves several independent purposes, all related to the ability of users to assess the suitability of a body of information for a specific use. Metadata provides information about quality, the degree to which contents match requirements, technical details about using the information, the legal and ethical constraints on use, and sources of further information.

With advancements in technology, our ability to share data has expanded, as has the concomitant complexity of metadata. Sharing of data with a colleague in the same department is relatively easy, since both the custodian and the potential user probably share a common discipline and language and common set of expectations. Sharing data over the Internet with potential users in other countries, cultures, and disciplines, on the other hand, introduces problems similar to those probably faced by early explorers in communicating with the native inhabitants of the Americas. Thus, there is the need for establishing good data standards governing quality.

The U.S. National Spatial Data Infrastructure, described earlier, includes the Content Standard for Digital Geospatial Metadata (CSDGM). Quality is a major part of the standard but falls short for current needs. Comber et al. (2007) argued for a more user-centric approach to metadata, and one that places greater emphasis on spatial data quality. Goodchild (2009) sets forth seven areas for improvement to the Federal standards relative to the use of metadata. They are summarized below.

2.6.1.1 Decoupling of Content from Positional Accuracy As described in the data section of this chapter, the representative fraction of an original map is often used as a measure of positional accuracy. However, in principle, representative fraction is not defined for digital data, since there are no distances in digital media to compare to distances in the real world. Goodchild and Proctor (1997) consequently argue for the decoupling of content, spatial resolution, and positional accuracy under this single surrogate measure. Current metadata standards do not adequately reflect this. The authors of the standards appear to be aware of the difficulties associated with representative fraction as a surrogate for several aspects of data quality, but have not fully adopted the decoupled approach that now seems needed in its place.

2.6.1.2 Uncertainty Early discussions of the quality of digital geographic datasets focused on concepts of accuracy and error, perhaps reflecting the roots of GIS in area measurement (Foresman, 1998) and the earlier work of Maling (1989). The terms *error* and *accuracy* are now generally avoided in the research community, which tends instead to favor *uncertainty* as the umbrella term, along with *imprecision*, *vagueness*, and terms more closely related to the theories of evidence and non-Boolean sets. Yet neither standard shows any evidence of this significant change of thinking. The term *accuracy* occurs 7 times in the ISO standard and 85 times in the FGDC standard, while *uncertainty* occurs in neither.

2.6.1.3 Separability The FGDC and ISO standards distinguish clearly between the accuracies of attributes and positions but it has long been known that in the case of geographic variation conceptualized as a continuous field where the two concepts are not readily separable. It therefore makes little sense to attempt to specify the positional accuracy of iso-lines, or to separate attribute and positional accuracies for area-class maps, as both the FGDC and ISO standards do.

2.6.1.4 Granularity In the earlier world dominated by paper maps, the body of information described by metadata was a single map, and an intimate association existed between a map's contents and its marginalia. In the digital world, however, the concept of a dataset is much more fluid. Existing arrangements for handling metadata attempt to describe the database at the level of the class or collection of features (the *feature dataset* in the terminology of ESRI's Geodatabase). But one could equally well argue that metadata are needed at the level of the entire database, and that the quality of the information about relationships between classes needs to be described.

2.6.1.5 Collection-Level Metadata Metadata that describe the properties of individual datasets are sometimes termed *object-level metadata*, since they focus on a single information object within the larger framework of an entire collection. Many such collections exist in the form of geospatial data warehouses, digital libraries, or geo-libraries, each containing potentially thousands of separate datasets, as described earlier. Users require guidance as to which collections to search based upon their individual needs. Collection-level metadata (CLM; Goodchild and Zhou, 2003) is defined as data about the contents of an entire collection, describing such characteristics as geographic and temporal coverage, the set of themes that dominate the collection, and the general level of data quality. Efforts have been made to develop content standards for CLM (http://www.alexandria.ucsb.edu/~lhill/alex-imp/Metadiversity_narrative.html), but the task of describing collections is far more complex than the task of describing individual datasets.

2.6.1.6 Autocorrelation Tobler's First Law (Tobler, 1970; Sui, 2004) describes the tendency for "nearby things to be more similar than distant things." There is now abundant evidence that this principle applies to errors and uncertainties in geographic datasets. Knowledge of covariance of errors may be of only limited significance to the visualization of geographic data in maps, but it is critical to any analysis of the propagation of uncertainties during manipulation of spatial datasets. Virtually all interesting products of GIS analysis, from simple measures of slope or area to complex analyses, respond directly to the covariances of errors and uncertainties. Thus, appropriately defined parameters should be an essential part of any attempt to describe data quality in metadata. Yet current standards focus entirely on marginal properties such as mean positional error.

2.6.1.7 Cross-Correlation This discussion of autocorrelation leads directly to the final issue, which is in many ways the most problematic. Although the ability to overlay disparate layers is often presented as a major advantage of a GIS approach, many users will have experienced the problems of misfit that almost always occur. The problem of conflation described earlier. If the positional uncertainties in two layers are other than perfectly correlated, and if both layers contain representations of the same features then the result of overlay will be a large number of small slivers, formed by the two versions of each feature. While it is possible to describe the uncertainties of each dataset independently, the results of overlay cannot be obtained from this information—misfit is a *joint* property

of a pair of datasets, rather than a *marginal* property of either of them. Such information seems essential to the entire GIS enterprise, in so far as it is based on the ability to overlay, and to extract layers of data from widely disparate sources. Great effort has been expended over the past decade at making geographic technologies and datasets interoperable. Yet data quality has received very little attention in this drive to open, interoperable GIS (<http://www.opengeospatial.org>), and the approach to metadata reflected in the standards is uniformly unary.

2.6.2 Data Visualization

Data visualization continues to be an emerging issue for the GIS-T community. The growing popularity of commercial visualization tools such as Microsoft's Virtual Earth and Google Earth have put pressure on GIS-T practitioners to build similar tools. The "look and feel" and speed of the commercial tools are sought by executives and the public. Traditional GIS tools, by themselves, do not have these attributes. Particular functions of interest are as follows:

- Data and network security concerns
- Additional and new licensing, maintenance, and development costs
- Executive and management expectations
- Mash-up mapping techniques
- Three-dimensional views

It is an exciting time to be involved in GIS with the advance of geospatial technology into the mainstream. However, expectations for the technology have risen above the resources available to deliver on them. Commercial technology integration with traditional GIS tools will require follow-up discussions concerning development, implementation, and lessons learned.

2.6.3 Enterprise GIS/Asset Management

Although a commonly used theme, this remains poorly defined to the GIS-T community. Without a proper definition, attainment cannot be determined nor measured, and the role of GIS remains obscure (AASHTO, 2009).

This chapter has provided a brief overview of GIS, defined terms, reviewed general principles and analysis technologies, identified issues, and described major application areas within the measurement-based GIS arena. This material can only serve as a superficial introduction to the applications of GIS to engineering measurement problems but it is hoped that the reader will gain valuable insight into how these systems work, where they have been applied and what difficulties GIS users face when implementing such systems. It is further hoped that, with the "veil of ignorance" removed, users will more readily consider this important class of tools for use.

3.1 INTRODUCTION AND BACKGROUND

In striving toward an environmentally conscious transportation system, the field of traffic congestion management offers a diverse toolbox of solutions to traffic and transportation engineers, all of which are aimed at mitigating the effect of congestion on emissions and air quality. Traffic congestion continues to be on an upward trajectory in the United States. According to the 2005 Urban Mobility Report by the

Texas Transportation Institute, urban daily vehicle miles of travel (VMT) more than doubled in the period of 1982–2003, resulting in a near threefold increase in peak hour delays experienced by motorists in the same time period (from 16 to 47 h of annual delay per peak traveler) (ICF International, 2006). The same study estimated that traffic operational improvements (not including public transportation solutions) could reduce the overall hours of delays by nearly 10% and annual congestion costs by nearly 9%.

The evidence connecting transportation sector use in the United States to prevailing emissions levels for various pollutants is indeed compelling: Direct emissions from surface transportation account for nearly 45% of total national annual emissions of nitrogen oxides (NO_x), 59% of CO, 38% of volatile organic compounds (VOC), and 50% of particulate matter less than 10 μm in diameter (PM_{10}) (Schrang and Lomax, 2005). In addition, electrified surface transportation systems, such as light rail or electric vehicles, generate indirect emissions at the power plants. NO_x , CO, and VOC are precursors to ozone formation in the troposphere layer (the lowest portion of Earth's atmosphere). This layer contains approximately 75% of the mass of the atmosphere and almost all the water vapors and aerosols. Tropospheric ozone is a greenhouse gas that contributes significantly to climate change. Over 158 million Americans live in regions exceeding the National Ambient Air Quality Standard (NAAQS) for ozone (EPA, 2006). Thus, traffic congestion management strategies, whose focus is on improving the operation of the surface transportation system, offer a realistic and substantive means of reducing emissions and improving air quality in the short- and long-term horizons.

3.2 SCOPE OF THE CHAPTER

Congestion management programs that are aimed at reducing overall vehicle emissions on a corridor or network generally fall into two classes: (1) those intended to *restrict the demand or travel intensity* of the transportation system and (2) those aimed at *improving the operational performance* of the transportation system. Some strategies, such as improved transit operations and ridership, could fall into both categories.

In this chapter, the first class will be referred to as *travel demand management (TDM) strategies* and the second as *traffic operational strategies (TOS)*. Absent from this classification are programs aimed at improving vehicle fleet characteristics as they relate to fuel efficiency, the use of alternative fuels, and the associated emission rates, and those targeted at specialized vehicle fleets, such as idling reduction programs for trucks and other heavy vehicles. Thus, the focus here is primarily on the aggregate traffic performance of the average commuter fleet.

Finally, while there are obvious linkages between vehicle emissions and regional air quality measures, these are not explored in this chapter. Air quality indicators generally incorporate multiple sources of emissions, including industrial, residential, and commercial uses, in addition to mobile sources, and are also affected by the regional topography and atmospheric conditions. Therefore, the presentation in this chapter focuses on the emission consequences of traffic management strategies, with the understanding that these strategies relate to only a portion of the total emissions inventory in a region. The relative magnitude of this portion will also vary according to the pollutant considered, as indicated in the national inventory statistics presented in Section 3.1.

3.3 ORGANIZATION OF THE CHAPTER

This chapter is organized around three principal themes. The first theme (Section 3.4) covers the *fundamental measures of emissions* and how they relate to vehicular activity at the individual and traffic stream levels. The second theme (Section 3.5) provides a *survey of traffic congestion management methods* aimed at reducing vehicle emissions, focusing on both demand and supply management. The last theme (Section 3.6) is related to emission-based *assessment methods of the effectiveness of congestion management techniques*, which form the empirical and modeling tools available to engineers and researchers to estimate or predict emission consequences of various traffic control actions or policies.

3.4 FUNDAMENTALS OF VEHICLE EMISSION ESTIMATION

Two fundamental measures underlie the estimation of emissions (E) as they relate to traffic congestion management. These are measures of the vehicle activity (A) and emission factors (EF), where $E = A \times \text{EF}$. In other words, the EF represents the generated emissions per unit vehicle activity.

Vehicle activity can be defined at various levels or scales of aggregation, each with its own purpose, and the associated emission factor. For traffic congestion management purposes, five activity measures are discussed in the following section:

1. Vehicle miles of travel (VMT)
2. Vehicle miles of travel at specified speeds or speed ranges (VMT-S)
3. Travel time distribution by driving mode (MODE)
4. Travel time distribution by vehicle specific power (VSP) mode
5. Travel time distribution using a hybrid VSP-speed (VSP-S) approach

3.4.1 VMT

At a very coarse level, one can define the vehicle activity to be the number of annual vehicle miles traveled by the average gasoline-powered, light-duty vehicle in the United States. According to the 2005 National Transportation Statistics such a vehicle has hydrocarbon (HC), carbon monoxide (CO), and nitrogen oxides (NO_x) emission factors that are equivalent to 1.25, 12.57, and 0.92 g/mile (U.S. Department of Transportation, Bureau of Transportation Statistics, 2005). Therefore, if such a vehicle traveled 10,000 miles per year, its contribution to the annual emission inventory would be 12.5, 125.7, and 9.2 kg/year for HC, CO, and NO_x emissions, respectively.

3.4.2 VMT-S

Although the previous approach could be useful in providing gross estimates of the effect of VMT changes on regional emission levels, it is fundamentally inadequate for characterizing the effectiveness of congestion management strategies. This is because the *nature* of the vehicle activity, and not just its *magnitude*, can have a profound effect on the corresponding emission factor. To illustrate this effect, consider the case where additional

TABLE 3.1 Illustrative Vehicle Speed Effect on CO Emissions

Speed range (mph)	≤10	10–30	30–50	>50
Annual mileage at given speed range	2000	3000	3000	2000
Corresponding EF (g/mile)	18	9	10	11
Annual emissions in speed range (kg)	36	27	30	22

information is known about the mileage distribution of the subject vehicle travel speed throughout the year, as summarized in Table 3.1 (considering CO emissions, and for illustrative purpose only). The implication here is that the emission factor varies with the vehicle speed. Activity in this context is defined as the annual miles traveled in a given speed range.

On the basis of the depicted values, the annual CO emissions in this case would add up to 115 kg/year (contrasted with the 125.7 kg/year value computed earlier). Therefore, a change in the speed distribution—due to changes in the prevailing congestion level—will be automatically reflected in the estimation of total annual emissions produced by the vehicle.

3.4.3 Mode

It is possible to further pursue this line of increased detail by refining the definition of vehicle activity to include the effects of short-term (also known as *microscale*) events that are associated with changes in the emission factor. A *microscale* event represents a different load requirement on the vehicle engine and, therefore, generates different fuel and emission rates. One way to represent these events is to categorize the trip time (or trip distance) into driving modes. A simplified modal emission model by Frey et al. (2002) considers four such modes: acceleration, deceleration, idle, and cruise. Each mode is then associated with a unique emission factor (per unit time or distance), and the activity is defined as the trip travel time spent in each of the four modes.

An example of modal emission factors computed from on-board vehicle measurements in the Frey study is illustrated in Figure 3.1, which depicts the average and 95th percentile

**FIGURE 3.1** Illustration of emission factors by driving mode.

TABLE 3.2 Driving Mode Effect on CO Emissions

Driving Mode	Acceleration	Deceleration	Cruise	Idle
Travel time by mode (h/year)	60	40	150	100
Corresponding EF (mg/s)	40	7	10	2
Annual emissions by mode (kg)	86.4	10.1	54	7.2

confidence intervals for four different pollutants. It is obvious that travel during the acceleration mode has a disproportionately higher emission factor for all pollutants considered, while the idle mode has the lowest emission factor. On an average, the emission factors in Figure 3.1 for CO are 48, 11, 6, and 1.2 g/s for the acceleration, cruise, deceleration, and idle modes, respectively. Therefore, a commuter trip that includes many acceleration and deceleration cycles is likely to generate higher emissions than one in which speed does not vary substantially.

An application of the driving mode approach is shown in Table 3.2, which represents driving conditions in a congested environment for an urban commuter. In this case, travel time by mode in lieu of distance is used to describe vehicle activity. The results indicate that while acceleration constituted only about 17% of the vehicle modal activity, it accounted for more than 55% of the overall annual CO emissions.

3.4.4 VSP

Three obvious deficiencies in the MODE vehicle activity descriptor involve (1) the lack of accounting for the various levels of accelerations (the mode where the highest emission rates occur), (2) the fact that the cruise mode has a fixed emission factor independent of speed, and (3) the fact that this approach does not account for the roadway infrastructure effects on power demand. These limitations can be partially overcome through the use of a *vehicle-specific power term*, or VSP. This parameter is highly correlated with emissions, and appears to form the basis for the development of the next generation emission models at the U.S. Environmental Protection Agency (Koupal et al., 2004; Frey et al., 2002). Instantaneous, second-by-second VSP values for a generic light duty vehicle is expressed as follows:

$$\text{VSP} = v \times [1.1a + 9.81 \times (\sin(a \tan(\varphi))) + 0.132] + 0.000302v^3 \quad (3.1)$$

where VSP = vehicle specific power (kW/ton), v = instantaneous vehicle speed (in m/s), a = instantaneous acceleration or deceleration rate (in m/s^2), \tan = inverse tangent function, equivalent to $\tan^{-1}(\varphi)$, φ = road grade (dimensionless fraction). It has been shown by Frey et al. (2002) that it is possible to discretize the VSP values computed from Equation (1) into a limited number of “bins,” each having a unique average emission factor, which is also significantly different from all other bins. The bin assignments for a light duty vehicle are depicted in Table 3.3.

An example of CO emission factors for a generic light-duty vehicle associated with the VSP bins defined in Table 3.3 is shown in Figure 3.2. Note that modes 1 and 2 represent deceleration models ($\text{VSP} < 0$), while mode 3 includes the idle mode ($\text{VSP} = 0$). All the remaining modes represent combinations of speed and (positive) accelerations.

One obvious difficulty in applying a modal activity model (whether the four-mode or VSP) to assess the impact of congestion management strategies on emissions is the

TABLE 3.3 VSP Modal Definitions

VSP Mode	Bin Range	VSP Mode	Bin Range
1	$VSP < -2$	2	$-2 \leq VSP < 0$
3	$0 \leq VSP < 1$	4	$1 \leq VSP < 4$
5	$4 \leq VSP < 7$	6	$7 \leq VSP < 10$
7	$10 \leq VSP < 13$	8	$13 \leq VSP < 16$
9	$16 \leq VSP < 19$	10	$19 \leq VSP < 23$
11	$23 \leq VSP < 28$	12	$28 \leq VSP < 33$
13	$33 \leq VSP < 39$	14	$VSP \geq 39$

Source: Frey et al. (2002).

requirement for high-resolution vehicle travel data (e.g., second-by-second), which are not typically available to transportation engineers and transit planners. On the rare occasions where a passenger car or transit vehicle fleet is equipped with an automatic vehicle location (AVL) system, speed profiles can be captured and geo-referenced to a point on the roadway, which enables the implementation of modal or VSP models to estimate instantaneous emissions in real time. In practice, however, an instrumented roadway infrastructure can at most produce measures of traffic flow and average speeds on those links that happen to be equipped with vehicle detectors at discrete points on the road. In this case, a hybrid approach that relates VSP to average speed on a roadway link offers a good compromise.

3.4.5 Hybrid VSP-S

This approach is derived from observational studies that are able to relate micro-scale events that occur on a traffic link, such as second-by-second VSP, to aggregate link performance measures, namely average traffic speed. It is based on taking concurrent measures of both parameters using portable emission measurement systems or PEMS (Frey et al., 2003). The concept is straightforward. For each range of average link speed, there appears to be a corresponding, and relatively stable, distribution of VSP values that can

**FIGURE 3.2** CO emission factors versus VSP bins.

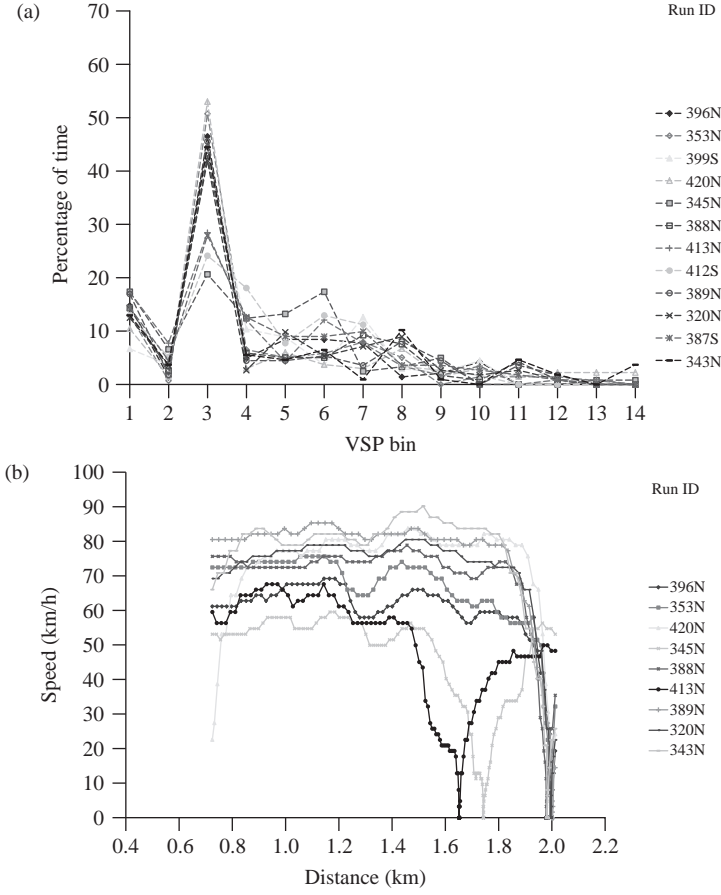

FIGURE 3.3 Speed profiles and VSP distribution (speed range 8–12 mph).

then be used to estimate emission factors (Frey et al., 2006). An example of this approach is shown in Figure 3.3. Figure 3.3a shows multiple speed profiles observed on a single roadway link. These profiles have one thing in common: the *average link speed* from all profiles varies from 8 to 12 mph. Figure 3.3b shows the corresponding travel time distribution of VSPs associated with that speed range. Remarkably, these distributions appear to be fairly uniform in shape, with a mode around VSP bin #3 (not surprising, given the low average speed on the link of 10 mph). The hybrid approach thus entails several steps, namely average link speed prediction, selection of the corresponding distribution of VSP, and application of the appropriate emission factor for each VSP bin (from Figure 2), to the link travel time. Mathematically, the emission estimation method is expressed as follows:

$$E_j = \sum_{t=1}^{T_j} a_{ijt} \times EF_i, \quad i = 1, \dots, 14 \text{ and } j = 1, 2, \dots, J \quad (3.2)$$

where E_j = emissions *per vehicle* traveling on link (j), in g/vehicle, a_{ijt} = 1 if VSP mode (i) occurs in time step (t) on link (j), zero otherwise, EF_i = emission factor associated with VSP mode (i) (e.g., Figure 3.2 for CO), T_j = average travel time on link j (computed as

link (j) length over average link travel speed). By multiplying the per-vehicle emission rate with the link traffic flow (typically on an hourly basis), the above equation produced the overall link emission over the hour for the subject link. Aggregating over all the network links will generate network-wide emissions. Further disaggregation of Equation (3.2) by vehicle type can be carried out to distinguish between emission factors for various vehicle classes (cars, buses, etc.).

3.5 INVENTORY OF TRAFFIC CONGESTION MANAGEMENT METHODS

3.5.1 Travel Demand Management (TDM)

Travel demand management involves a family of strategies that are aimed at altering the demand pattern of travelers' activities. This requires the reader to distinguish between travel demand that is expressed in *person-miles*, and *motorized vehicle-miles* of travel. An implicit assumption in the following discussion is that the demand for person-miles of travel remains unchanged in order to satisfy the individual's objectives to have access to employment and to exercise other desirable economic and social activities. Demand management therefore focuses on altering the motorized vehicle-miles of travel and associated emissions, in order to enable the accomplishment of one or more of the following objectives:

- An overall reduction in demand for vehicular travel activities (VMT)
- A spatial shift in the current vehicular travel demand to less congested facilities
- A temporal shift in the current vehicular travel demand to less congested periods of the day
- A modal shift in the current vehicular travel demand to less-polluting motorized or nonmotorized alternatives

A sampling of some commonly used TDM strategies is described next (ICF International, 2006). It should be noted that several of the strategies can affect more than one of the stated objectives.

- *Congestion and Parking Pricing*: These strategies are aimed at altering traveler behavior by increasing the out-of-pocket cost for users of the transportation system during peak demand periods. Some of the common technologies include toll roads, high occupancy toll or HOT lanes (these are physically separated lanes that provide reduced cost of access to vehicles meeting a pre-specified passenger occupancy and may provide more costly access to other vehicles not meeting the occupancy threshold), cordon pricing as exemplified by the Central London congestion pricing scheme (Litman, 2007), peak-period parking costs, or restrictions. Their intended primary effect is to produce a temporal reduction in peak period demand (Objective 3) for the high pollutant travel modes. When combined with preferential pricing policies toward the use of public transportation, these strategies could also affect a modal shift (Objective 4).
- *Flexible Work Hours*: These employer-based programs are aimed at reducing peak travel (Objective 3) by allowing employees some flexibility in the start and end hours of their workday, and in some cases compress the weekly work schedule into four working days.

- *Park-and-Ride Facilities*: Park-and-ride facilities are targeted toward inducing a modal shift (Objective 4) from private to public transportation modes (mostly bus, light rail, or heavy rail modes). In addition to providing direct access to those modes at the trip origin point, free or low-cost parking is often provided for commuters at those facilities.
- *High Occupancy Vehicle (HOV) Facilities*: HOV facilities apply to both car-pool and (normally) bus transit vehicles. The facilities are exclusive to the users of these modes and, therefore, offer an improved level of service as an incentive for the modal shift (Objective 4). It is important to note that providing easy access to and egress from those facilities is critical; otherwise, their use becomes of limited value to the traveler. This could be in the form of separate entry and exit ramps on free-ways, or by providing preferential access at the entry ramps to HOV facilities on freeways.
- *Ridesharing and Vanpool Programs*: These programs are aimed at producing a direct reduction in VMT (Objective 1) by promoting and facilitating ride sharing and (normally employer-based) vanpool programs. These may include incentives such as free parking, free fuel, and the use of HOV facilities among others. Membership in such programs would be on a subscription basis, although recent advances in computer-aided dispatching could enable real-time ride matching and vanpooling.
- *Nonmotorized Alternatives*: These programs promote nonpolluting walking and bicycling modes (Objective 4) through a variety of infrastructure improvements. Examples include dedicated bicycle lanes, wide sidewalks, grade-separated pedestrian crossings at busy intersections, and a variety of priority treatments at signalized intersections. To accommodate longer trips the provision of bicycle storage space on transit buses and rail cars, and exclusive bicycle park-and-ride facilities at train stations are often considered.
- *Transit Alternatives*: These programs are aimed primarily at shifting single occupancy vehicle (SOV) drivers to public transportation modes, which are highly effective in reducing pollutants per person-mile of travel (Objective 4). Improvements are generally implemented in four areas: (1) service, including added transit lines, shorter headways, and higher reliability; (2) amenities at bus and transit stops, including covered, and climatized shelters; (3) pricing, including reduced or fare-free rides for the general or special populations; and (4) travel information systems disseminated through a variety of media, including the internet, 511 call lines, cable television, and strategically located traveler information kiosks.
- *Land-Use Strategies*: These programs represent a significant departure from the predominant suburban land-use development patterns with their reliance on the auto mode for virtually all trip purposes, to one that is transit, pedestrian, and bicycle friendly. Known also as *smart growth*, or *neotraditional* patterns, these strategies promote mixed-use development that can negate or at least curtail the need for auto travel. By definition, such strategies are not expected to have a short- or even medium-term impact on trip making behavior, but in conjunction with improved vehicle emission technology, have the most significant potential for reducing emissions on a large scale through major reductions in auto VMT (Objective 1). The work by Johnston et al. and Rodier et al. quantifies the effect of land-use changes on vehicle emissions (Johnston and Ceerla, 1995; Rodier et al., 2002).

TABLE 3.4 Mapping TDM Strategies to VMT Changes and Time Horizon

Highway information services	✓	✓	✓	✓	1

- *Highway Information Services:* These strategies fall under the umbrella of *advanced traveler information systems* (ATIS). Their impact is ubiquitous in that they can affect the spatial, temporal, modal, and number of trips that are taken by the traveler (Objectives 1–4). Yet, the effect of ATIS on VMT of travel, much less emissions and air quality, remains somewhat elusive, due to the difficulty of acquiring the appropriate empirical data. Travel information can be imparted pre-trip (at home), which could alter the traveler's departure time, route, and mode taken or forgo the trip altogether; it could be given en route via changeable message signs (CMS) or from in-vehicle navigation and routing systems, which will tend to alter the spatial pattern of the trips.

Table 3.4 provides a summary of the general impacts of the stated travel demand management strategies on VMT-based activities.

3.5.2 Traffic Operational Strategies (TOS)

A common characteristic across TDM strategies is that they all tend to target trip-making behavior *before* the trip is actually made. Traffic operational strategies, by contrast, are geared towards reducing emissions under prevailing traffic conditions. In most cases, congestion mitigation measures will also have a positive impact on emission reductions. This section, therefore, focuses on strategies that have an effect on the individual and traffic speed profiles of vehicles as they travel through the network. It has been established in Section 3.3 that significant speed changes over a trip will result in increased emissions. A simple example by Unal illustrates this point vividly (Unal, 2002). Figure 3.4 shows speed profiles for two trips that have identical average travel speeds (19 mph), using the same vehicle on the same route. Trip 2, however, appears to have much larger speed variance than trip 1. Table 3.5 depicts the pollutant emissions measured for both trips using a portable emission measurement system (PEMS). It is evident that a speed profile that is not *smooth* will generate much higher emissions. In the case presented, CO emissions for

FIGURE 3.4 Speed profiles for two trips at an average speed of 19 mph.

trip 2 are three times as high as for trip 1; NO emissions for trip 2 are close to five times as high as those for trip 1. The same pattern applies to the other pollutant, although less dramatically. In the following presentation, while the focus may be on solutions that increase travel speed, it is critical to note that speed variance is the stronger indicator of emission impacts.

Traffic operational strategies are typically identified by the facility type where they are applied, namely freeways or surface streets (which includes arterials, collectors, and local roads). An important consideration of the effect of TOS is the possibility of induced traffic demand as an outcome of congestion mitigation. In other words, while TOS are intended to reduce the unit emissions by smoothing traffic flow, as evident from the preceding charts, they could have the unintended consequence of increasing the vehicle miles of travel, which could partially offset their benefits. Unfortunately, there are no standard methods to estimate the elasticity (or sensitivity) of travel demand to short TOS-type improvements, but the engineer should, nevertheless, be cognizant of such unintended consequences. Two comprehensive sources of information on the emission effects of traffic flow improvements include the USDOT Intelligent Transportation Systems Benefits Page and a National Cooperative Highway Research Project report by Dowling et al. (U.S. Department of Transportation, 2007; Dowling et al., 2005).

3.5.2.1 Freeway Operational Strategies

- **Ramp Metering:** Ramp metering has the beneficial effect of reducing traffic turbulence in the ramp entrance zone, particularly when the freeway mainline is operating close to capacity. Evidence shows that with ramp metering, average speeds increase, and delays are reduced when proper metering rates are applied (Piotrowicz and

TABLE 3.5 Measured Trip Emission Rates for Trips Shown in Figure 3.4

Trip	Pollutant Emission Rate			
	CO (mg/s)	NO (mg/s)	HC (mg/s)	CO ₂ (g/s)
1	6.1	0.41	0.91	2.3
2	19	1.9	1.2	3.1

Robinson, 1995). Metering can be implemented in an isolated fashion at selected ramps, or via a system-wide coordinated metering plan that covers entire corridors. Possible drawbacks of metering include the possibility of long queues at ramps that may spill back onto the surface street, and inducing large acceleration rates for entering traffic (see Figure 3.1).

- *Incident Management*: Incident management systems mitigate the effects of nonrecurring congestion due to accidents, stalled vehicles, unanticipated road work, and so on. Evidence shows that between 52 and 58% of all congestion delay may be due to nonrecurring events, or incidents (ICF International, 2006). By reducing the response and clearance times for such incidents, delays and travel times can be markedly reduced. There are also safety benefits that can accrue from a reduction in secondary (mostly rear-end) accidents that occur as a result of the large speed differentials between approaching traffic and traffic within the vicinity of the incident.
- *Bottleneck Mitigation*: Freeway bottlenecks are leading causes of recurring traffic congestion on urban freeways, resulting in local stop-and-go operations in their vicinity. They are typically activated when traffic demand surges over capacity downstream of a congested on-ramp or when geometric restrictions reduce the normal freeway capacity, as in the case of a lane drop or a weaving section. Besides major (and costly) capacity additions, there are low-cost solutions that may mitigate their effect, including short auxiliary lanes, the use of hard shoulders during the peak hours, and implementation of truck restrictions. A unique strategy that enables the use of a wide shoulder as a narrow lane for queue storage during peak flow periods only (called the plus-lane) has been applied in Utrecht, The Netherlands, and is illustrated in Figure 3.5 (Roupail and Chae, 2003).
- *Lane Control*: Lane control strategies are more commonly used in European cities to control speed and restrict lane use to specific time periods or vehicle classes. From an emissions control perspective, lane control promotes gradual speed reduction ahead of a congested region through the use of a series of advisory or regulatory speed limit signals erected on overhead gantries. This control will tend to smooth the traffic speed profile and minimize high acceleration and deceleration events. An example application of speed control ahead of a lane drop in Stockholm, Sweden, is illustrated in Figure 3.6.

In addition, many urban areas in the United States use a combination of reversible and HOV lanes to provide added capacity in the peak flow direction to meet the prevailing directional demand. More recently, entire directional freeway facilities have operated in the reverse direction to evacuate traffic from hurricane-threatened coastal areas (Williams et al., 2007).

- *High-Speed Tolling*: On toll facilities operating with manual toll collection, approaching vehicles will experience significant speed change cycles both upstream (deceleration) and downstream (acceleration) of the toll booth. The zone just downstream of the toll plaza, where large accelerations are prevalent, is considered to be a high CO emission hot spot (Coelho et al., 2005). The use of electronic, high-speed tolling negates the requirement for a vehicle to come to a full stop and then accelerate to freeway speeds, and, therefore, reduces the number and severity of speed change cycles in the vicinity of toll facilities. Such systems use electronic tag readers on the moving vehicle to record its arrival and to charge the user's account.

FIGURE 3.5 Bottleneck mitigation using plus-lane concept.

3.5.2.2 Surface Street Operational Strategies

- Signal Timing and Coordination:** Improved traffic signal timing and coordination is considered to be one of the most cost-effective measures for congestion mitigation and emission reductions on surface streets. According to the Institute for Transportation Engineers, there are over 300,000 traffic signals in the United States, with the majority needing upgrading of equipment or adjusting of the timing or coordination, while servicing nearly two-thirds of the vehicle-miles traveled (Institute for Transportation Engineers, 2007). Comprehensive signal retiming programs have documented benefits of a 7–13% reduction in overall travel time, a 15–37% reduction in delays, and a 6–9% fuel savings. Signal coordination, in particular, has a significant impact on reducing vehicular stop-and-go cycles. Section 6.1 discusses the results of a study on the effect of improved timing and coordination on real-world measured vehicle emissions.

FIGURE 3.6 Lane and speed control system (Courtesy Rouphail, 2001).

- *Tidal or Reversible Flow Lanes*: Similar to reversible lanes on freeways, tidal flow lanes on arterials are used to provide flexible capacity in one direction to accommodate peak flow traffic. These are also used to cater for special event traffic that requires the provision of capacity in different directions before, during, and after the event (sporting events, concerts, major evacuation, etc.).
- *Roundabouts*: This form of intersection traffic control is becoming very popular in the United States, with over 700 modern roundabouts installed (Kittelson and Associates Roundabout Database, 2007). From a vehicle emission perspective, roundabouts, especially those that are not highly congested, promote a smoother speed profile in the vicinity of the intersection, by not requiring traffic to stop at the circle, and by reducing overall speeds on the approach and in the circle. Evidence, from both empirical and modeling studies, indicates positive environmental effects. As an example, a recent study in Sweden shows that at a small roundabout that replaced a signalized intersection, CO emissions decreased by 29%, NO_x emissions by 21%, and fuel consumption by 28% (Varhelyi, 2002). At roundabouts, replacing yield-controlled intersections, CO emissions increased on average by 4%, NO_x emissions by 6%, and fuel consumption by 3%. An area that requires further investigation is the effect of exiting traffic on emissions, where drivers tend to accelerate from the circulating lane design speed to that of the open road ahead.
- *Continuous Flow Intersections*: Continuous flow intersections (CFIs) represents an innovative intersection design scheme that physically separates and services left-turn movements upstream of the main intersection, which are then rerouted to a lane to the left of the opposing flow. This design enables the left turns to merge without stopping into the cross-street traffic. According to recent studies, there are only two such installations in the United States, in New York and Maryland, with the majority of the installations in Mexico. Similar to other TOS strategies, CFIs have been shown to reduce delays and speed change cycles at intersections and, thus, would result in lower fuel and emission use. An illustration of an operational CFI in Mexico City is shown in Figure 3.7.
- *Bus Signal Priority*: This strategy entails the provision of traffic signal control priority for buses on arterials. This can be accomplished in several ways, depending on the signal indication when the bus arrives at the intersection: an early green start, an extension of the current green (if needed), or an off-sequence special green phase. The purpose of these strategies is to reduce transit travel time, improve its reliability, and, in the long term, help increase transit ridership (essentially a TDM strategy). The emissions consequences of implementing bus priority schemes are unclear and very much depend on the site conditions. Areas of concerns are the effect of the bus signal priority or preemption on disrupting the existing signal coordination plan, and on side street traffic that may be penalized as a result of the additional main street green times. Advanced algorithms that account for schedule delay (using automated vehicle location systems) and real-time passenger counts in deciding whether preemption is desirable may alleviate some of these concerns.

A comparison of TDM and TOS strategies indicates that the first has a diverse set of objectives, ranging from reducing travel demand, to shifting it in time, in space, or to other environmentally friendly modes. Traffic operational strategies, by contrast, tend to

FIGURE 3.7 Continuous flow intersection operation (Courtesy Francisco Miero).

hone on the single objective of smoothing traffic flow by reducing stop-and-go cycles, maintaining near-uniform speed profiles, and minimizing the episodes of high emissions associated with large acceleration and deceleration events.

3.6 ASSESSING EMISSION IMPACTS OF TRAFFIC CONGESTION MANAGEMENT

There are numerous methods available to transportation and environmental analysts to evaluate the effectiveness of traffic congestion management methods. These can be classified into two general categories: on-road direct measurements and emission estimation models. The latter can be further subdivided into emission factors and traffic models. Some methods combine elements of both types of models.

3.6.1 Direct Measurement Methods

This section covers two direct measurement methods for vehicle emissions.

3.6.1.1 Portable Emission Measurement Systems (PEMS)

Vehicle emissions can be directly measured under various traffic conditions using PEMS (Frey et al., 2003). This method is rapidly gaining wide acceptance by the user community and regulatory agencies such as the U.S. EPA. These devices are installed in a vehicle in a matter of minutes and enable the analyst to measure tailpipe emissions of several pollutants, including CO, NO, HC, CO₂, and O₂, in addition to fuel consumption, on a second-by-second basis under real-world traffic conditions. PEMS is connected and synchronized with the vehicle engine data scanner, which includes, among other variables, a second-by-second speed profile. It draws AC power from the cigarette lighter outlet. Figure 3.8 depicts a PEMS device, the engine data scanner, its positioning in the vehicle, and the connection to the tailpipe sampling probe.

An example assessment study using PEMS was reported by Unal et al. (2003). In this study, the effectiveness of a traffic signal timing and coordination scheme for an arterial corridor was carried out. The study involved multiple runs of two PEMS-instrumented

vehicles using the same drivers and data collection periods before and after the signal system was coordinated. Figure 3.9 shows speed and CO traces for a representative single run in the before and after case.

It is evident that this strategy was effective in reducing the corridor travel time, as well as smoothing the speed profile by reducing the number of stops and CO emissions. Summary statistics of traffic and emission changes after the signals were retimed are reported in Table 3.6 for both directions of traffic, two peak periods, and two vehicles. The results confirm the cost-effectiveness of signal control strategies as an emission mitigation measure.

The same referenced study also compared emissions for uncongested and congested traffic conditions on another corridor, by contrasting trip emissions in the peak and off-peak directions (Unal et al., 2003). The results were even more dramatic, with a decrease in trip emissions in the range of 40–60%, depending on the time period and the pollutant considered.

FIGURE 3.8 Example of a PEMS and its installation in a vehicle.

FIGURE 3.8 (Continued).

3.6.1.2 Remote Sensing Device (RSD)

Remote sensing technology utilizes infrared spectroscopy to flag high-emitting vehicles as they pass a point on the highway. It is motivated by statistics that show that only about 10% of the on-road vehicles are responsible for over 50% of the CO, NO_x, and HC emissions. The device consists of an infrared source that emits a light beam across the highway just before and during the vehicle crossing the measurement point, as shown in the schematic Figure 3.10 (EPA Fact Sheet OMS-15, 1993). The system determines the ratio of CO/CO₂ in the vehicle plume, and if the level of carbon monoxide (CO) is above a certain threshold, it is tagged as a high-emitting vehicle, typically using video detection technology. The device could also be used to assess the emission consequences of traffic control strategies. However, it has many limitations with regards to lane (one lane at a time) and spatial coverage (single point on the road), and as such could miss many of the high-

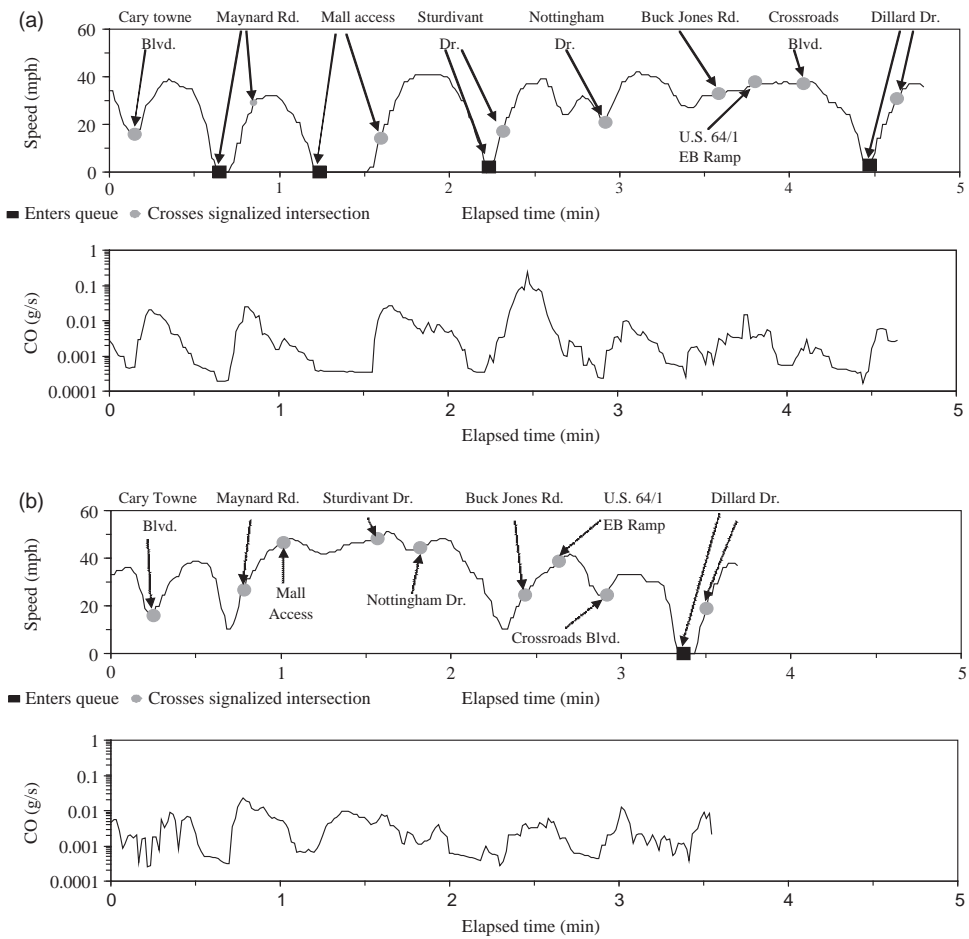

FIGURE 3.9 Representative speed profiles before and after signal coordination. *Source:* Unal et al. (2003).

acceleration events that are concomitant with episodes of high emissions. Unal et al. (1999) reported on the concurrent use of RSD and area-wide vehicle detection for the simultaneous analysis of traffic performance and emissions.

3.6.2 Mobile Emission Estimation Models

This section covers three models for estimating mobile emissions.

3.6.2.1 Mobile

By far, the most widely used family of mobile emission factor models is EPA's MOBILE series, of which MOBILE6.2 is the latest release (EPA User's Guide to MOBILE6.1 and MOBILE6.2, 2003). These models represent the state of the practice for developing emission inventories and control strategies at the regional or state levels, as part of the required state implementation plans (SIP) under the 1990 Federal Clean Air Act. MOBILE emission factor values represent *national average* conditions, in terms of vehicle fleet (classified into 28 vehicle categories), VMT distribution among roadway types, standardized driving cycles on these roadways, and speed distributions among roadway types. These averages can be modified to fit local conditions through a series of adjustments to the base emission factors on the basis of modified user input to better reflect local conditions. From a congestion management perspective, MOBILE inputs that are relevant include the types of roadways (freeways, ramps, arterials, and local streets), the VMT distribution across these facilities (national defaults are 34, 3, 50, and 13% for the four facilities), and the average speed on those facilities (national default *daily* speeds are 36.5, 34.6, 31.2, and 12.9 mph, respectively). The pollutants of interest include HC, CO, NO_x, and CO₂. MOBILE can represent any vehicle fleet from 1952 to 2050, making assumptions on the distribution of vehicle age in a given calendar year (CY). Sample results of the sensitivity of MOBILE6 freeway and arterial emission factors to average speed are shown in Figure 3.11.

The data shown are for the projected fleet for CY2008, and include light-duty vehicles *only*. Several patterns emerge from those data. First, MOBILE emission factors for freeways and arterials are not significantly different from each other when controlling for the pollutant type. This may be a result that the national default speed distributions between these two facilities are very similar as indicated earlier. Second, CO emissions factors

FIGURE 3.11 MOBILE6 emission factors' sensitivity to average speed on freeway and major arterials; in g/mile of travel.

exhibit a nonlinear relationship with speed. They tend to be lowest in a speed range of 25–35 mph, and increase below or above that range. However, HC and NO_x emissions factors decrease monotonically with speed for the low average speed range (15–30 mph) and then remain essentially unchanged for NO_x while HC emission rates continue to drop as speed increases. This indicates that stop-and-go traffic patterns are likely to be associated with high emissions of these two pollutants.

An important caution in the application of MOBILE6 factors for the assessment of traffic control measures is the need to acknowledge the sensitivity of travel demand (i.e., VMT) to level of service (LOS). The user must account for the possibility that improved traffic performance could generate additional (new) trips that could partially offset the benefits gained from reducing the emissions factors.

There are many more applications of MOBILE than can be covered in a comprehensive manner in this chapter. The reader is strongly encouraged to consult the MOBILE6 user guide and associated documentation on the EPA Office of Transportation and Air Quality, OTAQ (2007). It is noteworthy to mention that EPA is currently developing a new emission estimation framework called MOVES (MOTOR Vehicles Emission Simulator) that will rely on more refined data, based partly on the VSP approach explained earlier. MOVES will eventually replace MOBILE6. The current release MOVES2004 provides estimates for fuel consumption and greenhouse gas emissions for on-road vehicles only (EPA, 2005). Future releases will include the estimation of HC, CO, and NO_x, and for on-road vehicles (Koupal et al., 2004).

3.6.2.2 MODAL, VSP, and VSP-S Emission Factor Models

These models have been discussed in Section 3.4 and are mostly derived from microscale speed profile data gathered in the lab using engine dynamometers, or in the field using PEMS.

3.6.2.3 COMMUTER2.0 Model

This model, developed for EPA, estimates the travel and emission impacts of many of the transportation demand management strategies that were described in Section 5.1 (EPA, 2005). It is designed to focus on small programs and transportation control measures that do not have large regional travel impacts, in which case traditional regional travel demand models should be used. In COMMUTER2.0 travel impacts are modeled using a logit model formulation that produces modal and temporal shifts based on the value of a utility function of modal travel times, transfer times, and costs. By specifying a baseline scenario of mode choice, trip lengths, and current VMT, COMMUTER2.0 will estimate *changes* in VMT's and associated emissions, the latter mostly derived from the MOBILE6 model. Figure 3.12 shows a sample scenario output of this model, based on the input and traffic measures provided by the users. Additional details can be found in the model user guide.

3.6.3 Transportation Models

This section discusses the use of transportation models to assess the emission impacts of transportation control measures. For the most part, these models focus on estimating the travel or traffic impacts of regional and local transportation improvements, and, as such, the model selection depends on the nature and geographic impacts of the application. Models can be classified as travel demand models, macroscopic traffic operations models, and microscopic simulation models.

3.6.3.1 Travel Demand Models

This class of models is typically used for estimating long-term transportation system needs (15–20 years). Their focus is on predicting required link-level characteristics (type, capacity, etc.) that are needed to accommodate future traffic demands. Typically (with some exceptions), this class of models does have the capability of predicting emissions. Instead, a post-processing step is executed to use the travel model output (e.g., VMT by roadway class, vehicle type, and speed) as input into MOBILE6. Because MOBILE represents national average emission factors, it is important for the user to *not* rely on or use link-level emission estimates, since these are highly simplified. The intent is to obtain a fairly coarse estimate of the emission inventory on a regional scale. Commonly used travel demand models include TRANPLAN, EMME2, TransCad, and TRANUS (TRANPLAN homepage, 2007; TransCad homepage, 2005; Modelistica, 2007).¹

3.6.3.2 Macroscopic Traffic Operations Models

This class of models considers the effect of local or corridor-wide improvements (such as ramp metering, signalization, HOV lanes, and so on) on traffic performance with the implicit assumption that vehicle activities (i.e., VMT) remain fixed before and after the

improvements. Many of these models have also incorporated emission prediction algorithms within the models, although it is often unclear what the assumed vehicle fleet is and how the emission rates were calibrated. Some models, such as Synchro, use a fuel-based approach that relates HC, CO, and NO emissions to fuel consumption (per hour or per mile) (Husch, 1998). Others, most notably aaSIDRA and SIGNAL200, incorporate four-mode (acceleration, deceleration, cruise, and idle) and three-mode (acceleration, idle, and deceleration) modal emission models in their software, respectively (Akcelik and Beskley, 2003; Strong, 2007). The U.S. Highway Capacity Manual, the most widely

used macroscopic traffic operational model in the United States (and possibly worldwide), has no provisions for emission estimation (Transportation Research Board, 2000). This has led users of the HCM to rely on other macroscopic or microscopic models to meet those needs.

3.6.3.3 Microscopic Traffic Simulation Models

This class of models traces individual vehicle movements over a traffic network, with vehicle position and speeds updated at one second or subsecond resolutions. The advance logic is based on driver behavioral models, such as car following, lane changing, and gap acceptance. Driver level of aggressiveness, which could have a significant impact on acceleration rates and emissions, is also considered, although rarely calibrated from empirical observations. Because these models can produce individual speed profiles their results can be easily integrated with microscale emission rate models such the MODE or VSP models described earlier to produce second-by-second emissions. Often, this integration is built in the simulation, as in the CORSIM model that uses a speed-acceleration look-up table (by vehicle type) to calculate emissions based on unpublished dynamometer testing at the Oak Ridge National Laboratory (Federal Highway Administration, 1997). A similar approach is adopted in the INTEGRATION model, the VISSIM model, and the PARAMICS model (M. Van Aerde and Transportation Systems Group, 1995; Paramics, 2007).²

It is often advisable to decouple the simulated speed profiles from the default emission estimation methods embedded in the simulators. This is because the emissions calibration data could be either out of date or not representative of the U.S. vehicle fleet. An example of representative speed profiles in the VISSIM model based on a study that compared traffic operations on an urban arterial using a series of signals (baseline) and roundabouts (proposed) is shown in Figure 3.13 (Rouphail and Chae, 2003). These vehicles were selected as their travel time coincided with the average travel time. While both profiles show considerable speed variations, there were more stops in the signalized arterial case. By applying the VSP approach described in Section 3.4, VSP values, VSP bins, and associated emission rates were estimated. Table 3.7 summarizes the emission effects of replacing the signalized intersection system with a series of roundabouts. Multiplying

TABLE 3.7 Unit Emissions for Traffic Signal and Roundabout Control

Direction and Type of Control		NO (g/veh.)	HC (g/veh.)	CO ₂ (g/veh.)	CO (g/veh.)
EB	Signal	0.65	0.29	733.06	6.86
	Roundabout	0.59 (−9.4%)	0.23 (−19.5%)	693.38 (−5.4%)	4.71 (−31.3%)
WB	Signal	0.63	0.24	630.22	7.65
	Roundabout	0.61 (−2.3%)	0.28 (+15.4%)	816.45 (+29.6%)	4.77 (−37.7%)
Overall	Signal	1.28	0.53	1363.29	14.51
	Roundabout	1.20 (−0.9%)	0.51 (−3.5%)	1509.84 (10.7%)	9.48 (−34.7%)

these values by the corresponding VMT in each case gives the overall emission impacts (Rouphail and Chae, 2003).

3.7 SUMMARY

This chapter presents a survey of the impacts of traffic congestion management strategies on vehicular emissions and, by extension, on air quality. It begins with the premise that mobile source emissions are a significant contributor to the national emission inventory for some pollutants and that congestion mitigation strategies that focus on both transportation demand and supply sides can significantly reduce the harmful effects of airborne pollutants. The chapter also discusses tools that are available to the engineer and analyst to measure, estimate, and predict emissions in response to changes in supply or demand-oriented transportation strategies. Although the literature contains a wealth of information on such effects, there is no general consensus in the transportation and environmental community on which tools are appropriate for what types of analysis, especially those at the corridor and local intersection levels. The author hopes that the material presented herein, although by necessity much abbreviated, will be of assistance to the users in identifying and evaluating the available tools

and in understanding the tools' strengths and limitations. Regardless of the method selected, the analyst must be cognizant of and account for the *long-term effects* of traffic control measures on overall emissions, particularly the impact of improved traffic flow conditions on latent demand and modal choice effects. Emerging EPA emission estimation paradigms exemplified by the MOVES model will, in the future, enable the analyst to carry out multi-scale level analyses that are sensitive to regional as well as local transportation improvements. Finally, whenever possible it is critical that local travel behavior and emission rates be used, especially if the analysis is in response to regulatory requirements such as state implementation plans (SIPs) mandated under the 1990 Clean Air Act.

ACKNOWLEDGMENTS

The author is grateful to many colleagues and graduate students whose work has been cited in this document. In particular, I am indebted to my colleague Chris Frey, professor of civil and environmental engineering at NC State University, who first raised my interest in the topic of transportation and air quality and whose continuous contributions in this field have been noted nationally and internationally. I would also like to thank Dr. Billy Williams, assistant professor of civil engineering, for his insightful comments and suggestions on a previous draft, and Ms. Katie McDermott, communications manager at ITRE, for being exceedingly thorough as my first-round editor. Many thanks to several former and current NC State students whose research was cited in this document: Alper Unal, Kosok Chae, James Colyar, and Haibo Zhai. Last but not least, I am grateful to my wife, Dr. Maria Roupail, who persevered while this manuscript was being written, for her incisive editing and advice, without which this chapter could not have been completed.

4.1 INTRODUCTION

Seismic behavior of structures is quite complex. This is due to the nonlinearity effect of the structure itself coupled with the erratic movement of the ground. The seismic response and the damage pattern have yet to be discovered because of the rapid evolution of the construction specifications and codes. Computational models for analyses of structural systems are simpler than the actual behavior and mechanisms

of the structures. The complexity in the structure response lies in the repetition of large cycles of deformation coupled with the geometric nonlinearity of the structure. Therefore, laboratory experiments are conducted where loading can be applied in controlled environment and where the response of the structure can be observed and measured. Laboratory and field studies are fundamental part of earthquake engineering research. Several examples can be shown of how limited amount of testing have already improved the seismic response of highway bridges. The dramatically improved responses of new versus older reinforced concrete bridges during the Northridge Earthquake are true statements about the efficacy of seismic experimental investigation. The poor performance of older reinforced concrete bridges has demonstrated the need, yet again, to the importance of experimental testing of structures in order to improve their response during large ground motions. The significant economic loss and the social disruption after each earthquake proved the need to enhance the U.S. seismic standards for construction.

Out of the laboratory studies, using earthquake simulators (shake tables) is considered one of the main tools that can be used to determine the seismic response of structures. Shake-table testing provides the most realistic means of simulating seismic effect in the laboratory. This type of testing subjects the structure to seismic motions that have controlled intensity, frequency of content, and duration. One of the drawbacks of the shake-table testing is the payload limitation of the simulator itself since the specimen has to be scaled down in order to fail the specimen under realistic ground motion. In general a structure model is said to have similarity with the real structure (prototype) if the two share geometric, kinematic, and dynamic similarity. The most effective type of similarity is the kinematic similarity where the path and the velocity of the moving particles are same.

4.2 SIMILITUDE REQUIREMENTS

Civil engineering structures such as highway bridges are large such that experimental testing at full scale is economically and technologically difficult. Scaled model testing is favored over full-scale testing because it can be performed inside a laboratory with a more controlled environment. The similitude requirements, when followed properly, provide scaled models that capture the behavior of the full-scale structure. The seismic response of structures is a dynamic mechanical problem where the fundamental physical quantities measured are length (L), force (F), and time (T).

4.2.1 Dimensional Analysis

Buckingham's Pi Theorem (Buckingham, 1914; Harris and Sabnis, 1999) states that any dimensionally homogeneous equation involving certain physical quantities can be reduced to an equivalent equation involving a complete set of dimensionless products. For n physical variables, it can be shown that any equation of the form

$$F(X_1, X_2, \dots, X_n) = 0 \quad (4.1)$$

can be equivalently expressed in the form

$$G(\pi_1, \pi_2, \dots, \pi_m) = 0 \quad (4.2)$$

The π terms are dimensionless products of the n physical variables. The number of π terms that can be defined by the variables X_1, X_2, \dots, X_n is equal to

$$m = n - r \quad (4.3)$$

where r is the number of fundamental measures like length (L), force (F), and time (T). To illustrate, consider the axial deformation of a steel bar given by the equation

$$u = \frac{PL}{EA} \quad \text{or} \quad uEA - PL = 0 \quad (4.4)$$

where u is the axial deformation, P is the axial force, E is the modulus of elasticity of material, A is the cross-sectional area, and L is the length. Equation (4.4) has five variables and has the form of Equation (4.1) thus,

$$F(u, P, L, A, E) \quad (4.5)$$

Writing the displacement as a function of the other variables,

$$u = F'(P, L, A, E) \quad (4.6)$$

Any equation of this form can be represented as a product of powers

$$u = KP^a L^b A^c E^d \quad (4.7)$$

where K is a dimensionless constant. Equation (4.7) expressed in dimensional form using the fundamental measures of length (L) and force (F) becomes

$$L \doteq F^a L^b (L^2)^c (FL^{-2})^d \quad (4.8)$$

where \doteq means dimensional equivalence. Writing the exponential equalities gives the following

$$\text{for } F : \quad 0 = a + d \quad (4.9)$$

$$\text{for } L : \quad 1 = b + 2c - 2d \quad (4.10)$$

Equations (4.9) and (4.10) have four unknowns and thus there is twofold infinity of solutions. Solving the equations in terms of a and b ,

$$a = -d \quad (4.11)$$

$$b = 1 - 2c + 2d \quad (4.12)$$

It should be noted that the exponents a and b were chosen because it takes in the fundamental measures F and L in Equation (4.7). Then, substituting Equations (4.11) and (4.12) to Equation (4.7) gives

$$u = KP^{-d}L^{1-2c+2d}A^cE^d \quad (4.13)$$

$$\left(\frac{u}{L}\right) = K\left(\frac{L^2E}{P}\right)^d\left(\frac{A}{L^2}\right)^c \quad (4.14)$$

Thus,

$$G\left(\frac{u}{L}, \frac{L^2E}{P}, \frac{A}{L^2}\right) = 0 \quad (4.15)$$

The terms inside the parenthesis of Equation (4.15) are called the π terms. As shown, the five variables were reduced to three dimensionless products as determined from Equation (4.3)

$$m = n - r = 5 - 2 = 3$$

where the two fundamental measures (r) are L and F . Therefore, the dimensionless π terms are

$$\pi_1 = \frac{u}{L}, \quad \pi_2 = \frac{L^2E}{P}, \quad \pi_3 = \frac{A}{L^2} \quad (4.16)$$

For complete similarity,

$$\pi_{1p} = \pi_{1m}, \quad \pi_{2p} = \pi_{2m}, \quad \pi_{3p} = \pi_{3m} \quad (4.17)$$

where π_{ip} refers to the prototype and π_{im} refers to the model. Then, using these relations to determine the scale factors,

$$\frac{\pi_{1p}}{\pi_{1m}} = 1 = \frac{(u/L)_p}{(u/L)_m} = \frac{(u_p/u_m)}{(L_p/L_m)} = \frac{S_u}{S_L} \quad \text{or} \quad S_u = S_L \quad (4.18)$$

$$\frac{\pi_{2p}}{\pi_{2m}} = 1 = \frac{(L^2E/P)_p}{(L^2E/P)_m} = \frac{S_L^2 S_E}{S_P} \quad \text{or} \quad S_P = S_L^2 S_E \quad (4.19)$$

$$\frac{\pi_{3p}}{\pi_{3m}} = 1 = \frac{(A/L^2)_p}{(A/L^2)_m} = \frac{S_A}{S_L^2} \quad \text{or} \quad S_A = S_L^2 \quad (4.20)$$

If the same material is used in the prototype and the model, Equation (4.19) becomes

$$S_P = S_L^2 \quad (4.21)$$

It was shown above that the formulation of scaling relations can be established by translation of the π terms into required scale factors. The procedure to determine the scaling relations can be summarized as

1. Select the set of quantities
2. Derive the set of π terms
3. Establish the similitude relations.

Lack of similarity between the prototype and the model will lead to erroneous results. Most often, however, the selection of model geometric scale and material properties are limited by the available equipments and materials. Thus, certain degree of lack of similarity is allowed provided that the behavioral difference between the prototype and the model is negligible.

4.2.2 Seismic Modeling

The basic quantities in earthquake loading are length (L), force (F), time (T), modulus of elasticity (E), mass (M), and acceleration (a). Following the procedure described above, some of the π terms that can be derived from these quantities are

$$G\left(a, \frac{L}{T^2}, \frac{L^2 E}{F}, \frac{ML}{FT^2}\right) = 0 \quad (4.22)$$

It follows that

$$S_a = 1 \quad (4.23)$$

$$S_L = S_T^2 \quad \text{or} \quad S_T = \sqrt{S_L} \quad (4.24)$$

$$S_F = S_L^2 S_E \quad (4.25)$$

$$S_M = \frac{S_F S_T^2}{S_L} \quad (4.26)$$

Substituting Equations (4.24) and (4.25) to Equation (4.26), it can be shown that

$$S_M = \frac{(S_L^2 S_E) S_L}{S_L} = S_L^2 S_E \quad (4.27)$$

If the prototype and the model is made of the same material,

$$S_M = S_L^2 \quad (4.28)$$

Thus, the required mass of the model M_m^r is given by

$$M_m^r = \frac{M_p}{S_L^2} \quad (4.29)$$

where M_p is the mass of the prototype. However, by scaling the dimensions of the prototype to get the geometry of the model and using the same material, the actual mass of the model is less than what is required by Equation (4.29), as explained below. From the relationship mass M equals density ρ times volume V , it can be shown that

$$S_M = S_\rho S_V^3 = S_\rho S_L^3 \quad (4.30)$$

which follows that the actual mass of the model is

$$M_m^a = \frac{M_p}{S_\rho S_L^3} \quad (4.31)$$

Subtracting Equation (4.31) from Equation (4.29) to determine the difference between the required and actual mass gives

$$\Delta M = M_m^r - M_m^a = M_p \left(\frac{1}{S_L^2} - \frac{1}{S_\rho S_L^3} \right) \quad (4.32)$$

ΔM can also be expressed in terms of the actual model mass by substituting Equation (4.31) to Equation (4.32)

$$\Delta M = M_m^a S_\rho S_L^3 \left(\frac{1}{S_L^2} - \frac{1}{S_\rho S_L^3} \right) = M_m^a (S_\rho S_L - 1) \quad (4.33)$$

Since the prototype and the model is of the same material as assumed in Equation (4.28),

$$\Delta M = M_m^a (S_L - 1) \quad (4.34)$$

This indicates that additional mass is needed in the model for correct dynamic simulation. For example, if $S_L = 3$ and the model weight is 50 kN, an additional weight of 100 kN is needed. The added weight must be dispersed throughout the model volume for complete similarity. However, this would be difficult to achieve so an artificial mass simulation where the added mass is concentrated at certain locations is usually used (see Section 4.2.3).

Other scaling relations typically used for seismic testing is shown in Table 4.1. Note that when the materials used in the prototype and the model are the same, the scale factors become a function of length L only.

4.2.3 Example

This example shows the three-span, steel I-girders, horizontally curved bridge used for seismic testing at University of Nevada, Reno (Buckle et al., 2011). The bridge has a high curvature (total subtended angle of 104°) representing a highway on-ramp or off-ramp. A 2.5 scale (S_L) model of this bridge is tested using the Network for Earthquake Engineering Simulation (NEES) multiple shake tables at the University of Nevada, Reno.

TABLE 4.1 Typical Scale Factors for Complete Similarity Seismic Modeling

Parameter	Dimension	Scale Factors and Relations
Length, L	L	S_L
Area, A	L^2	S_L^2
Volume, V	L^3	S_L^3
Force, F	F	$S_E S_L^2$
Pressure, q	FL^{-2}	S_E
Acceleration, a	LT^{-2}	1.00
Velocity, v	LT^{-1}	$S_L^{1/2}$
Displacement, u	L	S_L
Time, t	T	$S_L^{1/2}$
Frequency, f	T^{-1}	$S_L^{-1/2}$
Modulus of elasticity, E	FL^{-2}	S_E
Stress, σ	FL^{-2}	S_E
Strain, ε	—	1.00
Poisson's ratio, ν	—	1.00
Mass density, ρ	$FL^{-4}T^2$	S_E/S_L
Energy, E	FL	$S_E S_L^3$

The model is used to experimentally study the seismic performance of a highly curved bridge in variety of configurations including:

- conventional superstructure, columns, and bearings without live load (benchmark bridge) and with live load (see Figure 4.1);
- fully base isolated superstructure on conventional columns;
- partially isolated superstructure with ductile cross-frames on conventional columns (hybrid protective system);
- conventional superstructure on rocking foundation;
- conventional superstructure and columns with abutment interaction and simulated backfill.

FIGURE 4.1 3D rendering of the curved bridge model on shake tables with trucks on deck representing the live loads.

The total weight of the model superstructure (girder, cross-frames, and deck) is 476 kN. As explained in Section 4.2.2, additional mass is required for simulation because the prototype and the model materials have the same densities. Due to the difficulty in distributing the additional mass throughout the volume or surface of the model, they are added externally and are distributed on discrete locations on the deck using steel and lead plates (see also Section 4.3.2). The steel and lead plates are evenly distributed on the deck such that the bridge center-of-mass is not changed. Using the scaling relations described above, the additional mass weighs 714 kN.

Due to the technological improvements, seismic testing of bridges nowadays usually involves large-scale models. The University of Nevada, Reno (UNR) has been in the forefront of seismic testing of large-scale bridges, which includes 1-span steel I-girder bridge, 4-span concrete bridge, and 3-span curved steel I-girder bridge. The NEES facility at UNR is unique because of the four relocatable shake tables that can be configured for bridge seismic testing at large-scale.

After the dimension of the model has been finalized, the construction drawings are produced. Because of the size and complexity of the bridge components, contractors are usually hired to fabricate the bridge components. Depending on the type of the project, different contractors may be hired to fabricate the superstructure and the substructure. The components are then assembled inside the laboratory by the contractor or by the researchers and laboratory staff. The researchers are responsible for the coordination and quality control. In the case of curved steel bridge, an AISC-certified steel bridge erector was hired to fabricate the deck while a concrete contractor was hired to fabricate the columns. The typical process in specimen fabrication is discussed below with the curved bridge fabrication used as an example.

Usually, the main concern in column fabrication is the size of reinforcement. For large-scale models, which is usually the case in bridge seismic testing nowadays, regular deformed bars are used for longitudinal (main) reinforcement and either deformed bars or

plain wires are used for transverse (lateral) reinforcement. In the United States, the smallest available deformed bar is #2 (No. 6) but the most readily available is #3 (No. 10). Whenever the scale factor does not permit the use of an exact scaled size of reinforcement, the number and size of reinforcement is determined by keeping the steel ratio (total steel area over total concrete area) the same in the prototype and the model.

Figure 4.4 shows the rebar cage of the 24-in. (610-mm) diameter column used in the curved bridge model, deformed bars are used in the main and lateral reinforcements because of large scale. The main reinforcement is #5 (No. 16) deformed bars and the lateral reinforcement is #3 (No. 10) deformed bars. The researchers provided the contractor the bar cut-off schedule for accurate bar arrangement and placement. After the rebar cage was assembled, locations where the strain gages will be attached are marked. The strain gages are usually placed at the expected location of plastic deformation in the column, which is at the bottom of the column above the footing and/or at the top of the column below the cap beam. After grinding and cleaning, the strain gages are glued to the main and lateral reinforcements and wrapped with an electrical tape to protect from damage during the concrete pour. To protect the strain gage wires from damage during concrete pour, they are inserted into plastic tubes as shown in Figure 4.5.

The footing is cast first. Then, after the footing concrete has hardened, the forms for the column and the cap beam are placed. Threaded rods, used for mounting of displacement transducers that will monitor the column rotation, are inserted into the sides of the

FIGURE 4.4 Complete column rebar cage.

FIGURE 4.5 Close-up of the rebar cage showing the locations of the strain gages.

column (see Figure 4.6). The column and cap beam may be cast at once or at different stages. Concrete cylinder samples are obtained during each concrete pour. These will be used to determine the concrete strength at 7, 14, and 28 days. Usually, extra concrete cylinders are also cast to determine the concrete strength at the day of bridge test.

Figure 4.7 shows the completed columns with the footing and cap beam. The footing is usually bigger than needed because it will be rigidly attached to the shake tables by post-tensioning. The footing is designed based on the column capacity and the clamping forces between the footing and the shake table. Also shown in Figures 4.6 and 4.7 are the lifting

FIGURE 4.6 Picture showing the threaded rods inserted into the column sides and the lifting eye on the footing.

FIGURE 4.7 Completed columns.

eyes in the footing that will be used to transport the column from the fabrication yard to inside the laboratory.

4.3.2 Superstructure

Superstructures of highway bridges can be classified as either stiff or flexible. Examples of stiff superstructures are concrete box-girder and steel box-girder that are not only stiff laterally but also torsionally. Examples of laterally and torsionally flexible superstructures are steel I-girder bridges.

For structures that are laterally and torsionally stiff, equivalent superstructure can be used. Figure 4.8 shows the bridge model of a 4-span bridge on shake tables (Nelson et al.,

FIGURE 4.8 4-Span bridge on shake tables (Nelson et al., 2007).

FIGURE 4.9 Placement of the superstructure of the 4-span bridge (Nelson et al., 2007).

2007). The superstructure of the prototype was post-tensioned concrete box-girder, which is relatively high in strength and stiffness compared to the substructure. Since the superstructure is essentially rigid, damage in the bridge during seismic testing is concentrated in the columns only. Because of this, instead of fabricating the scaled concrete box-girder, a solid rectangular section was used to represent the superstructure. The dimensions of the solid rectangular section superstructure were chosen such that the bending properties are the same as that of scaled box-girder. The model superstructure was designed to carry its weight, the weight of the added mass (shown as concrete blocks on top of the deck in Figure 4.8), and the seismic forces. The superstructure was constructed as three separate post-tensioned rectangular beams running in the longitudinal direction (see Figure 4.9). The three beams were then tied together to act as one by post-tensioning in the transverse direction.

For structures that are laterally and torsionally flexible, like the curved steel I-girder bridge discussed in Section 4.2.3, it is important to model the actual geometry and components of the superstructure. Figure 4.10 shows the as-built superstructure of the curved steel I-girder bridge. Due to the bridge model size and complexity, an AISC-certified steel bridge erector was hired to fabricate the superstructure. The girders are built-up steel plates, the cross-frames are angle sections, stiffener plates are provided at each cross-frame locations, and shear connectors are provided (see Figure 4.11) just as it was designed in the prototype bridge. The shear connectors provided the composite action between the girders and the deck. Their size, length, and spacing are the exact scale of those in the prototype which is, again, possible because of the large scale. In case this is not possible, shear connector size, length, and spacing in the model must be designed to provide composite action. Care must be taken when selecting the shear connector size in the model because when the shear connector diameter is larger than the thickness of the plate it is welded to, there is tendency for the shear connector to fail by fracture at the connection. The girders were cambered and the amount of camber was determined from

FIGURE 4.10 As-built superstructure of the curved bridge.

the model weight and the added weight. Figure 4.12 shows the steel reinforcement in the deck. Plywood was used for the forms in this deck. For larger deck thickness, permanent corrugated steel deck forms may be used.

The bridge model length is 145 ft (44.21 m). It is not possible to construct the entire superstructure as one continuous segment so the superstructure was divided into three segments. The abutments and piers were placed on the shake tables first then the superstructure end segments were placed on top of them. Figure 4.13 shows one of the end

FIGURE 4.11 Picture showing the assembled girders and cross-frames, and shear connectors.

FIGURE 4.12 Deck steel reinforcement.

segments being flown onto position. The middle segment was added last and connected to the two end segments as shown in Figure 4.14. The splice connections are at the location of inflection point of the center span.

Finally, the added masses using lead and steel plates were bolted into the deck. They were placed evenly at discrete locations on the deck, as shown in Figure 4.15. It is important to note that the added masses should be positioned such that the bridge center-of-mass is not changed.

FIGURE 4.13 One of the curved bridge segments being flown into position.

FIGURE 4.14 The middle segment of the curved bridge is connected to the end segments.

FIGURE 4.15 Picture showing the added mass on the deck.

4.4 INPUT MOTION

In shake-table studies that involve spatially long structural systems such as bridges, preliminary sensitivity analyses on reliable numerical/computational models must be conducted to ensure that wide range of ground motions with characteristics that are critical to the seismic response evaluation of the prototype/model structure is determined. When multiple shake tables are used, the possible account of the spatial variability of seismic

ground motions can also be evaluated. It is important to note that the selection of ground motions with high amplitudes of spectral acceleration in the expected frequency range of the shake table and the model structure must be considered such that the peak response parameters (displacement, velocity, and acceleration) do not exceed the physical limits of the shake table. These verifications can be done based on the numerical simulation of the scaled model structure where the time axes of the acceleration and displacement records are condensed by applying the time scale factor. In other words, the ground motion records that will be used in the numerical simulation as well as the shake table signal must be compressed in time by $S_T = \sqrt{S_L}$ to satisfy the similitude requirements. In this way the relationship between the frequency content of the compressed record and the natural period of the undamaged scale model is maintained with respect to that of the original record and the prototype structure (Harris and Sabnis, 1999). In most cases, the ground motion signals will also need to be filtered to eliminate the high-frequency content outside the performance range of the shake table and the low-frequency content that correspond to large displacements exceeding the displacement limits of the shake table. The effect of filtering should also be verified based on the numerical simulation studies of the prototype and the scaled model structures.

In general, the shake-table input signals that can be used are (1) simulated (artificial) spectrum compatible records; (2) synthetic acceleration records; and (3) recorded (historical) ground motions.

Spectrum-compatible signals can be obtained by generating a frequency domain function, for example, power spectral density function from a code-specified response spectrum, and deriving signals compatible to that spectrum. However, in most of the cases, this approach could lead to accelerograms not reflecting the real phasing of seismic waves and cycles of motion, and therefore frequency and energy content. Regardless, the most common approach in generating spatially variable seismic ground motions is by means of simulations; the motions are modeled as stochastic vector processes, described by their power spectral density, coherency, and wave propagation (Deodatis, 1996).

Synthetic acceleration records are obtained via modeling of the seismological source and may account for path and site effects. These methods range from stochastic simulation (Boore, 2003) of point or finite sources to dynamic models of rupture. However, they often require setting of physical parameters associated with the ground motion characteristics and mechanisms (e.g., rupture parameters, rise-time, and so on). Some state-of-the-art simulation methods seem to overcome these shortcomings, but they are not readily available to engineers. Also, it is noted that the synthetic acceleration records provide time histories that do not necessarily incorporate spatial coherency models that may be critical in multiple the shake-table studies of long structural systems.

Historical ground motions are recorded from real events, which become more and more readily available. The availability of online, user-friendly, databases of strong motion recordings, and the rapid development of digital seismic networks worldwide, has increased the accessibility to recorded accelerograms, which, therefore, have become the most promising candidates for the use in shake-table studies (e.g., PEER Ground Motion Database, http://peer.berkeley.edu/peer_ground_motion_database/). However, there is large variability in the recorded ground motions in terms of ground motion parameters, seismic source, soil conditions, and so on, and these may not exactly represent the specific scenario and/or seismic hazard demand desired for the bridge. Because of the highly complex nature of and uncertainties involved in the earthquake ground motions, earthquake engineering research has focused for the past two decades on the selection of recorded

ground-motions for the seismic response assessment and evaluation (both analytically and experimentally) of structural systems.

4.5 INSTRUMENTATION

Instruments are placed on the model to understand and characterize its behavior. For seismic testing of highway bridges, the typical quantities measured are strain, displacement, force, and acceleration. Strains are measured to determine the local component inelasticity. Displacements measure the global and local response of the system as well as its components. Forces measure the base shear and the distribution of forces among the boundary supports. Accelerations are measured to determine the model's dynamic response.

It is always tempting to put as many instruments in the model but these may not be needed and could significantly increase the cost of the experiment. Thus, analytical investigations are conducted prior to the experiment to determine the critical locations where the quantities mentioned above must be measured. Several factors that should be taken into account in planning the instrumentation include available number of instruments, cost if additional instruments are needed, available channels in the data acquisition hardware, installation of the instruments (absolute or relative measurements), and applicability and sensitivity of the instruments that will be used.

4.5.1 Strain Measurement

Strain gages are used to measure local strain of the components. The most widely used type of strain gage is the electrical resistance strain gage due to its small size, lightweight, highly sensitive to strain, low cost, and ease of attachment. The increase and decrease in the gage resistance is used to determine the amount of elongation and contraction in the component where the strain gage is attached. The strain is measured by relating the change in electrical resistance (ΔR) to the strain using gage factor (K_g)

$$K_g = \frac{\Delta R/R}{\Delta L/L} = \frac{\Delta R/R}{\epsilon} \quad (4.35)$$

where R is the original electrical resistance and ϵ is the strain. Typical value for K_g is about 2.0.

Figure 4.16 shows the typical electrical resistance, foil strain gage used to measure uniaxial strain. End A of the strain gage is glued to the surface of the component while end B is plugged into the strain gage block (see Figure 4.17). Installation of the strain gage is relatively easy. For example, the typical strain gage installation procedure in a column rebar is

1. surface is grinded, cleaned, and coated with metal neutralizer;
2. adhesive is applied to end A of the strain gage;
3. strain gage is attached to the rebar surface by applying thumb pressure;
4. rubber mastic tape is placed around the strain gage;
5. moisture sealing electrical tape is placed on the area;

FIGURE 4.16 Typical uniaxial foil strain gage.

6. strain gage wire is inserted into heat shrink plastic tube (see Figure 4.18) to protect it against damage during concrete pour.

In columns, the strain gages are placed on the main and lateral reinforcements at the expected plastic hinge location. For a column behaving in single curvature, the plastic hinge location is at the bottom of the column above the footing. For a column behaving in double curvature, the plastic hinge locations are at the top (below the cap beam) and the

FIGURE 4.17 Strain gage block where end B of strain gage is plugged into.

FIGURE 4.18 Strain gage wires are inserted into plastic tubes to protect from damage during concrete pour.

bottom (above the footing) of the column. In the girders, the stresses can be measured by attaching strain gages at the flanges and webs. Strain gages placed on the top and bottom flanges can be used to determine the vertical and lateral girder moments. In the cross-frames, the axial forces are determined by placing strain gages in the legs of the angle section used as cross-frame member. Cross-frame forces are usually monitored at the support locations where the deck seismic forces are transferred to the bearings through the cross-frames.

4.5.2 Displacement Measurement

Displacement transducers are used to measure the bridge global displacements as well as displacements of local components. The bridge global displacements are measured by attaching displacement transducers in the longitudinal, transverse, and vertical directions. This provides a three-dimensional response of the bridge at any particular time during the test. For large displacements, such as deck displacements, cable extension transducer or string pot (UniMeasure, Celesco Transducer Products, Inc.) is one of the ideal instruments. This instrument utilizes a flexible cable and a potentiometer to detect and measure linear position. Figure 4.19 shows some of the string pots attached to the deck of the curved bridge. The recorded displacement can be either absolute or relative displacement depending on the location where the other end of the instrument is attached. Those instruments that are connected to fixed points in the laboratory records absolute displacements while those connected to rigid structures moving with the shake-table records relative displacements. In the end, only the relative values are reported so the absolute displacements are converted into relative displacements by subtracting the shake-table displacements.

Relative displacement between the girders can be measured using linear potentiometric transducers as shown in Figure 4.20. This instrument records the diagonal displacement between the girders that are then used to determine the girder rotation and drift.

FIGURE 4.19 String pots attached to the deck of the curved bridge.

The column curvature can also be measured using displacement transducers. One common transducer used for this purpose is the position sensors with restoring springs (NovoTechnik U.S., Inc.) which are attached to the opposite sides of the column as shown in Figure 4.21. With the distance between the opposite transducers known, the column rotation is measured using the recorded displacement in the opposite transducers. Similar to strain gages, these instruments are placed at the expected plastic hinge locations.

FIGURE 4.20 Picture showing the displacement transducer connected diagonally between the girders.

FIGURE 4.21 Displacement transducers attached to the column sides to measure column curvature.

4.5.3 Force Measurement

Forces in the boundary supports are measured using load cells. The typical load cells used in bridge seismic testing are strain gage load cells because of their relatively low cost and they can be easily fabricated using the equipments available in a laboratory. The load cell principles are basically the same as those for the strain gages. The strain gages are attached to the sides of the structural section (e.g., steel tube, pipe, or beam) used as load cell. The electrical signals are converted into strains that in turn are converted into force. The strain gages can be configured to measure axial force, shear, and bending moments. Figure 4.22 shows the load cells placed between the bearings and the cap beam of the

FIGURE 4.22 Load cells (colored black) between the bearings and cap beam.

FIGURE 4.23 Triaxial micro electro-mechanical accelerometer on the curved bridge deck.

curved bridge to measure the girder support reactions and the force transmitted to the column.

4.5.4 Acceleration Measurement

Accelerations in the structure are measured for system identification, mode shapes, natural frequency, comparison between the input motion and bridge response, and for estimation of inertia loads. Accelerometers are placed on strategic locations on the deck like those at the midspan of each span and at the supports. In the curved bridge test, accelerometers are also placed on the cap beam to calculate the inertia loads in the cap beam. Figure 4.23 shows the triaxial micro electro-mechanical accelerometer to measure the deck acceleration in the longitudinal, transverse, and vertical directions. Although the input motions are in the longitudinal and transverse directions only, vertical acceleration is measured because vertical vibration is one of the dominant vibration modes of the bridge.

4.6 DATA ACQUISITION AND PROCESSING

Data acquisition (DAQ) systems convert the signals recorded by sensors (e.g., the electrical signals recorded by the strain gages) into digital numeric values, known as data. A typical data production chain is comprised of the sensor attached to the model, the cable connecting the sensor to the DAQ hardware, the DAQ hardware processing the signal, and the PC recording the data. Figure 4.24 shows the DAQ hardware used at the Large-Scale Structures Laboratory (LSSL) at UNR.

Data is the most important aspect of any test. It must be recorded, saved, and be accurate relative to the test. In order for the data to be meaningful and processed properly, metadata such as instrument location and polarity must be known, the instrument was not damaged during the test, and instrument was not altered between the tests. The researcher

FIGURE 4.24 DAQ system used at UNR's Large Scale Structures Laboratory.

must be aware of the errors introduced in the instrument, such as kinematic error, error due to instrument calibration, and error due to DAQ calibration. Kinematic error is due to instrument location and structure movement. For example, consider the two string pots attached to the deck of a straight bridge to measure longitudinal and transverse displacements, as shown in Figure 4.25. Because the bridge moves diagonally, the recorded displacement is larger than the actual longitudinal or transverse displacement. This error must be recognized and corrected during data processing. It can be minimized during instrument installation by increasing the distance between the measured point and the reference point. The error due to instrument calibration and DAQ calibration is usually small compared to that due to instrument attachment.

FIGURE 4.25 Diagram (plan view) illustrating the kinematic error in measuring longitudinal and transverse displacement.

4.7 RESULTS

Several experimental results can be reported but the most important ones include the following:

- force–displacement hysteresis plots
- energy dissipated
- system capacity
- ductility
- damage progression
- natural frequency
- damping

The force–displacement hysteresis is plotted from the load cell readings and the corresponding displacement transducer readings. Total base shears can be determined from the shake-table outputs that include the shake-table lateral forces. Energy dissipated due to hysteretic damping is calculated by integrating the area inside the hysteresis loops. Also, from the hysteresis plots, the system capacity (force versus displacement) is established by plotting the envelope (maximum and minimum) force–displacement relationship obtained from each run. The resulting “backbone curve” of system capacity is used to determine the yield capacity and ultimate capacity. Then the ductility, ratio of ultimate deformation to yield deformation, is determined.

The damage progression is evaluated locally (at the component level) and globally (at the system level). Local damage progression is reported by plotting the strain history for each test and also by visual inspection of each component after each test.

At the system level, damage progression is established by exciting the bridge with randomly generated low level motion (called as white noise). The frequency response spectrum is plotted and frequency shift of the dominant modes is observed by comparing it with those from the previous tests. The natural frequency corresponds to the peak value of the frequency response curve. Also, from the frequency response curve, damping can be evaluated using the half-power bandwidth (Chopra, 2007). For example, consider the frequency response curve shown in Figure 4.26, the natural frequency f_n is the frequency

FIGURE 4.26 Frequency response curve.

corresponding to the maximum response amplitude r_{\max} . The damping is calculated using the equation

$$\zeta = \frac{f_2 - f_1}{2f_n} \quad (4.36)$$

where ζ is the damping ratio and f_1 and f_2 are the frequencies corresponding to $r_{\max}/\sqrt{2}$.

In addition, the measured quantities are used to calibrate the analytical models such that the measured value is almost equal to those obtained from the analysis.

5.1 INTRODUCTION

Environmental engineers apply the sciences to improve the public health and ecosystems. As such, they must have reliable data and information about the condition of air, water, soil, sediment, and biota (see Figure 5.1).

FIGURE 5.1 Sites of environmental measurements. *Source:* Letcher and Vallero (2011).

Environmental monitoring is dependent on the quality of sample collection, preparation, and analysis. Sampling is a statistical term, and usually a geostatistical term.

An environmental sample is a fraction of air, water, soil, biota, or other environmental media (e.g., paint chips, food, and so on for indoor monitoring) that represents a larger population or body. For example, a sample of air may consist of a canister or bag that holds a defined quantity of air that will be subsequently analyzed. The sample is representative of a portion of an air mass. The number of samples must be collected and their results aggregated to ascertain with defined certainty the quality of an air mass. More samples will be needed for a large urban air shed than for that of a small town. Intensive sampling is often needed for highly toxic contaminants and for sites that may be particularly critical, for example, near a hazardous waste site or in an “at risk” neighborhood (such as one near a manufacturing facility that uses large quantities of potentially toxic materials). Similar to other statistical measures, environmental samples allow for statistical inference. In case, inferences are made regarding the condition of an ecosystem and the extent and severity of exposure of a human population.

For example, to estimate the amount of a chemical compound in a lake near a chemical plant, an engineer gathers a 500 mL sample in the middle of the lake that contains 1 million liters of water. Thus, the sample represents only 5×10^{-7} of the lake’s water. This is known as a “grab” sample, that is, a single sample taken to represent an entire system. Such a sample is limited in location vertically and horizontally, so there is much uncertainty. However, if 10 samples are taken at 10 spatially distributed sites, the inferences are improved. Furthermore, if the samples were taken in each season, then there would be some improvement to understanding of intra-annual variability. If the sampling is continued for several years, the inter-annual variability is better characterized. Indeed, this approach can be used in media other than water, for example, soil, sediment, and air.

5.1.1 Data Quality Objectives

A monitoring plan must be in place before samples are collected and arrive at the laboratory. The plan includes quality assurance provisions and describes the procedures to be employed. These procedures must be strictly followed to investigate environmental conditions. The plan describes in detail the sampling apparatus (e.g., real-time probes, sample bags, bottles, and soil cores), the number of samples needed, and sample handling and transportation. The quality and quantity of samples are determined by data quality objectives (DQOs), which are defined by the objectives of the overall contaminant assessment plan. DQOs are qualitative and quantitative statements that translate nontechnical project goals into scientific and engineering outputs need to answer technical questions (U.S. Environmental Protection Agency, 2006).

Quantitative DQOs specify a required level of scientific and data certainty, whereas qualitative DQOs express decisions goals without specifying those goals in a quantitative manner. Even when expressed in technical terms, DQOs must specify the decision that the data will ultimately support, but not the manner that the data will be collected. DQOs guide the determination of the data quality that is needed in both the sampling and the analytical efforts. U.S. Environmental Protection Agency (2001) has listed three examples of the range of detail of quantitative and qualitative DQOs:

1. *Example of a Less Detailed, Quantitative DQO:* Determine with greater than 95% confidence that contaminated surface soil will not pose a human exposure hazard.
2. *Example of a More Detailed, Quantitative DQO:* Determine to a 90% degree of statistical certainty whether the concentration of mercury in each bin of soil is less than 96 ppm.
3. *Example of a Detailed, Qualitative DQO:* Determine the proper disposition of each bin of soil in real time using a dynamic work plan and a field method able to turn-around lead (Pb) results on the soil samples within 2 h of sample collection.

If the condition in question is tightly defined, for example, the seasonal change in pH near a fish hatchery, a small number of samples using simple pH probes would be defined as the DQO. Conversely, if the environmental assessment is more complex and larger in scale, for example, the characterization of year-round water quality for trout in the stream, the sampling plan's DQO may dictate that numerous samples at various points be continuously sampled for inorganic and organic contaminants, turbidity, nutrients, and ionic strength. This is even more complicated for biotic systems, which may also require microbiological monitoring.

The sampling plan must include all environmental media, for example, soil, air, water, and biota, which are needed to characterize the exposure and risk of any biotechnological operation. The sampling and analysis plan should explicitly point out which methods will be used. For example, if toxic chemicals are being monitored, the U.S. EPA specifies specific sampling and analysis methods (U.S. EPA, 1994, 2002, 2011c).

The geographic area where data are to be collected is defined by distinctive physical features such as volume or area, for example, metropolitan city limits, the soil within the property boundaries down to a depth of 6 cm, a specific water body, length along a shoreline, or the natural habitat range of a particular animal species. Care should be taken to define boundaries. For example, Figure 5.2 shows a sampling grid, with a sample taken from each cell in the grid (U.S. EPA, 2002). The target population may be divided into

FIGURE 5.2 Environmental assessment area delineated by map boundaries. *Source:* U.S. Environmental Protection Agency (2002).

relatively homogeneous subpopulations within each area or subunit. This can reduce the number of samples needed to meet the tolerable limits on decision errors and to improve efficiency.

Time is another essential parameter that determines the type and extent of monitoring needed. Conditions vary over the course of a study due to changes in weather conditions, seasons, operation of equipment, and human activities. These include seasonal changes in groundwater levels, seasonal differences in farming practices, daily or hourly changes in airborne contaminant levels, and intermittent pollutant discharges from industrial sources. Such variations must be considered during data collection and in the interpretation of results. Some examples of environmental time-sensitivity are as follows:

- concentrations of lead in dust on windowsills that may show higher concentrations during the summer when windows are raised and paint/dust accumulates on the windowsill;
- terrestrial background radiation levels that may change due to shielding effects related to soil dampness;
- amount of pesticides on surfaces that may show greater variations in the summer because of higher temperatures and volatilization;
- instruments that may not give accurate measurements when temperatures are colder; and
- airborne particulate matter measurements that may not be accurate if the sampling is conducted in the wetter winter months rather than the drier summer months.

Feasibility should also be considered. This includes gaining legal and physical access to the properties, equipment acquisition and operation, and environmental conditions, times and conditions when sampling is prohibited (e.g., freezing temperatures, high humidity, and noise).

5.1.2 Monitoring Plan Example

Consider a plan to measure mobile source air toxics (MSAT) concentrations and variations in concentrations as a function of distance from the highway and to establish relationships between MSAT concentrations as related to highway traffic flows including traffic count, vehicle types and speeds, and meteorological conditions such as wind speed and wind direction. Specifically, the monitoring plan has the following goals (Kimbrough et al., 2008):

1. Identify the existence and extent of elevated air pollutants near roads.
2. Determine how vehicle operations and local meteorology influence near road air quality for criteria and toxic air pollutants.
3. Collect data that will be useful in evaluating and refining, if necessary, models used to determine the emissions and dispersion of motor vehicle related pollutants near roadways.

A complex monitoring effort requires management and technical staff with a diversity of skills that can be brought to bear on the implementation of this project. This diverse skill set includes program management, contracts administration, field monitoring experience, laboratory expertise, and quality assurance oversight.

The purpose of any site selection process is to gather and analyze sufficient data that would lead one to draw informed conclusions regarding the selection of the most appropriate site for the monitoring at a specific location. Moreover, the site selection process needs to include programmatic issues to ensure an informed decision is reached.

5.1.3 Selection of a Monitoring Site

Selecting a monitoring site must be based on scientific and feasibility factors, as shown in Table 5.1 and Figure 5.3. Each step has varying degrees of complexity due to “real-world” issues. The first step was to determine site selection criteria (Table 5.2). The follow-on steps include (2) develop list of candidate sites and supporting information; (3) apply site selection filter (“coarse” and “fine”), (4) site visit; (5) select candidate site(s) via team discussion; (6) obtain site access permission(s); and (7) implement site logistics.

A list of candidate sites based on these criteria can then be developed. Geographic information system (GIS) data, tools and techniques, and on-site visits would be used to compare various sites that meet these criteria.

Quite commonly, even a well-designed environmental monitoring plan will need to be adjusted during the implementation phase. For example, investigators may discover barriers or differing conditions from what was observed in the planning phase (e.g., different daily traffic counts or new road construction).

After applying site selection criteria as a set of “filters,” candidate sites are incrementally eliminated. For example, the first filter would be sites with low traffic counts; the next filter, the presence of extensive sound barriers, eliminates additional sites; and other

TABLE 5.1 Example of Steps in Selecting an Air Quality Monitoring Site

Step	Site Selection Steps	Method	Comment
1	Determine site selection criteria	Monitoring protocol	
2	Develop list of candidate sites	Geographic information system data; on-site visit(s)	Additional sites added as information is developed
3	Apply coarse site selection filter	Team discussions, management input	Eliminate sites below acceptable minimums
4	Site visit	Field trip	Application of fine site selection filter
5	Select candidate site(s)	Team discussions, management input	
6	Obtain site access permissions	Contact property owners	If property owners do not grant permission, then the site is dropped from further consideration
7	Site logistics (i.e., physical access, utilities—electrical and communications)	Site visit(s), contact utility companies

filters, for example, complex geometric design or lack of available traffic volume data, eliminates additional sites. Next, feasibility considerations would eliminate additional candidate sites.

An important component of “groundtruthing” or site visit is to obtain information from local sources. Local businesses and residents can provide important information needed in

Selection Considerations	Monitoring Protocol Criteria
<i>Essential criteria for this monitoring study</i>	
AADT (>150,000)	Only sites with more than 150,000 annual average daily traffic (AADT) are considered as candidates
Geometric design	The geometric design of the facility, including the layout of ramps, interchanges and similar facilities, will be taken into account. Where geometric design impedes effective data collection on MSATs and PM _{2.5} , those sites will be excluded from further consideration. All sites have a “clean” geometric design
Topology (i.e., sound barriers, road elevation)	Sites located in terrain making measurement of MSAT concentrations difficult or that raise questions of interpretation of any results will not be considered. For example, sharply sloping terrain away from a roadway could result in under representation of MSAT and PM _{2.5} concentration levels on monitors in close proximity to the roadway simply because the plume misses the monitor as it disperses
Geographic location	Criteria applicable to representing geographic diversity within the United States as opposed to within any given city
Availability of data (traffic volume data)	Any location where data, including automated traffic monitoring data, meteorological or MSAT concentration data, is not readily available or instrumentation cannot be brought in to collect such data will not be considered for inclusion in the study
Meteorology	Sites will be selected based on their local climates to assess the impact of climate on dispersion of emissions and atmospheric processes that affect chemical reactions and phase changes in the ambient air
<i>Desirable, but not essential criteria</i>	
Downwind sampling	Any location where proper siting of downwind sampling sites is restricted due to topology, existing structures, meteorology, and so on may exclude otherwise suitable sites for consideration and inclusion in this study
Potentially confounding air pollutant sources	The presence of confounding emission sources may exclude otherwise suitable sites for consideration and inclusion in this study
Site access (admin/physical)	Any location where site access, is restricted or prohibited either due to administrative or physical issues, will not be considered for inclusion in the study

a decision process, such as types of chemicals stored previously at a site, changes in vegetation or even ownership histories.

The use of spatial tools in decision processes is increasing (Malczewski, 2009). Until recently, the use of GIS and other spatial tools in decision processes has required the acquisition of large amounts of the data. In addition, the software has not been user-friendly. GIS data have now become more readily available in both quantity and quality, and GIS exists in common operating system environments.

Typical data layers that are required are the location of suitable soils, wells, surface water sources, residential areas, schools, airports, roads, and so on. From these data, layers queries are formulated to provide the most suitable sites (e.g., depth to water table may help identify sources of pollution). Typically, quantitative weighting criteria are associated with the siting criteria as well as elements of the data layers (e.g., certain types of soils would be more suitable than others and thus would have applicable quantitative values; ESRI, 1995).

5.2 ENVIRONMENTAL SAMPLING APPROACHES

Engineers use various methods of collecting environmental samples. As mentioned, the grab sample is simply a measurement at a site at a single point in time. Grab sampling generally consists of steps to ensure representativeness, including consistent collection, to prevent postsampling contamination, and proper storage and transport. For regulated samples, this also includes good record keeping (labeling, chain-of-custody, accountability). For example, grab sampling of effluents under the Clean Water Act requires the following steps (U.S. EPA, 1992):

- Sample containers must be labeled before sampling event.
- Cooler with ice must be available at time of sampling at the sampling point (to slow chemical and microbial reactions within the sample).
- Grab is made according to flow (e.g., from the horizontal and vertical center of a water channel).
- Disturbances must be avoided (e.g., not stirring up bottom sediments if interested in the water column).
- Container is held so the opening faces upstream.
- Gloves must be worn and the inside of the container must not be touched to prevent contamination.
- Water samples must be free from uncharacteristic floating debris.
- Samples are transferred into proper containers (e.g., from bucket to sample container), with notable exceptions (e.g., fecal coliform, fecal streptococcus, phenols, and oil and gas samples should remain in original containers).
- If taking numerous grabs, samples must be kept separate and clearly labeled.
- Safety and other sampling factors may vary by the media and site specifics (e.g., water versus air; surface water versus ground water; indoor versus outdoor air measurements; manufacturing versus disposal sites).

Composite sampling physically combines and mixes multiple grab samples (from different locations or times) to allow for physical, instead of mathematical, averaging. The acceptable composite provides a single value of contaminant concentration measurement that can be used in statistical calculations. Multiple composite samples can provide improved sampling precision and reduce the total number of analyses required compared to noncomposite sampling (U.S. EPA, 2011a) (e.g., “grab” or integrated soil sample of x mass or y volume), the number of samples needed (e.g., for statistical significance) the minimum acceptable quality as defined by the quality assurance (QA) plan and sampling standard operating procedures (SOPs), and sample handling after collection.

A weakness of composite sampling is the false negative effect. Composite sampling must be avoided whenever the integrity of the individual sample values changes, that is, due to physical mixing of samples. Integrity is diminished as a result of chemical precipitation, exsolution, or volatilization during sample mixing. For example, constituents with relatively high vapor pressures may be lost when mixed or reactive constituents may form new compounds within the mixture. This often requires extraction of individual samples within a laboratory environment instead of mixing individual samples, as they are collected.

The U.S. EPA notes that

... compliance with the land disposal regulation (LDR) numeric treatment standards is to be determined using “grab” samples rather than composite samples. Grab samples processed, analyzed, and evaluated individually normally reflect maximum process variability, and thus reasonably characterize the range of treatment system performance. In those cases in which only composite data were available to develop a treatment standard, the EPA used these data. For wastes for which the standards are based on composite data, enforcement of the standard is to be based on composite data. (U.S. EPA, 2011b)

Consider, for example, samples collected from an evenly distributed grid of homes to represent a neighbor exposure to a contaminant, as shown in Figure 5.4. The assessment found the values of 3, 1, 2, 12, and 2 mg/L, and the mean contamination concentration is only 4 mg/L. If cleanup is needed above the threshold of 5 mg/L, the mean concentration would indicate that the area does not need remediation and would be reported below the threshold level. However, the fourth home is well above the safety level. This could also have a false positive effect. For example, if the mean concentration were 6 mg/L in the example, the whole neighborhood may not need cleanup if the source is isolated to a confined area in the yard of home 5.

FIGURE 5.4 Composite sampling grid for a neighborhood.

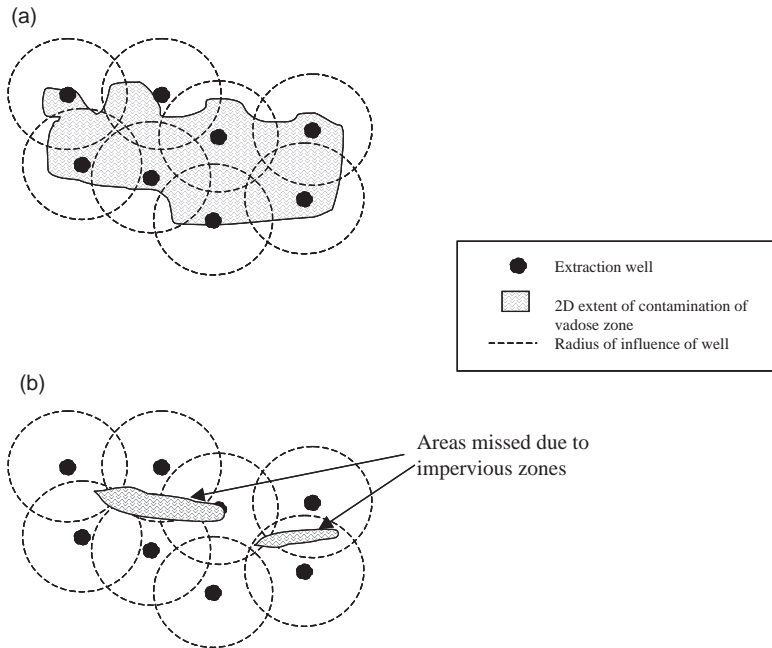

FIGURE 5.5 Extraction well locations on a geometric grid, showing hypothetical cleanup after 6 months. (a) Before treatment. (b) After treatment.

Another example of where geographic composites may not be representative is in cleaning up and monitoring the success of cleanup actions. For example, if a grid is laid out over a contaminated groundwater plume (Figure 5.5), it may not take into account horizontal and vertical impervious layers, unknown sources (e.g., tanks), and flow differences among strata, so that some of the plume is eliminated but pockets are left (as shown in Figure 5.5b).

It is often good practice to assume that a contaminated site will have a heterogeneous distribution of contamination. The amount of heterogeneity will influence not only the number of samples needed, but also the manner in which the samples are interpreted. Some of the most common sampling approaches include (Australian Department of Health and Ageing, 2002) as follows:

Random Sampling: While it has the value of statistical representativeness, with a sufficient number of samples for the defined confidence levels, for example, x samples needed for 95% confidence, random sampling may lead to large areas of the site being missed for sampling due to chance distribution of results. It also neglects prior knowledge of the site. For example, if maps show an old tank that may have stored contaminants, a purely random sample will not give any preference to samples near the tank.

Stratified Random Sampling: By dividing the site into areas and randomly sampling within each area, avoiding the omission problems of random sampling alone.

Stratified Sampling: Contaminants or other parameters are targeted. The site is subdivided and sampling patterns and densities varied in different areas. Stratified sampling can be used for complex and large sites, such as mining.

Grid or Systematic Sampling: The whole site is covered. Sampling locations are readily identifiable, which is valuable for follow-on sampling, if necessary. The grid does not have to be rectilinear. In fact, rectangles are not the best polygon to use in the value is to be representative of a cell. Circles provide equidistant representation, but overlap. Hexagons are sometimes used as a close approximation to the circle. The U.S. Environmental Monitoring and Assessment Program (EMAP) has used a hexagonal grid pattern, for example.

Judgmental Sampling: Samples are collected based on knowledge of the site. This overcomes the problem of ignoring sources or sensitive areas, but is vulnerable to bias of both inclusion and exclusion. Obviously, this would not be used for spatial representation, but for pollutant transport, plume characterization, or monitoring near a sensitive site (e.g., a day care center).

At every stage of monitoring from sample collection through analysis and archiving, only qualified and authorized persons should be in possession of the samples. This is usually ensured by requiring chain-of-custody manifests. Sample handling includes specifications on the temperature range needed to preserve the sample, the maximum amount of time the sample can be held before analysis, special storage provisions (e.g., some samples need to be stored in certain solvents), and chain-of-custody provisions (only certain, authorized persons should be in possession of samples after collection).

Each person in possession of the samples must require that recipient sign and date the chain-of-custody form before transferring the samples. This is because samples have evidentiary and forensic content, so any compromising of the sample integrity must be avoided.

5.3 LABORATORY ANALYSIS

Although real-time analysis of air and other media is becoming more commonplace, most environmental samples must be brought to a laboratory analyzed after collection. The steps that must be taken to interpret the concentration of a chemical in the sample are known as “wet chemistry.”

5.3.1 Extraction

When an environmental sample arrives at the laboratory, the next step may be “extraction.” Extraction is needed for two reasons. First, the environmental sample may be in sediment or soil, where the chemicals of concern are sorbed to particles and must be freed for analysis to take place. Second, the actual collection may have been by trapping the chemicals onto sorbents; meaning that the chemicals must first be freed from the sorbent matrix. Numerous toxic chemicals have low vapor pressures and may not be readily dissolved in water. Thus, they may be found in various media, for example, sorbed to particles, in the gas phase, or in the water column suspended to colloids (and very small amounts dissolved in the water itself). To collect such chemicals in the gas phase, a common method calls for trapping it on polyurethane foam (PUF). Thus, to analyze dioxins in the air, the PUF and particle matter must first be extracted, and to analyze dioxins in soil and sediment, those particles must also be extracted.

Extraction makes use of physics and chemistry. For example, many compounds can be simply extracted with solvents, usually at elevated temperatures. A common solvent

extraction is the Soxhlet extractor, named after the German food chemist, Franz Soxhlet (1848–1913). The Soxhlet extractor (the U.S. EPA Method 3540) removes sorbed chemicals by passing a boiling solvent through the media. Cooling water condenses the heated solvent, and the extract is collected over an extended period, usually several hours. Other automated techniques apply some of the same principles as solvent extraction, but allow for more precise and consistent extraction, especially when large volumes of samples are involved. For example, supercritical fluid extraction (SFE) brings a solvent, usually carbon dioxide to the pressure and temperature near its critical point of the solvent, where the solvent's properties are rapidly altered with very slight variations of pressure (Ekhtera et al., 1997). Solid phase extraction (SPE) uses a solid and a liquid phase to isolate a chemical from a solution, and is often used to clean up a sample before analysis. Combinations of various extraction methods can enhance the extraction efficiencies, depending on the chemical and the media in which it is found. Ultrasonic and microwave extractions may be used alone or in combination with solvent extraction. For example, the U.S. EPA Method 3546 provides a procedure for extracting hydrophobic (i.e., not soluble in water) or slightly water soluble organic compounds from particles such as soils, sediments, sludges, and solid wastes. In this method, microwave energy elevates the temperature and pressure conditions (i.e., 100–115°C and 50–175 psi) in a closed extraction vessel containing the sample and solvent(s). This combination can improve recoveries of chemical analytes and can reduce the time needed compared than the Soxhlet procedure alone.

5.3.2 Chromatography

Not every sample needs to be extracted. For example, air monitoring using canisters and bags allows the air to flow directly into the analyzer. Water samples may also be directly injected. Surface methods, such as fluorescence, sputtering, and atomic absorption, require only that the sample be mounted on specific media (e.g., filters). Also, continuous monitors such as the chemiluminescent system mentioned in the next section provide ongoing measurements.

Chromatography consists of separation and detection. Separation makes use of the chemicals' different affinities for certain surfaces under various temperature and pressure conditions. The first step, injection, introduces the extract to a "column." The term column is derived from the time when columns were packed with sorbents of varying characteristics, sometimes meters in length, and the extract was poured down the packed column to separate the various analytes. Today, columns are of two major types, gas and liquid. Gas chromatography (GC) makes use of hollow tubes (columns) coated inside with compounds that hold organic chemicals. The columns are in an oven, so that after the extract is injected into the column, the temperature is increased, as well as the pressure, and the various organic compounds in the extract are released from the column surface differentially, whereupon they are collected by a carrier gas (e.g., helium) and transported to the detector. Generally, the more volatile compounds are released first (they have the shortest retention times), followed by the semivolatile organic compounds. So, boiling point is often a very useful indicator as to when a compound will come off a column. This is not always the case, since other characteristics such as polarity can greatly influence a compound's resistance to be freed from the column surface. For this reason, numerous GC columns are available to the chromatographer (different coatings, interior diameters, and lengths). Rather than coated columns, liquid chromatography (LC) makes use of columns packed with different sorbing materials with differing affinities for compounds.

FIGURE 5.6 Chromatogram. Source: Vallero (2003.).

Also, instead of a carrier gas, LC uses a solvent or blend of solvents to carry the compounds to the detector. In the high-performance LC (HPLC), pressures are also varied.

Detection is the final step for quantifying the chemicals in a sample. The type of detector needed depends on the kinds of pollutants of interest. Detection gives the “peaks” that are used to identify compounds (Figure 5.6). For example, if hydrocarbons are of concern, GC with flame ionization detection (FID) may be used. GC-FID gives a count of the number of carbon atoms, so for example, long chains can be distinguished from short chains. The short chains come off the column first and have peaks that appear before the long-chain peaks. However, if pesticides or other halogenated compounds are of concern, electron capture detection (ECD) is a better choice.

Numerous detection approaches are also available for LC. Probably, the most common is absorption. Chemical compounds absorb energy at various levels, depending on their size, shape, bonds, and other structural characteristics. Chemicals also vary in whether they will absorb light or how much light they can absorb depending on wavelength. Some absorb very well in the ultraviolet (UV) range, while others do not. Diode arrays help to identify compounds by giving a number of absorption ranges in the same scan. Some molecules can be excited and will fluoresce. The *Beer–Lambert Law* states that energy absorption is proportional to chemical concentration:

$$A = eb [C] \quad (5.1)$$

where A is the absorbency of the molecule, e is the molar absorptivity (proportionality constant for the molecule), b is the light’s path length, and $[C]$ is the chemical concentration of the molecule. Thus, the concentration of the chemical can be ascertained by measuring the light absorbed.

One of the most popular detection methods for environmental pollutants is mass spectrometry (MS), which can be used with either GC or LC separation. The MS detection is highly sensitive for organic compounds and works by using a stream of electrons to consistently break apart compounds into fragments. The positive ions resulting from the fragmentation are separated according to their masses. This is referred to as the “mass to charge ratio” or m/z . No matter which detection device is used, software is used to decipher the peaks and to perform the quantitation of the amount of each contaminant in the sample.

For inorganic substances and metals, the additional extraction step may not be necessary. The actual measured media (e.g., collected airborne particles) may be measured by surface techniques such as atomic absorption (AA), X-ray fluorescence (XRF), inductively coupled plasma (ICP), or sputtering. As for organic compounds, the detection approaches can vary. For example, ICP may be used with absorption or MS. If all one needs to know is elemental information, for example, to determine total lead or nickel in a sample, AA or XRF may be sufficient. However, if speciation (i.e., knowing the various compounds of a metal), then significant sample preparation is needed, including a process known as derivatization. Derivatizing a sample is performed by adding a chemical agent that transforms the compound in question into one that can be recognized by the detector. This is done for both organic and inorganic compounds, for example, if the compound in question contains too many polar functional groups (e.g., $-OH$) it may not be detected with MS.

5.3.3 Limits of Detection

The physical and chemical characteristics of the compounds being analyzed must be considered before visiting the field and throughout all the steps in the laboratory. The quality of results generated about contamination depends on the sensitivity and selectivity of the analytical equipment. Table 5.3 defines some of the most important analytical chemistry threshold values.

TABLE 5.3 Expressions of Chemical Analytical Limits

Type of Limit	Description
Limit of detection (LoD)	Lowest concentration or mass that can be differentiated from a blank with statistical confidence. This is a function of sample handling and preparation, sample extraction efficiencies, chemical separation efficiencies, and capacity and specifications of all analytical equipment being used (see IDL below).
Instrument detection limit (IDL)	The minimum signal greater than noise detectable by an instrument. The IDL is an expression of the piece of equipment, not the chemical of concern. It is expressed as a signal to noise (S:N) ratio. This is mainly important to the analytical chemists, but the engineer should be aware of the different IDLs for various instruments measuring the same compounds, so as to provide professional judgment in contracting or selecting laboratories and deciding on procuring for appropriate instrumentation for all phases of remediation.
Limit of quantitation (LoQ)	The concentration or mass above which the amount can be quantified with statistical confidence. This is an important limit because it goes beyond the “presence–absence” of the LoD and allows for calculating chemical concentration or mass gradients in the environmental media (air, water, soil, sediment, and biota).
Practical quantitation limit (PQL)	The combination of LoQ and the precision and accuracy limits of a specific laboratory, as expressed in the laboratory’s quality assurance/quality control (QA/QC) plans and standard operating procedures for routine runs. The PQL is the concentration or mass that the engineer can consistently expect to have reported reliably.

TABLE 5.4 Limits of Detection for Mercury and Monomethylmercury

Measurement	Method	Method Detection Limits
Total mercury in water	EPA 1631	0.121 ng/L (ppt)
Monomethylmercury in water	EPA 1630 with distillation	0.0192 ng/L (ppt)
Total mercury in sediment/soil	EPA 1631	0.302 ng/g (ppb)
Monomethylmercury in sediment/soil	EPA 1630 with extraction	0.0124 ng/g (ppb)
Total mercury in tissue	EPA 1631	0.378 ng/g (ppb)
Monomethylmercury in tissue	EPA 1630 with digestion	1.29 ng/g (ppb)

Source: Pacific Northwest National Laboratory and Mercury Analytical Laboratory (2009).

The limit of detection is the lowest concentration or mass that can be differentiated from a blank with statistical confidence, which is a function of sample handling and preparation, sample extraction efficiencies, chemical separation efficiencies, and capacity and specifications of all analytical equipment being used. For example, sampling aerosols around a bioreactor is limited to about 0.002–100 μm aerodynamic diameter, since this is the lower limit of detection using a condensation nucleus counter, and that assumes proper sampling prior to the analysis.

The method detection limit (MDL) is the minimum concentration of a substance that can be measured and reported with 99% confidence that the analyte concentration is greater than zero and is determined from analysis of a sample in a given matrix containing the analyte.¹ The MDL is expected to apply to a wide range of environmental sample including water and wastewater effluent. As such, the MDL for an analytical procedure can vary according to the kind of sample taken and requires a complete, specific, and well-defined analytical method. The minimum limit (ML) is the lowest concentration at which an entire analytical system must give a recognizable signal and acceptable calibration point for the analyte. It is equivalent to the concentration of the lowest calibration standard, so long as the system employs all method-specified sample weights, volumes, and cleanup procedures. The ML is calculated as the product of the MDL by 3.18 and rounding the result to the number nearest to $(1, 2, \text{ or } 5) \times 10n$, where n is an integer.

Many states have adopted water quality criteria for the protection of aquatic life and human health that require chemical measurements at very low concentrations. For example, they may limit mercury (Hg) in the range of 1–50 ppt, although current federal methods in the United States do not detect or quantify Hg in this range. A nondetect result using the U.S. Environmental Protection Agency Method 1631, for example, would show only that Hg concentrations are below 200 ppt but would not establish that they are at or below the applicable water quality criterion (Hanlon, 2007). The current limits of detection for Hg are shown in Table 5.4. Note that these are all below the lowest ambient water quality criterion for Hg of 12 ng/L² (nationwide)² and 1.3 ng/L² (Great Lakes)³.

¹United States Code of Federal Regulations: 40 CFR 131.6, Appendix B—Definition and procedure for determination of the method detection limit—Revision 1.11.

²United States Code of Federal Regulations: 40 CFR 132.6, Table 4.

³United States Code of Federal Regulations: 40 CFR 131.6. The method detection limit, according to 40 CFR 136, Appendix B, is 0.2 ng L⁻¹ and the minimum level of quantitation is 0.5 ng L⁻¹.

Following are the steps needed to find the limit of detection:⁴

1. Select an estimated detection limit using one of the following
 - (a) The concentration value corresponding to an instrument signal/noise ranging from 2.5 to 5.
 - (b) The concentration equivalent of three times the standard deviation of replicate instrumental measurements of the analyte in reagent water.
 - (c) That region of the standard curve where there is a significant change in sensitivity, that is, a break in the slope of the standard curve.
 - (d) Instrumental limitations.
 2. Prepare reagent (blank) water that is as free of analyte as possible. Reagent or interference free water is defined as a water sample in which analyte and interferent concentrations are not detected at the method detection limit of each analyte of interest. Analytes are the compounds that are being investigated, for example, if a pesticide is being analyzed. The analytes would include the active ingredient and the so-called inert ingredients (so-called, because the term “active” applies only to the particular biocidal mode of action that makes the pesticide efficacious against a particular pest, not to whether a chemical is chemically or biologically active). The interferents are the substances, when present may interfere with the particular analytical method and add to incorrect findings. Interferences are defined as systematic errors in the measured analytical signal of an established procedure caused by the presence of interfering chemical species. Thus, the interferent concentration is pre-supposed to be normally distributed in representative samples of a given matrix.
 3. (a) If the MDL is to be determined in reagent (blank) water, prepare a laboratory standard (analyte in reagent water) at a concentration that is at least equal to or in the same concentration range as the estimated method detection limit. (Recommend between one and five times the estimated method detection limit.) Proceed to Step 4.
 - (b) If the MDL is to be determined in another sample matrix, analyze the sample. If the measured level of the analyte is in the recommended range of one to five times the estimated detection limit, proceed to Step 4.
 - (c) If the measured level of analyte is less than the estimated detection limit, add a known amount of analyte to bring the level of analyte between one and five times the estimated detection limit.
- If the measured level of analyte is greater than five times the estimated detection limit, and there are two options.
- (i) Obtain another sample with a lower level of analyte in the same matrix if possible.
 - (ii) The sample may be used as is for determining the method detection limit if the analyte level does not exceed 10 times the MDL of the analyte in reagent water. The variance of the analytical method changes as the analyte concentration increases from the MDL; hence, the MDL determined under these circumstances may not truly reflect method variance at lower analyte concentrations.

⁴This procedure is taken directly from United States Code of Federal Regulations: 40 CFR 131.6, Appendix B—Definition and procedure for determination of the method detection limit—Revision 1.11.

4. (a) Take a minimum of seven aliquots of the sample to be used to calculate the method detection limit and process each through the entire analytical method. Make all computations according to the defined method with final results in the method reporting units. If a blank measurement is required to calculate the measured level of analyte, obtain a separate blank measurement for each sample aliquot analyzed. The average blank measurement is subtracted from the respective sample measurements.
- (b) It may be economically and technically desirable to evaluate the estimated method detection limit before proceeding with 4a. This will (1) prevent repeating this entire procedure when the costs of analyses are high and (2) ensure that the procedure is being conducted at the correct concentration. It is quite possible that an inflated MDL will be calculated from data obtained at many times the real MDL even though the level of analyte is less than five times the calculated method detection limit. To ensure that the estimate of the method detection limit is a good estimate, it is necessary to determine that a lower concentration of analyte will not result in a significantly lower method detection limit. Take two aliquots of the sample to be used to calculate the method detection limit and process each through the entire method, including blank measurements as described above in 4a. Evaluate these data
 - (i) If these measurements indicate the sample is in desirable range for determination of the MDL, take five additional aliquots and proceed. Use all seven measurements for calculation of the MDL.
 - (ii) If these measurements indicate the sample is not in correct range, re-estimate the MDL, obtain new sample as in 3 and repeat either 4a or 4b.
5. Calculate the variance (S^2) and standard deviation (S) of the replicate measurements as follows:

$$S^2 = \frac{1}{n-1} \left[\sum_{i=1}^n x_i^2 - \frac{(\sum_{i=1}^n X_i)^2}{n} \right] S = (S^2)^{1/2} \quad (5.2)$$

where X_i ; $i = 1$ to n , are the analytical results in the final method reporting units obtained from the n sample aliquots; and Σ refers to the sum of the X values from $i = 1$ to n .

6. (a) Compute the MDL:

$$\text{MDL} = (n-1, 1-\alpha=0.99)(S) \quad (5.3)$$

where MDL = the method detection limit; $t(n-1, 1-\alpha=0.99)$ = the student's t value appropriate for a 99% confidence level and a standard deviation estimate with $n-1$ degrees of freedom (see Table 5.5).

- (b) The 95% confidence interval estimates for the MDL derived in 6a are computed according to the following equations derived from percentiles of the χ^2 over degrees of freedom distribution (χ^2/df).

$$\text{LCL} = 0.64 \text{ MDL}$$

$$\text{UCL} = 2.20 \text{ MDL}$$

where LCL and UCL are the lower and upper 95% confidence limits, respectively based on seven aliquots.

TABLE 5.5 Students' t Values at the 99% Confidence Level

Number of Replicates	Degrees of Freedom ($n - 1$)	$t_{(n-1, 0.99)}$
7	6	3.143
8	7	2.998
9	8	2.896
10	9	2.821
11	10	2.764
16	15	2.602
21	20	2.528
26	25	2.485
31	30	2.457
61	60	2.390
00	00	2.326

Source: United States Code of Federal Regulations: 40 CFR 131.6, 49 FR 43430, FR 694, 696, FR 23703.

7. Optional iterative procedure to verify the reasonableness of the estimate of the MDL and subsequent MDL determinations.

- If this is the initial attempt to compute MDL based on the estimate of MDL formulated in Step 1, take the MDL as calculated in Step 6, spike the matrix at this calculated MDL and proceed through the procedure starting with Step 4.
- If this is the second or later iteration of the MDL calculation, use S^2 from the current MDL calculation and S^2 from the previous MDL calculation to compute the F-ratio. The F-ratio is calculated by substituting the larger S^2 into the numerator S^2A and the other into the denominator S^2B . The computed F-ratio is then compared with the F-ratio found in the table which is 3.05 as follows: if $S^2A/S^2B < 3.05$, then compute the pooled standard deviation by the following equation:

$$S_{\text{pooled}} = \left[\frac{6S^2A + 6S^2B}{12} \right]^{1/2} \quad (5.4)$$

If $S^2A/S^2B > 3.05$, respoke at the most recent calculated MDL and process the samples through the procedure starting with Step 4. If the most recent calculated MDL does not permit qualitative identification when samples are spiked at that level, report the MDL as a concentration between the current and the previous MDL that permits qualitative identification.

- Use the S_{pooled} as calculated in 7b to compute the final MDL according to the following equation

$$\text{MDL} = 2.681 (S_{\text{pooled}}) \quad (5.5)$$

where 2.681 is equal to $t(12, 1 - \alpha = 0.99)$.

- The 95% confidence limits for MDL derived in 7c are computed according to the following equations derived from percentiles of the χ^2 over degrees of

freedom distribution.

$$\text{LCL} = 0.72 \text{ MDL}$$

$$\text{UCL} = 1.65 \text{ MD}$$

where LCL and UCL are the lower and upper 95% confidence limits respectively based on 14 aliquots.

8. An example calculation of the MDL is

A laboratory conducts seven runs of a sample containing 0.1 ng/mL/Hg, with a SD = 0.007.

The standard deviation of 7 runs of 0.1 ng/mL = $0.007 \times \text{Student's } t \text{ value at the } 99\% \text{ confidence level}$. From Table 5.5., this is found to be 3.143.

Therefore, the MDL = $0.007 \text{ ng/mL} \times 3.143 = 0.022 \text{ ng/mL}$.

9. Report the results. The analytical method used must be specifically identified by number or title and the MDL for each analyte expressed in the appropriate method reporting units. If the analytical method permits options that affect the method detection limit, these conditions must be specified with the MDL value. The sample matrix used to determine the MDL must also be identified with MDL value. Report the mean analyte level with the MDL and indicate if the MDL procedure was iterated. If a laboratory standard or a sample that contained a known amount analyte was used for this determination, also report the mean recovery.

If the level of analyte in the sample was below the determined MDL or exceeds 10 times the MDL of the analyte in reagent water, do not report a value for the MDL.

The limit of detection is both an analytical and a sampling threshold. If an instrument can only detect down to 1 ppb, this is an analytical limitation. However, in reality, if the sample has been held for some time, or the sample must be extracted from the soil or trapping device in the field, this is a limit, even if the laboratory can detect down to 1 ppb. Statistical methods for dealing with nondetects are used, but a nondetect should never be reported as 0, since one can only say with confidence that it was not seen. It may not be present, but the scientist or engineer can only report what is known, and that is dictated by the limits of detection.

The performance is expressed in terms of precision, accuracy, specificity, false positives, and false negatives. Precision describes how refined and repeatable an operation can be performed, such as the exactness in the instruments and methods used to obtain a result. It is an indication of the uniformity or reproducibility of a result. This can be likened to shooting arrows⁵ with each arrow representing a data point. The spread of arrows is equally precise in targets A and B in Figure 5.7. Assuming that the center of the target, that is, the bull's eye, is the "true value," data set B is more accurate than A. If the archer is consistently missing the bull's eye in the same direction at the same distance, this is an example of bias (systematic error). This consistent deviation from the true value can be corrected by calibration and adjustments to equipment (e.g., by running known standards in our analytical equipment). To stay with the archery analogy, the archer would move her sight up and to the right.

⁵The target is a widely used way to describe precision and accuracy, so originator is unknown to author.

FIGURE 5.7 Precision and accuracy. The bull's eye represents the true value. Targets A and B demonstrate data sets that are precise; targets B and D data sets that are accurate, and targets C and D data sets that are imprecise. Target B is the ideal data set, which is precise and accurate.

5.3.4 Aerosol Limits of Detection

In the earlier Hg example, total mercury in water consists of the various chemical species of Hg (e.g., elemental— Hg^0 , alkylated—mono- or dimethylmercury) and whether they are in solution or part of the solids (suspended or sediment). However, in atmospheric sciences; the most important phase distribution is that of vapor versus particulate phase. The distinction between gases and vapors has to do with the physical phase that a substance would be under environmental conditions, for example, at standard temperature and pressure. Particulate matter (PM) is an expression of all particles, whether liquid or solid. An aerosol is a liquid or solid particle that is suspended in a gas; in environmental sciences this gas is usually air, but in reactors, stacks and other nonambient conditions, this can be various flue gases. Standard atmospheric conditions can be defined as 1 atm pressure (760 mmHg) and 25° (29°K) (U.S. Environmental Protection Agency, 1998).

The Clean Air Act established the national ambient air quality standards (NAAQS) for particulate matter in 1971, requiring measurements of total suspended particulates (TSP) as measured by a high volume sampler, that is, a device that collected a large range of sizes of particles (aerodynamic diameters up to $50\text{ }\mu\text{m}$). Smaller particles are more likely to be inhaled than larger particles, so in 1987 the U.S. EPA changed the standard for PM from TSP to PM_{10} , that is, particle matter $\leq 10\text{ }\mu\text{m}$ diameters. The diameter most often used for airborne particle measurements is the “aerodynamic diameter.” The aerodynamic diameter (D_{pa}) for all particles greater than $0.5\text{ }\mu\text{m}$ can be approximated as the product of the Stokes particle diameter (D_{ps}) and the square root of the particle density (ρ_p):

$$D_{\text{pa}} = D_{\text{ps}} \sqrt{\rho_p} \quad (5.6)$$

If the units of the diameters are in μm , the units of density are g/cm^3 .

The Stokes diameter D_{ps} is the diameter of a sphere with the same density and settling velocity as the particle. The Stokes diameter is derived from the aerodynamic drag force caused by the difference in velocity of the particle and the surrounding fluid. Thus, for smooth, spherical particles, the Stokes diameter is identical to the physical or actual diameter.

Aerosol textbooks provide methods to determine the aerodynamic diameter of particles less than $0.5\text{ }\mu\text{m}$. For larger particles, gravitational settling is more important and the aerodynamic diameter is often used.

FIGURE 5.8 Mechanical processes important to filtration. *Source:* Vallero (2008); adapted from Rubow (2004).

The NAAQS for PM_{10} became a 24-h average of $150 \mu\text{g}/\text{m}^3$ (not to exceed this level more than once per year), and an annual average of $50 \mu\text{g}/\text{m}^3$ arithmetic mean. However, subsequent research showed the need to protect people breathing even smaller PM in air, since most of the particles that penetrate deeply into the air–blood exchange regions of the lung are quite small. Thus, in 1997, the U.S. EPA added a new fine particle (diameters ≤ 2.5), known as $\text{PM}_{2.5}$.⁶

Aerosols are collected using equipment that separates out the size fraction of concern. Filtration is an important technology in every aspect of environmental engineering, that is, air pollution, wastewater treatment, drinking water, and even hazardous waste and sediment cleanup. Basically, filtration consists of four mechanical processes: (1) diffusion; (2) interception; (3) inertial impaction; and (4) electrostatics (Figure 5.8).

Diffusion is important only for very small particles ($\leq 0.1 \mu\text{m}$ diameter) because the Brownian motion allows them to move away in a “random walk” away from the air stream. Interception works mainly for particles with diameters between 0.1 and $1 \mu\text{m}$. The particle does not leave the air stream but comes into contact with the filter medium (e.g., a strand of fiberglass). Inertial impaction collects particles that are sufficiently large to leave the air stream by inertia (diameters $\geq 1 \mu\text{m}$). Electrostatics consists of electrical interactions between the atoms in the filter and those in the particle at the point of contact (Van der Waal’s force), as well as electrostatic attraction (charge differences between particle and filter medium). Other important factors affecting filtration efficiencies include the thickness and pore diameter of the filter, the uniformity of particle diameters and pore sizes, the solid volume fraction, the rate of particle loading onto the filter (e.g., affecting particle “bounce”), the particle phase (liquid or solid), capillarity and surface tension (if either the particle or the filter media are coated with a liquid), and characteristics of air or other carrier gases, such as velocity, temperature, pressure, and viscosity.

Thus, aerosol measurement is an expression of the mass of a particle size of particle. Figure 5.9 shows an inlet of the $\text{PM}_{2.5}$ sampler that is designed to extract ambient aerosols

⁶For information regarding particle matter (PM) health effects and inhalable, thoracic, and respirable PM mass fractions (see U.S. Environmental Protection Agency, 1996), Air Quality Criteria for Particulate Matter. Technical Report No. EPA/600/P-95/001aF, Washington, DC.

FIGURE 5.9 Flow of air through a sampler inlet head used to collect particulate matter with aerodynamic diameters $<2.5\ \mu\text{m}$ ($\text{PM}_{2.5}$). WINS = well impactor ninety-six, that is, the design of the particle impactor specified by the U.S. EPA for reference method samplers for $\text{PM}_{2.5}$. *Source:* U.S. EPA (1998).

from the surrounding airstream, remove particles with aerodynamic diameters $>10\ \mu\text{m}$, and move the remaining smaller particles to the next stage. Figure 5.10 illustrates the impactor and filter assembly for removing those particles $<10\ \mu\text{m}$ but $>2.5\ \mu\text{m}$ in diameter but allows particles of $2.5\ \mu\text{m}$ in diameter to pass and be collected on a filter surface. Particles $<10\ \mu\text{m}$ but $<2.5\ \mu\text{m}$ are removed downstream from the inlet by a single-stage, single-flow, single-jet impactor assembly. Aerosols are collected on filters that are weighed before and after sampling. This system uses 37 mm diameter glass filters immersed in low volatility, low viscosity diffusion oil. The oil is added to reduce the impact of “bounce,” that is, particle hit the filter and are not reliably collected (U.S. EPA, 1996).

The before and after weight difference represents the particulate mass in a given air volume, expressed in units of mass (e.g., ng) per units of volume (most often m^3), that is, ng/m^3 . This represents the mass concentration of aerosols in ambient air requires a sensitivity of $\pm 100\ \text{ng}$ for PM_{10} on standard $0.20 \times 0.25\ \text{m}^2$ filter and a sensitivity of $\pm 1\ \text{ng}$ for 3 mm or 47 mm diameter Teflon filters. The LD for the balance must be good enough to meet the atmospheric limits of detection of $60\ \text{ng}/\text{m}^3$ for PM_{10} and $40\ \text{ng}/\text{m}^3$ for $\text{PM}_{2.5}$. This assumes a 24-h sampling period on a standard filter for PM_{10} at a flow rate of $0.0189\ \text{m}^3/\text{s}$, and a 24-h sampling period on a 47 mm diameter filter for $\text{PM}_{2.5}$ at a flow rate of $2.78 \times 10^{-4}\ \text{m}^3/\text{s}$ (Solomon et al., 2001).

FIGURE 5.10 Flow of air through an impactor well and filter holder used to collect particulate matter with aerodynamic diameters $<2.5\ \mu\text{m}$ ($\text{PM}_{2.5}$). *Source:* U.S. EPA (1998).

Preweighing must account the relative humidity (i.e., water in the filter adds mass), not only during weighing but for a substantial amount of time (e.g., 24-h preceding period), as part of numerous calibration steps.

Precision and accuracy in aerosol measurements are greatly affected by collection efficiency. Accuracy is the same as that defined in the previous section, but precision for aerosols is defined the random variation among individual measurements of the same property, usually under prescribed identical conditions. For ambient particulate concentration measurements, precision is usually expressed in terms of a standard deviation estimated by collocated sampling or by reweighing filters and comparing reproducibility. Typical precision is within 5%.⁷

5.3.5 Microbial Limits of Detection

Regulatory agencies pursue ways to achieve lower levels of detection for microbes. As an example, the Invitrogen Corporation developed the PathAlert™ detection kits for the bacteria *Francisella tularensis* (*F. tularensis*), *Yersinia pestis* (*Y. pestis*), and *Bacillus anthracis* (*B. anthracis*) as part of the Environmental Technology Verification Program

⁷United States Code of Federal Regulations, Part 58, Appendix A, 1997; and U.S. Environmental Protection Agency (1998).

TABLE 5.6 Accuracy of Bacteria Test Kit Based on Percentage of Positive Results Compared to Total Replicates for Each Bacteria Species

Bacteria	Concentration Range of Samples Used in Accuracy Calculations (cfu/mL)	Overall Accuracy (Positive Results Out of Total Replicates)
<i>F. tularensis</i>	2×10^4 to 5×10^5	100% (20/20)
<i>Y. pestis</i>	2×10^2 to 5×10^3	100% (16/16)
<i>B. anthracis</i>	2×10^4 to 5×10^5	100% (16/16)

Source: U.S. Environmental Protection Agency and Battelle National Laboratory (2004).

(U.S. Environmental Protection Agency and Battelle National Laboratory, 2004). In the verification of the bacterial test, precision was determined from the overall percentage of consistent responses for all the sample sets. Responses were deemed to be consistent if all responses of the four replicates were the same. For *F. tularensis* replicates, 95% of the sample sets (20 out of 21) showed consistent results. Likewise, 95% of the sample sets (20 out of 21) were consistent for *Y. pestis*. For both, the inconsistency resulted from an inconclusive result for a drinking water (DW) replicate for each bacterium. *B. anthracis* also showed 95% consistency (20 out of 21), but the one sample set with inconsistent results was the infective dose in a performance test (PT) sample. Here, three of the four samples were inconclusive, but the fourth sample was positive for *B. anthracis*. The infective dose of *B. anthracis* was below the method level of detection (MLD) for this bacterium.

Accuracy was assessed by evaluating how often the results were positive in the presence of a concentration of contaminant above the MLD. Contaminant-only performance testing (PT) samples were used for this analysis. An overall percent agreement was determined by dividing the number of positive responses by the overall number of analyses of contaminant-only PT samples above the method LD. The results are presented in Table 5.6.

For *F. tularensis*, *Y. pestis*, and *B. anthracis*, all samples at concentration levels above the vendor-stated method LD generated positive responses for each set of replicates, resulting in 100% agreement for the overall accuracy of the detection kit for each bacterium. The infective/lethal dose for *Y. pestis* is 0.28 colony-forming units per milliliter (cfu/mL) and for *B. anthracis* is 200 cfu/mL. Both doses were below the MLD and not included in the accuracy calculations for those bacteria.

Specificity is the ability of a test to show a negative response when the contaminant is in fact absent. The specificity rate of this kit was determined by dividing the number of negative responses by the total number of unspiked samples. Unspiked interferent PT samples and unspiked DW samples were used to assess specificity. For *F. tularensis* and *Y. pestis*, one unspiked DW replicate for each bacterium produced an inconclusive response (Table 5.7).

A false positive response is defined as a detectable or positive test response when the agent is not present, in this case it was the interferent PT samples or DW samples that were not spiked. The false positive rate was the frequency of false positive results out of the total number of unspiked samples. The false negative response was defined as a negative response when the sample was spiked with a contaminant at a concentration greater than the MLD. Spiked PT (contaminant and interferent) samples and spiked DW samples were included in the analysis.

TABLE 5.7 Specificity of Bacteria Test Kit Based on Percentage of Negative Results Compared to Total Replicates for Each Bacteria Species

Bacteria	Overall Specificity (Negative Results Out of Total Replicates)
<i>F. tularensis</i>	96% (23/24)
<i>V. pestis</i>	96% (23/24)
<i>B. anthracis</i>	100% (22/22)

Source: U.S. Environmental Protection Agency and Battelle National Laboratory (2004).

TABLE 5.8 False Positive and False Negative Response Rates of Bacteria Test Kit

Bacteria	False Positive Rate	False Negative Rate
<i>F. tularensis</i>	0/24	0/60
<i>Y. pestis</i>	0/24	0/56
<i>B. anthracis</i>	0/22	0/56

Source: U.S. Environmental Protection Agency and Battelle National Laboratory (2004).

Conversely, the false negative rate was reported as the frequency of false negative results out of the total number of spiked samples for a particular contaminant. The results are presented in Table 5.8. No false positives or false negatives were found for any of the sample matrices for any bacteria for this kit. One replicate for unspiked DW in two different DW samples showed an inconclusive result for *F. tularensis* and one for *Y. pestis*. Two inconclusive results were reported; one for *F. tularensis* in one DW sample and one for *Y. pestis* in a different DW sample (See Table 5.8).

5.4 MEASUREMENT UNCERTAINTY

Contaminant assessments have numerous sources of uncertainty. There are two basic types of uncertainty: Types A and B. Type A uncertainties result from the inherent unpredictability of complex processes that occur in nature. These uncertainties cannot be eliminated by increasing data collection or enhancing analysis. The scientist and engineer must simply recognize that Type A uncertainty exists, but must not confuse it with Type B uncertainties, which can be reduced by collecting and analyzing additional scientific data.

The first step in an uncertainty analysis is to characterize potential uncertainties. Sources of Type B uncertainty take many forms (Finkel, 1990). There can be substantial uncertainty concerning the numerical values of the attributes being studied (e.g., contaminant concentrations, wind speed, discharge rates, groundwater flow, and other variables). Modeling generates its own uncertainties, including errors in selecting the variables to be included in the model, such as surrogate contaminants that represent whole classes of compounds (e.g., does benzene represent the behavior or toxicity of other aromatic compounds?). The application of the findings, even if the results themselves have tolerable uncertainty, leads to the propagation of uncertainties when ambiguity arises regarding their meaning. For example, a decision rule is a statement about which alternative will be selected, for example, for cleanup, based on the characteristics of the decision situation.

A “decision-rule uncertainty” occurs when there are disagreements or poor specification of objectives (i.e., is our study really addressing the client’s needs?).

Variability and uncertainty must not be confused. Variability consists of measurable factors that differ across populations such as soil type, vegetative cover, or body mass of individuals in a population. Uncertainty consists of unknown or not fully known factors that are difficult to measure, such as the inability to access an ideal site that would be representative because it is on private property.

Modeling uncertainties, for example, may consist of extrapolations from a single value to represent a whole population, that is, a point estimate (e.g., 70 kg as the weight of an adult male). Such estimates can be typical values for a population or an estimate of an upper end of the population’s value, for example, 70 years as the duration of exposure used as a “worse case” scenario. Another approach is known as the Monte Carlo technique (Figure 5.11). The Monte Carlo-type exposure assessments use probability distribution functions, which are statistical distributions of the possible values of each population characteristic according to the probability of the occurrence of each value. These are derived using iterations of values for each population characteristic. While the Monte Carlo technique may help to deal with the point estimate limitation, it can suffer from confusing variability with uncertainty.

Other data interpretation uncertainties can result from the oversimplification of complex entities. For example, assessments consist of an aggregation of measurement data, modeling, and combinations of sampling and modeling results. However, these

FIGURE 5.11 Principles of the Monte Carlo method for aggregating data. *Source:* Australian Department of Health and Ageing (2002).

complicated models are providing only a snapshot of highly dynamic human and environmental systems. The use of more complex models does not necessarily increase precision, and extreme values can be improperly characterized. For example, a 50th percentile value can always be estimated with more certainty than a 99th percentile value.

The bottom line is that uncertainty is always present in sampling, analysis, and data interpretation, so the monitoring and data reduction plan should be systematic and rigorous. The uncertainty analysis must be addressed for each step of the contaminant assessment process, including any propagation and enlargement of cumulative error (e.g., an incorrect pH value that goes into an index where pH is weighted heavily, and then used in another algorithm for sustainability). The characterization of the uncertainty of the assessment includes selecting and rejecting data and information ultimately used to make environmental decisions, and includes both qualitative and quantitative methods (See Table 5.9).

Uncertainty factors (UFs) are applied to address both the inherent and study uncertainties upon which to establish safe levels of exposure to contaminants. The UFs consider the uncertainties resulting from the variation in sensitivity among the members of the populations, including interhuman and intraspecies variability; the extrapolation of animal data to humans (i.e., interspecies variability); the extrapolation from data gathered

TABLE 5.9 Example of an Uncertainty Table for Exposure Assessment

<i>Assumption</i>	Effect on Exposure ^a		
	Potential magnitude for over-estimation of exposure	Potential magnitude for under-estimation of exposure	Potential magnitude for over- or under-estimation of exposure
<i>Environmental sampling and analysis</i>			
Sufficient samples may not have been taken to characterize the media being evaluated, especially with respect to currently available soil data			Moderate
Systematic or random errors in the chemical analyses may yield erroneous data			Low–high
<i>Exposure parameter estimation</i>			
The standard assumptions regarding body weight, period exposed, life expectancy, population characteristics, and lifestyle may not be representative of any actual exposure situation			Moderate
The amount of media intake is assumed to be constant and representative of the exposed population	Moderate		
Assumption of daily lifetime exposure for residents	Moderate to high		

Source: Australian Department of Health and Ageing (2002).

^aAs a general guideline, assumptions marked as “low” may affect estimates of exposure by less than one order of magnitude, assumptions marked as “moderate” may affect estimates of exposure by between one and two orders of magnitude, and assumptions marked as “high” may affect estimates of exposure by more than two orders of magnitude.

in a study with less-than-lifetime exposure to lifetime exposure, that is, extrapolating from acute or subchronic to chronic exposure; the extrapolation from different thresholds, such as the LOAEL rather than from a NOAEL; and the extrapolation from an incomplete data base is incomplete. Note that most of these sources of uncertainty have a component associated with measurement and analysis.

The numerical value uncertainties are directly related to the quality and representativeness of the sampling design and the analytical expressions described in Table 5.9. When these values are used in environmental models, they are known as “parameter uncertainties.” They account for imprecision and inaccuracy associated with the measurement and analytical equipment, systemic weaknesses in data gathering (i.e., bias).

5.5 MEASUREMENT DECISION MAKING

Environmental contaminants may be physical, chemical, or biological. Heat is physical contaminant since every species has a unique range of temperature tolerance. Chemical contaminants are probably the first type that comes to mind, since they are often measured in surface and well water, soil, air, and bodily fluids. Biological contaminants may be pathogenic microbes (e.g., fecal coliform bacteria in water), but they may also include organisms that upset environmental conditions, for example, animals such as the zebra mussels that destroy biodiversity in the Great Lakes or plants such as kudzu that cover large swaths of ecosystems in the southeastern United States.

The value of a water body can be directly related to water temperature since it is directly proportional to dissolved oxygen content, which is a limiting factor of the type of fish communities that can be supported by a water body (see Tables 5.10 and 5.11). A trout stream is a highly valued resource that is adversely impacted if mean temperatures increase. Rougher, less valued fish (e.g., carp and catfish) can live at much lower ambient water body temperatures than can salmon, trout and other coldwater fish populations. Thus, net increase in heat may directly stress the game fish population. That is, fish species vary in their ability to tolerate higher temperatures, meaning that the less tolerant, higher value fish will be inordinately threatened.

The threat may not be completely explained as heat stress due directly to the increase in temperature (U.S. EPA, 1997). Much can be explained by the concomitant decrease in the stream’s dissolved oxygen (DO) concentrations (see Figures 5.12 and 5.13), which deems the water body hostile to the fish. Even if the adult fish can survive at the reduced DO levels, their reproductive capacities decreases. Or, the reproduction is not adversely affected, but the survival of juvenile fish can be reduced.

The increased temperature can also increase the solubility of substances toxic to organisms, which increases the exposure. For example, greater concentrations of mercury and other toxic metals will occur with elevated temperatures. The lower DO concentrations will lead to a reduced environment where the metals and compounds will form sulfides, and other compounds that can be toxic to the fish. Thus, the change in temperature, the resulting decrease in DO and increasing metal concentrations, and the synergistic impact of the combining the hypoxic water and reduced metal compounds is a cascade of harm to the stream’s ecosystems (Figure 5.14).

Biota also plays a role in the heat-initiated effect. Combined abiotic and biotic responses occur. Notably, the growth and metabolism of the bacteria results in even more rapidly decreasing DO levels. Algae both consume DO for metabolism and produce DO

TABLE 5.10 Relationship Between Water Temperature and Maximum Dissolved Oxygen (DO) Concentration in Water (at 1 atm)

Temperature (°C)	Dissolved Oxygen (mg/L)	Temperature (°C)	Dissolved Oxygen (mg/L)
0	14.60	23	8.56
1	14.19	24	8.40

22	8.72	45	5.95

Sources: Vallero (2010) and U.S. Environmental Protection Agency (1997).

by photosynthesis. The increase in temperature increases their aqueous solubility, and the decrease in DO is accompanied by redox changes, for example, formation of reduced metal species, such as metal sulfides. This is also being mediated by the bacteria, some of which will begin reducing the metals as the oxygen levels drop (reduced conditions in the

TABLE 5.11 Normal Temperature Tolerances of Aquatic Organisms

Organism	Taxonomy	Range in Temperature Tolerance (°C)	Minimum Dissolved Oxygen (mg/L)

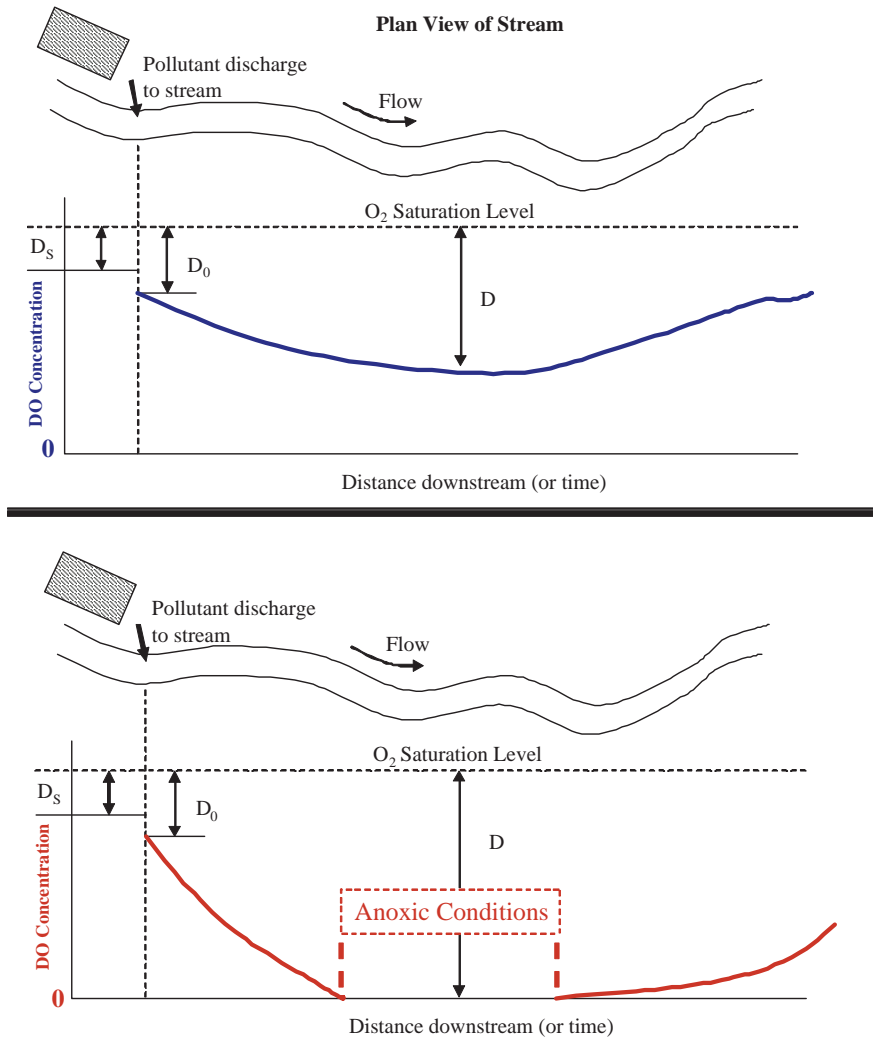

FIGURE 5.12 Dissolved oxygen (DO) deficit downstream from a heated effluent. The increased temperature can result in an increase in microbial kinetics, as well as more rapid abiotic chemical reactions, both consuming DO. The concentration of dissolved oxygen in the top curve remains above 0, so although the DO decreases, the overall system DO recovers. The bottom sags where dissolved oxygen falls to 0, and anoxic conditions result and continue until the DO concentrations begin to increase. D_s is the background oxygen deficit before the pollutants enter the stream. D_0 is the oxygen deficit after the pollutant is mixed. D is the deficit for contaminant A that may be measured at any point downstream. The deficit is overcome more slowly in the lower curve (smaller slope) because the re-oxygenation is dampened by the higher temperatures and changes to microbial system, which means the system has become more vulnerable to another insult, for example, another downstream source could cause the system to return to anoxic conditions.

FIGURE 5.13 Cumulative effect of a second heat source, causing an overall system to become more vulnerable. The rate of re-oxygenation is suppressed, with a return to anoxic conditions.

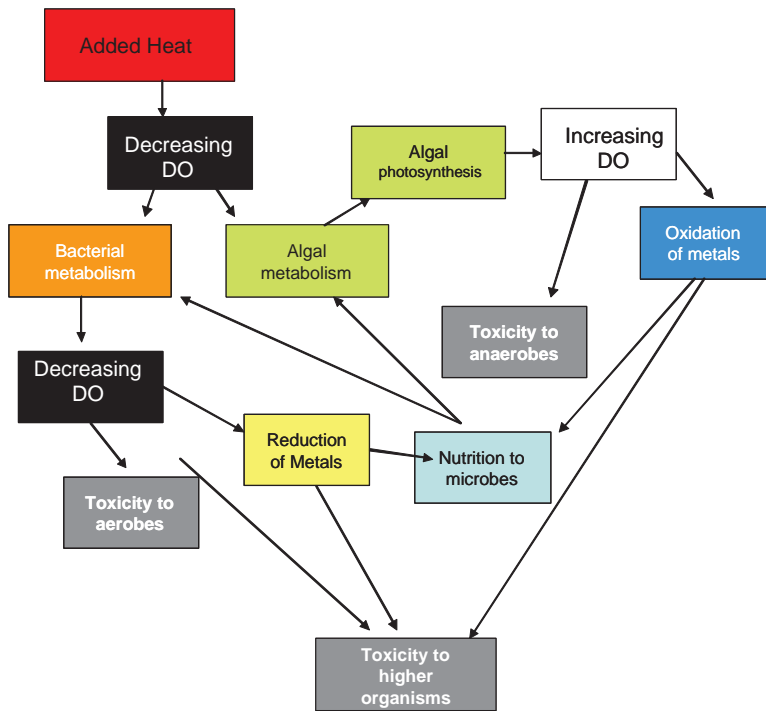

FIGURE 5.14 Adverse effects in the real world usually result from a combination of conditions. In this example, the added heat results in an abiotic response (i.e. decreased dissolved oxygen (DO) concentrations in the water). *Source:* Vallero (2010).

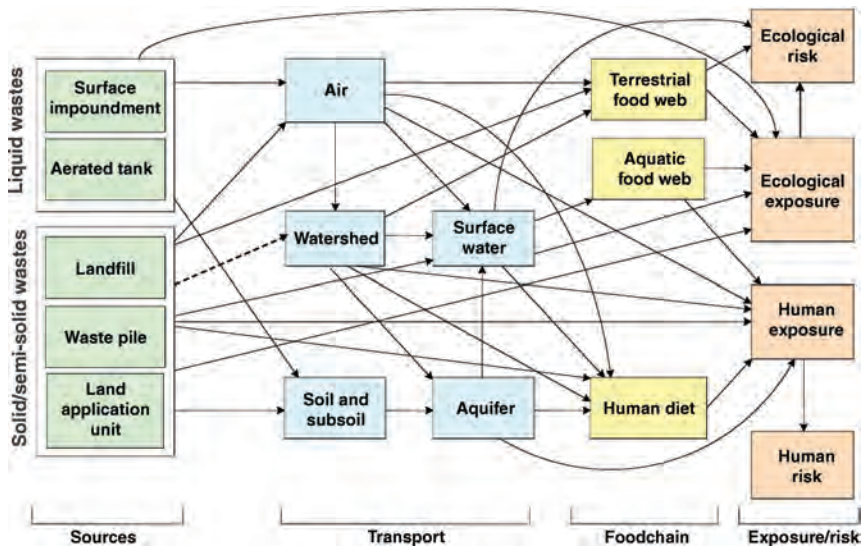

FIGURE 5.15 Environmental transport pathways can be affected by net heat gain. Compounds (nutrients, contaminants), microbes and energy (e.g., heat) follow the path through the environment indicated by arrows. The residence time within in any of the boxes is affected by conditions, including temperature. Adapted from Vallero et al. (2007).

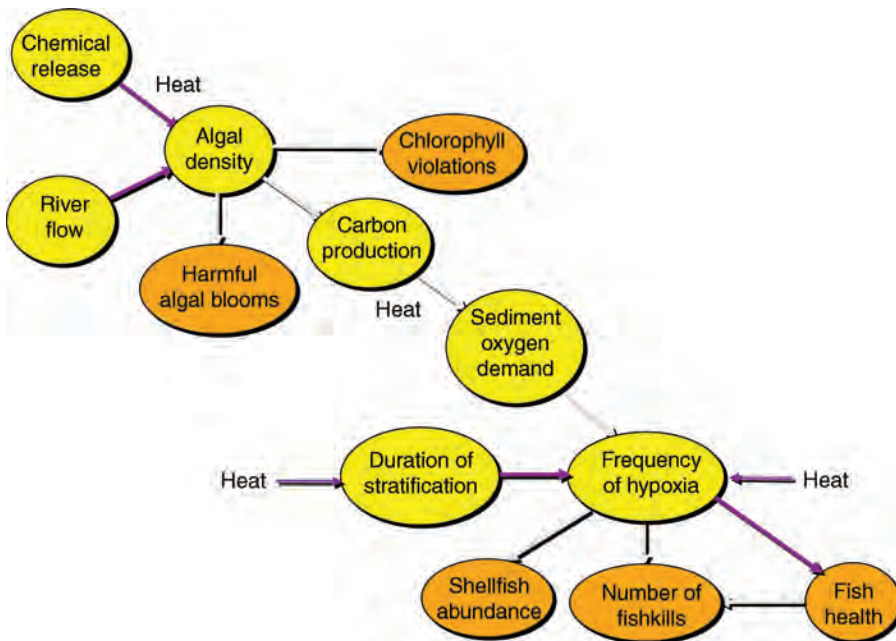

FIGURE 5.16 Flow of events and conditions leading to fish kills, indicating some of the points where added heat can exacerbate the likelihood of a fish kill or other adverse environmental event Vallero et al. (2007). Graphics adapted from U.S. Environmental Protection Agency (2007).

water and sediment). However, the opposite is true in the more oxidized regions, that is, the metals are forming oxides. The increase in the metal compounds combined with the reduced DO, combined with the increased temperatures can act synergistically to make the conditions toxic for higher animals, for example, a fish kill.

The first-order abiotic effect (i.e., increased temperature) results in an increased microbial population. However, the growth and metabolism of the bacteria results in decreasing the DO levels, but the growth of the algae both consume DO for metabolism and produce DO by photosynthesis. Meanwhile, a combined abiotic and biotic response occurs with the metals. The increase in temperature increases their aqueous solubility and the decrease in DO is accompanied by redox changes, for example, formation of reduced metal species, such as metal sulfides. This is also being mediated by the bacteria, some of which will begin reducing the metals as the oxygen levels drop (reduced conditions in the water and sediment). However, the opposite is true in the more oxidized regions, that is, the metals are forming oxides. The increase in the metal compounds combined with the reduced DO, combined with the increased temperatures can act synergistically to make the conditions toxic for higher animals, for example, a fish kill (Vallero et al., 2007). Predicting the likelihood of a fish kill can be quite complicated, with many factors that either mitigate or exacerbate the outcome (see Figures 5.15 and 5.16).

5.6 ENVIRONMENTAL INDICATORS

Measurements alone are seldom sufficient to determine environmental conditions. These data must often be combined with other information in the form of indicators and indices.

5.6.1 Oxygen Indicators

The biochemical oxygen demand (BOD) is the amount of oxygen that bacteria will consume in the process of decomposing organic matter under aerobic conditions. The BOD is measured by incubating a sealed sample of water for 5 days and measuring the loss of oxygen by comparing the O_2 concentration of the sample at time = 0 (just before the sample is sealed) to the concentration at time = 5 days (known specifically as BOD_5). Samples are commonly diluted before incubation to prevent the bacteria from depleting all of the oxygen in the sample before the test is complete (State of Georgia, 2003). BOD_5 is merely the measured DO at the beginning time, that is, the initial DO (D_1), measured immediately after it is taken from the source, minus the DO of the same water measured exactly 5 days after D_1 , that is, D_5 :

$$BOD = \frac{D_1 - D_5}{P} \quad (5.7)$$

where P = decimal volumetric fraction of water utilized. D units are in mg/L. If the dilution water is seeded, the calculation becomes

$$BOD = \frac{(D_1 - D_5) - (B_1 - B_5)f}{P} \quad (5.8)$$

where B_1 = initial DO of seed control; B_5 = final DO of seed control; and f = the ratio of seed in sample to seed in control = % seed in D_1 / % seed in B_1 . B units are in mg/L.

For example, to find the BOD₅ value for a 10 mL water sample added to 300 mL of dilution water with a measured DO of 7 mg/L and a measured DO of 4 mg/L 5 days later

$$P = \frac{10}{300} = 0.03$$

$$\text{BOD}_5 = \frac{7 - 4}{0.03} = 100 \text{ mg/L}$$

Thus, the microbial population in this water is demanding 100 mg/L dissolved oxygen over the 5-day period. So, if a conventional municipal wastewater treatment system is achieving 95% treatment efficiency, the effluent discharged from this plant would be 5 mg/L.

Chemical oxygen demand (COD) does not differentiate between biologically available and inert organic matter, and it is a measure of the total quantity of oxygen required to oxidize all organic material completely to carbon dioxide and water. COD values always exceed BOD values for the same sample. COD (mg/L) is measured by oxidation using potassium dichromate (K₂Cr₂O₇) in the presence of sulfuric acid (H₂SO₄) and silver. By convention, 1 g of carbohydrate or 1 g of protein accounts for about 1 g of COD. On average, the ratio BOD:COD is 0.5. If the ratio is <0.3, the water sample likely contains elevated concentrations of *recalcitrant* organic compounds, that is, compounds that resist biodegradation (Gerba and Pepper, 2009). That is, there are numerous carbon-based compounds in the sample, but the microbial populations are not efficiently using them for carbon and energy sources. This is the advantage of having both BOD and COD measurements. Sometimes, however, COD measurements are conducted simply because they require only a few hours compared with the 5 days for BOD.

Since available carbon is a limiting factor, the carbonaceous BOD reaches a plateau, that is, ultimate carbonaceous BOD (see Figure 5.17). However, carbonaceous compounds are the only substances demanding oxygen. Microbial populations will continue to demand O₂ from the water to degrade other compounds, especially nitrogenous

FIGURE 5.17 Biochemical oxygen demand (BOD) curve showing ultimate carbonaceous BOD and nitrogenous BOD. Adapted from Gerba and Pepper (2009).

compounds, which account for the bump in the BOD curve. Thus, in addition to serving as an indication of the amount of molecular oxygen needed for biological treatment of the organic matter, BOD also provides a guide to sizing a treatment process, assign its efficiency and giving operators and regulators information about whether the facility is meeting its design criteria and is complying with pollution control permits.

If effluent with high BOD concentrations reaches surface waters, it may diminish DO to levels lethal some fish and many aquatic insects. As the water body reaerates as a result of mixing with the atmosphere and by algal photosynthesis, O_2 is added to the water, the oxygen levels will slowly increase downstream. The drop and rise in DO concentrations downstream from a source of BOD is known as the DO sag curve, because the concentration of dissolved oxygen “sags” as the microbes deplete it. So, the falling O_2 concentrations fall with both time and distance from the point where the high BOD substances enter the water.

The stress from decreasing DO is usually indicated by the BOD. Similar to most environmental systems, the water bodies that receive sediment loads are complex in their response to increased input of materials. The DO will respond both positively and negatively to increased nutrient levels. Since the biota have unique optimal ranges of growth and metabolism that varies among species (e.g., algae will add some O_2 with photosynthesis, but use some O_2 for metabolism, whereas the bacteria will generally be net consumers of molecular oxygen).

5.6.2 Indices

The most widely applied environmental indices are those that follow the framework of an index of biological integrity. In biological systems, integrity is the capacity of a system to sustain a balanced and healthy community. This means the community of organisms in that system meets certain criteria for species composition, diversity and adaptability, often compared with a reference site that is a benchmark for integrity. As such, biological integrity indices are designed to integrate the relationships of chemical and physical parameters with each other and across various levels of biological organization. They are now used to evaluate the integrity of environmental systems using a range of metrics to describe system.

Thus, environmental indices combine attributes to determine a system's condition (e.g., diversity and productivity) and to estimate stresses. The original index of biotic integrity developed by Karr (1981) was based on fish fauna attributes and has provided predictions of how well a system will respond to a combination of stresses. In fact, the index is completely biological, with no direct chemical measurements. However, the metrics (see Table 5.12) are indirect indicators of physicochemical factors (e.g., the abundance of game fish is directly related to dissolved oxygen concentrations). The metrics provide descriptions of a system's structure and function.

An example of the data that is gathered to characterize a system is provided in Table 5.13. The information that is gleaned from these data is tailored to the physical, chemical, and biological conditions of an area, for example, for large spatial regions. The information from a biologically based index can be used to evaluate a system, as shown in Figure 5.18.

Systems involve scale and complexities in both biology and chemistry.

For example, a fish's direct aqueous exposure (AE in $\mu\text{g}/\text{day}$) is the product of the organism's ventilation volume, that is, the flow Q (in mL/day), and the compound's aqueous concentration, C_w ($\mu\text{g}/\text{mL}$). The fish's exposure by its diet (DE, in $\mu\text{g}/\text{day}$) is the

TABLE 5.12 Biological Metrics Used in the Original Index of Biological Integrity (IBI)

Integrity Aspect	Biological Metric
Species richness and composition	Total number of fish species (total taxa) Number of <i>Catostomidae</i> species (suckers) Number of darter species Number of sunfish species Number of intolerant or sensitive species
Indicator species metrics	Percent of individuals that are <i>Lepomis cyanellus</i> (Centrarchidae) Percent of individuals that are omnivores
Trophic function metrics	Percent of individuals that are insectivorous Cyprinidae Percent of individuals that are top carnivores or piscivores Percent of individuals that are hybrids
Reproductive function metrics	Abundance or catch per effort of fish
Abundance and condition metrics	Percent of individuals that are diseased, deformed, or that have eroded fins, lesions, or tumors (DELTs)

Source: Karr (1981).

product of its feeding rate, F_w (g wet weight/day), and the compound's concentration in the fish's prey, C_p ($\mu\text{g/g}$ wet wt). If the fish's food consist of single type of prey that is at equilibrium with the water, fish's aqueous and dietary exposures and the bioconcentration factor (BCF) can be calculated when they are equal:

$$AE = DE; QC_w = F_w C_p; BCF = \frac{Q}{F_w} \quad (5.9)$$

The ventilation-to-feeding ratio for a 1 kg trout has been found (Erickson and McKim, 1987; Stewart et al., 1983) to be on the order of $10^{4.3}$ mL/g. Assuming the quantitative structure activity relationship (QSAR) for the trout's prey is $BCF = 0.048$ times the octanol–water coefficient (K_{ow}); it appears that the trout's predominant route of exposure for any chemical with a $K_{ow} > 10^{5.6}$. Exposure must also account for the organism's assimilation of compounds in food, which for very lipophilic compounds, will probably account for the majority of exposure compared with that from the water. Even though chemical exchange occurs from both food and water through passive diffusion (Fick's law relationships), the uptake from food, unlike direct uptake from water, does not necessarily relax the diffusion gradient into the fish. The difference between digestion and assimilation of food can result in higher contaminant concentrations in the fish's gut.

Predicting uptake where the principal route of exchange is dietary is complicated in that most fish species exhibit well defined, size-dependent, taxonomic, and temporal trends regarding their prey. This means that a single bioaccumulation factor (BAF) may help to assess the risk to all fish species. In fact, the BAF may not even apply to different sizes of the same species.

The systematic biological exchange of materials between the organism, in this case various species of fishes, is known as uptake, which can be expressed by the following three differential equations for each age class or cohort of fish (Barber, 2008):

$$\frac{dB_f}{dt} = J_g + J_i + J_{bt} \quad (5.10)$$

TABLE 5.13 Biological Metrics that Apply to Various Regions of North America^a

where J_g represents the net chemical exchange ($\mu\text{g/d}$) across the fish's gills from the water; J_i represents the net chemical exchange ($\mu\text{g/d}$) across the fish's intestine from food; and J_{bt} is the chemical's biotransformation rate ($\mu\text{g/d}$).

Physiologically based models for fish growth are often formulated in terms of energy content and flow (e.g., kcal/fish and kcal/day). Equation 5.4 is basically the same as such bioenergetic models because energy densities of fish depend on their dry weight (Kushlan et al., 1986; Hartman and Brandt, 1995; Schreckenbach et al., 2001). Obviously, feeding depends on the availability of suitable prey, so the mortality of the fish is a function of the individual feeding levels and population densities of its predators. Thus, the fish's dietary

exposure is directly related to the organism's feeding rate and the concentrations chemicals in its prey.

5.7 EXTENDING MEASUREMENT DATA USING MODELS

Models take many forms, from conceptual models that explain the way a system works, such as delineation of all the factors and parameters of how a particle moves in the air after release. In general, developing a model requires two main steps. First, a model of the domain and the processes being studied must be defined. Then, at the model boundaries, a model of the boundary conditions is especially needed to represent the influencing environment surrounding the study domain. Physical or dynamic models are used to estimate the location of chemical expected to move under controlled conditions, but on a much smaller scale than real life. These can include chambers to model the fate of chemical. Like all models, the dynamic model's accuracy is dictated by the degree to which the actual conditions can be simulated and the quality of the information that is used.

Numerical models apply mathematical expressions to approximate a system. Transport and fate models can be statistical and/or deterministic. Statistical models include the pollutant dispersion models, such as the Lagrangian models, which follow the movement of a substance starting from the source to the receptor locations. These often assume idealized Gaussian distributions from a point of release; that is, the pollutant concentrations are normally distributed in both the vertical and the horizontal directions from the source. The Lagrangian approach is common for atmospheric releases, and recent models based on this approach have incorporated additional descriptions of complex turbulence. Stochastic models are statistical models that assume that the events affecting the behavior of a chemical in the environment are random, so such models are based on probabilities. These are being commonly adopted in the modeling of human exposures.

Deterministic models are used when the physical, chemical, and other processes are sufficiently understood so as to be incorporated to reflect the movement and fate of chemicals. Often, they are difficult to develop because each process must be represented by a set of algorithms in the model. Also, the relationship between and among the systems, such as the kinetics and mass balances, must also be represented. Thus, the modeler must "parameterize" every important event following a chemical's release to the environment. Hybrid models use both statistical and deterministic approaches, for example, when one part of a system tends to be more random while another has a very strong basis in physical principles.

Numerous models are available to address the movement of chemicals through a single environmental medium, but increasingly, engineers applying multimedia models, such as compartmental models that help to predict the behavior and changes to chemicals as they move within and among reservoirs (e.g., soil in an ecosystem or carpet in a house), in the air as dust and vapors, and in exchanges with surfaces.

Measurement data can be used to evaluate these models. Conversely, once a model is considered to be reliable, measurements can be used as inputs to the model to represent larger areas than those actually measured. Measurements may also be input into models to predict different scenarios. The engineer may be able to use current and previous measurements to extrapolate environmental conditions in both space and time. This is very useful when deciding on ways to clean up pollution or to consider possible problems that may be encountered if a substance is used. In this way, models can be very useful to the environmental engineer who must choose from various interventions or who must consider the life cycle of an ingredient in a product. Thus, measurement interpolation and extrapolation with models is an important tool to predicting reliability, risk and in support of optimization.

5.8 SUMMARY

The environment consists of very complex systems ranging in scale from the cell to the planet. These systems are comprised of matrices of nonliving (i.e., abiotic) and living (biotic) components. Various means of measurement are required to determine the condition of such systems. Many of these measurements are direct physical and chemical measurements, for example, temperature, density, and pH of soil and water. Others are indirect, such as light scattering as indication of the number of aerosols in the atmosphere. This chapter provides an overview of some of the most important measurement methods in use today. In addition, the chapter introduces some of the techniques available for sampling, analysis, and extrapolation and interpolation (e.g., models) of measured results.

NOMENCLATURE

<i>A</i>	Absorption
<i>AA</i>	Atomic absorption
<i>AADT</i>	Annual average daily traffic
<i>AE</i>	Aquatic exposure
<i>B</i>	Final DO of seed control
<i>b</i>	Path length of light
<i>B₁</i>	Initial DO of seed control
<i>BAF</i>	Bioaccumulation factor
<i>BCF</i>	Bioconcentration factor
<i>BOD</i>	Biochemical oxygen demand
<i>cfu</i>	Colony-forming units
<i>cm</i>	Centimeter
<i>COD</i>	Chemical oxygen demand
<i>C_p</i>	Chemical concentration in fish prey
<i>C_w</i>	Compound's aqueous concentration
<i>[C]</i>	Chemical concentration
<i>°C</i>	Degrees Celsius
<i>D</i>	Aerodynamic diameter
<i>D₁</i>	Initial DO measurement on day 1
<i>D₅</i>	DO measurement on day 5
<i>DE</i>	Exposure by diet
<i>DELT</i>	Diseased, deformed, eroded fins, lesions, or tumors
<i>DO</i>	Dissolved oxygen
<i>D_{ps}</i>	Stokes particle diameter
<i>DQO</i>	Data quality objective
<i>DW</i>	Drinking water
<i>e</i>	Molar absorptivity
<i>ECD</i>	Electron capture detection
<i>f</i>	Ratio of seed in sample to seed in control
<i>FID</i>	Flame ionization detection
<i>F_w</i>	Feeding rate
<i>g</i>	Gram
<i>GC</i>	Gas chromatography
<i>GIS</i>	Geographic information system

HPLC	High-performance liquid chromatography
IBI	Index of biological integrity
ICP	Inductively coupled plasma
IDL	Instrument detection limit
J_{bt}	Biotransformation rate
J_g	Net chemical exchange across fish gill
J_i	Net chemical exchange across the fish's intestine from food
K_{ow}	Octanol–water coefficient
K	Kelvin
L	Liter
LC	Liquid chromatography
LDR	Land disposal regulation
LoD	Limit of detection
LoQ	Limit of quantitation
MDL	Method detection limit
mL	Milliliter
ML	Minimum limit
mmHg	Millimeters of mercury (pressure)
MS	Mass spectroscopy
MSAT	Mobile source air toxic
μg	Microgram
μm	Micron (micrometer)
NAAQS	National Ambient Air Quality Standards
ng	Nanogram
P	Decimal volumetric fraction of water
PM	Particulate matter
PM ₁₀	Particulate matter ≤ 10 micron aerodynamic diameter
PM _{2.5}	Particulate matter ≤ 2.5 micron aerodynamic diameter
ppb	Parts per billion
ppt	Parts per trillion
PQL	Practical quantitation limit
PT	Performance testing
PUF	Polyurethane foam
ρ_p	Particle density
Q	Flow
QA	Quality assurance
QC	Quality control
QSAR	Quantitative structure activity relationship
S	Standard deviation
LCL	Lower 95% confidence limit
S^2	Variance
SFE	Supercritical fluid extraction
SOP	Standard operating procedures
SPE	Solid phase extraction
TSP	Total suspended particulates
UCL	Upper 95% confidence limit
UF	Uncertainty factor
XRF	X-ray fluorescence

6.1 INTRODUCTION

Hydrology is the study of the occurrence, movement, and quality of water in the environment, including both surface and subsurface systems. Surface water hydrology focuses on aboveground flow and transport, including overland, channel, lake, and wetland environments, whereas subsurface hydrology considers both groundwater (saturated) and soil-water (unsaturated) environments.

Sciences closely related to hydrology include geology, atmospheric sciences, glaciology, ecology, and oceanography. Engineering, law, economics, political science, and management sciences also rely on hydrologic knowledge because of water's important role in human systems, such as thermoelectric and hydroelectric power production; navigation; and municipal, industrial, and agricultural water uses.

This section summarizes hydrologic measurements in natural systems. The goal of gathering these measurements is to develop a quantitative understanding of the hydrologic system being investigated. This understanding—with relevant data—can then be used for design, prediction, and management purposes.

6.1.1 Stage

Stage is used to describe the water-surface elevation relative to an arbitrary datum. While stage could be referenced to mean absolute sea level, reference to any local datum can be used.¹ In saturated, subsurface environments, the *hydraulic head* is used instead of stage to describe the height of water in a well. The head can also be inferred for water held in saturated pores near the well by assuming equilibrium between the well and the formation.²

Manual stage measurements include the use of a *staff gauge*, which is a precision measurement scale mounted vertically in the water body so that the water stage can be visually determined from the gauge. The staff gauge is permanently placed in a location where it can be observed over a wide range of stages, either directly or through a remote video feed. If a single staff gauge is not visible or submerged at high flows (or dry during low flows), then additional staff gauges can be placed uphill or downhill of each other.

A *sounder* or *depth-indicator* is used to obtain manual water-level measurements in a well or below a bridge. The sounder probe is lowered until it reaches the water surface, at which point either a sound or a light is triggered. The water-surface elevation is determined by subtracting the depth to water from the measurement elevation.

A *hook-gage* is commonly used for more precise water-level measurements (e.g., in an evaporation pan). These gauges can measure water levels to a precision of 20 μm (<0.001 in.), but require a stilling well that has been accurately leveled.

Automated stage (depth) sensors, include vibrating wires, strain-type pressure transducers, bubblers, and acoustic level indicators, which can be used to continuously monitor water levels. These devices are mounted either below the water surface (e.g., vibrating wires, transducers, bubbler hoses), or above the water surface looking downward to measure fluid pressure (e.g., acoustic sensors). Sensors that monitor fluid

¹ If a geo-referenced elevation is required, then the elevation of the local datum can be found and stages can be converted to an absolute elevation.

² In unsaturated, subsurface environments, a negative pressure (or *soil water tension*) is used instead of hydraulic head, as discussed in a subsequent section.

pressure may not provide accurate readings of water levels if a significant water velocity is present or if the fluid density changes due to temperature, entrained gasses, sediments, and dissolved solids.

6.1.2 Velocity

Water velocities, v , are determined using various types of flow meters, such as a *Doppler*, *electromagnetic*, or *Gurly-type*. *Acoustic Doppler Velocity* (ADV) meters generate a sound source that produces an echo from particulates in the moving water. The frequency (Doppler) shift of the echo relative to the source is used to find the two- or three-dimensional velocity field in the vicinity of the flow meter. An electromagnetic flow meter generates an electromagnetic field that is distorted by a moving electrolyte. The Gurly-type flow meter employs rotating vanes that spin as the fluid moves past the device.

Tracers can also be used to measure water velocity. *Natural*, or *environmental*, tracers are ones that are already present within a system. For example, the presence of synthetic compounds that have been generated recently (e.g., chlorofluorocarbons, radionuclides from atomic testing) can be used to distinguish between older and newer waters in the subsurface. Also, radiocarbon (^{14}C) dating can be used to determine the time since groundwater was recharged.

Introduced tracers are added intentionally for the purpose of determining travel times and velocities. In this case, care must be taken that the tracer does not cause environmental harm. Ideally, the tracer should be conservative, for example, it does not decay or sorb along the way. Examples include dissolved noble gasses (e.g., helium, argon, krypton) and fluorobenzoic acids. Tracers can be added as a single spike or at a constant rate over a longer period of time. They can also be added at a point, along a line, or over an area.

In surface water, the total flow, Q , is found by multiplying the flow velocity, v , by the cross-sectional area perpendicular to flow, A ($Q = vA$), or if the total flow and area are known, then $v = Q/A$. Alternatively, the velocity can be found using the time of travel, τ , of a tracer along a travel path of length L ($v = L/\tau$), which leads to $Q = V/\tau$, where $V = AL$ is the total volume of water moving along the travel path.

Within the subsurface, the *Darcian velocity* or *flux*, q , is used to characterize the volumetric flow rate, that is, $q = Q/A$, where Q is the total rate and A is the cross-sectional area normal to flow. The fluid velocity can be determined by dividing the flux by the porosity, n ($v = q/n$). Note that the flux only equals the velocity when a unit porosity is present. The flux can be difficult to measure directly, so *Darcy's Law* ($\mathbf{q} = -K\nabla h$) is commonly used to infer the flux using the hydraulic conductivity, K , and the hydraulic gradient, ∇h , where h is the hydraulic head.

A third type of velocity is the *celerity*, *kinematic*, or *wave velocity*, c , which is used to describe dynamic changes in stage or head. The celerity can be found either by observing the time of arrival, τ , of flood peaks across a distance, L ($c = L/\tau$), or estimated using $c = dQ/dA$, which is the marginal change in discharge, dQ , per unit change in cross-sectional area, dA .

6.1.3 Water Budget

The *water budget* is an accounting of the stores and flows of water in a hydrologic system, and provides an overview of the important elements of the hydrologic system

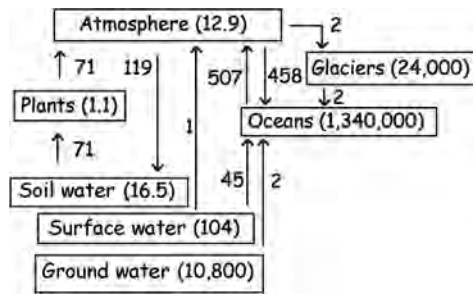

FIGURE 6.1 Annual global hydrologic budget. Volumes in PL. Flows in PL/year (1 PL = 10¹⁵L).

being studied. The budget is used to account for quantities of water in storage, as well as the movement of water between storage elements. As such, it can become the organizing tool for guiding hydrologic investigations.

For example, Figure 6.1 shows a global water budget that quantifies the volume of water in various global storages. Note that the oceans dominate the total inventory, followed by glaciers, and then groundwater. Also note the rate of flow between the storage elements. The water budget for a specific study area will likely be unique, and understanding the volumes and exchanges between elements helps to understand the hydrologic behavior of the study area.

The water budget can also be used to show changes in storage over time within storage elements. For dynamic systems, changes in storage are found using $\Delta S/\Delta t = I - O$, where $\Delta S/\Delta t$ is the change in storage per unit time, and I and O are the inflows and outflows to a storage element, respectively. These quantities can be expressed either as a volume, V , or as a depth, D ($D = V/A$), where A is the catchment area.

While simple in concept, accounting for the spatial and temporal complexity of water storage and movement in natural systems requires that careful attention be paid to monitoring design. Figure 6.2 illustrates a simplified conceptualization of hydrologic monitoring components, which are more fully discussed in subsequent sections.

Note that the conceptual model can be organized in different ways. For example, atmospheric exchanges of water can be divided into precipitation inputs and evapotranspiration outputs. Interactions within the subsurface can also be lumped or divided into various

FIGURE 6.2 Simplified conceptual model of hydrologic system showing water storage elements and exchanges between elements.

regions (e.g., soil water, shallow groundwater). And the surface water can be divided into overland, channel, and water bodies (e.g., wetlands, lakes, reservoirs).

6.1.4 Residence Time

Another useful tool for organizing data collection efforts is the definition of the water *residence time*, which is the average length of time water spends in each reservoir. Many chemical and biological conditions are influenced by the residence time, and many of the measurements described in the following sections are used to quantify this attribute of the hydrologic system.

The concept of the residence time is relatively simple; a small reservoir with a large flow through it has a shorter residence time than a large reservoir with small flows. The mean residence time, τ , is calculated by dividing the storage volume, V , by the average flow rate, Q ($\tau = V/Q$). Another means for calculating the residence time in a flowing system (such as a river) is to use $\tau = L/v$, where L is the distance between two points and v is the fluid velocity.

Although a system with stable flow rates and volumes has a constant residence time, this would not be true if flows change rapidly with time. In this case, the average residence time can be dynamically updated using $\tau(t) = \Delta t + \alpha \tau(t - \Delta t)$, where $\tau(t - \Delta t)$ was the mean residence time during the previous time, Δt is the time interval, $\alpha = 1 - \Delta V/V$ is the fraction of “old” water carried over from one time step to the next, and where $\Delta V = Q(t) \Delta t$ is the volume of “new” water entering the system.

6.2 PRECIPITATION

Atmospheric precipitation is the primary input to hydrologic systems, and can occur as rain, snow, sleet, or hail. Precipitation often varies rapidly in both space and time and is a challenge to measure accurately over large areas, especially in mountainous regions where orographic conditions may influence accumulation. Precipitation is commonly measured using ground- and satellite-based systems.

6.2.1 Rain Gauges

A rain gauge is a standard method for collecting atmospheric precipitation. Rain gauges should be placed away from taller objects (e.g., trees, buildings) that might obstruct precipitation collection. Gauges should also be placed sufficiently high so that *ground splash* does not affect the reading. Locating the gauge near shrubbery, which attenuates wind near the gauge but does not obstruct the rain, should minimize wind effects.

Both manual (nonrecording) and automated (recording) rain gauges are available, the selection of which depends on the temporal frequency of required data. A *manual rain gauge* normally consists of a collection funnel that concentrates collected rainfall into a smaller, inner collection tube (Figure 6.3). The purpose of funneling water into the inner tube is to enhance the measurement resolution of the device. When the capacity of the inner tube is exceeded, the excess rainfall overflows into a larger diameter, outer collection tube. The depth of rainfall is determined by measuring the depth of rainfall collected within the inner tube, as well as the excess in the outer tube, if present. The excess water

FIGURE 6.3 Manual rain gauge showing collection funnel, inner collection tube (1 in. capacity), outer collection tube (10 in. capacity), and mounting post. Credit: www.agry.purdue.edu/turf/tips/2006/raingauge.jpg

in the outer tube is measured by pouring it into the inner tube at the time of measurement. Manual rain gages are commonly read on a daily basis.

Automated rain gauges typically use a funnel to route precipitation to a pair of tipping buckets that alternately collect increments of precipitation (Figure 6.4). An electronic signal is generated for each bucket tip (generally every 0.2 mm or 0.01 in.). Depending on the recording device used, the recorded data could consist of either the total number of bucket tips over a specified time increment (e.g., every 5 min) or the time of each tip.

6.2.2 Snow Accumulation

Frozen precipitation (e.g., snow, sleet, freezing rain) is more difficult to monitor using rain gauges, both because of wind blowing snow past the gauge as well as the accumulation of frozen precipitation within the funnel. While a *wind shield* can be placed around the gauge to minimize blowing snow, and a *heating element* can be used to melt frozen precipitation, these methods are still prone to error.

FIGURE 6.4 Automated rain gauge showing tipping bucket used to measure precipitation increments.

Alternatively, the amount of snow on an exposed horizontal surface can be recorded. The *snow water equivalent*, D_{sw} , can be directly measured using *snow pillows* that measure the weight of snow that accumulates over time. A snow pillow consists of an inflated chamber, the pressure within being directly related to the weight of the overlying snow.

For cases where only the snow depth, D_s , is known, a core sample should be collected to determine the *snow density*, ρ_s . The density is determined by weighing the mass of

snow collected within a core barrel of known volume. The snow water equivalent is then found using $D_{\text{sw}} = \rho_s D_s$. While the snow water equivalent is useful for predicting the potential runoff volume, it does not directly provide a measure of the likelihood for snow-melt. The *snow cold content*, E_s , is the energy required to raise the snow temperature to 0°C , $E_s = H_T T_s D_{\text{sw}}$, where H_T is the specific heat of ice ($0.5 \text{ cal/g}^\circ\text{C}$), and T_s is the snow temperature below freezing. The snow temperature can be measured manually or using automated techniques.

6.2.3 Remote Sensing

Remotely sensed precipitation estimates are also available, including ground and satellite sources. Remote sensing uses active (e.g., radar) or passive microwave signals to determine the atmospheric density of precipitation. The Tropical Rainfall Monitoring Mission³ is a satellite-based platform that provides both active and passive estimates of precipitation between the latitudes of $\pm 50^\circ$. Ground-based radar sources are also available in many countries (e.g., NEXRAD). The advantage of these estimates is that they can provide improved spatial and temporal resolution over large areas, but may be less accurate in mountainous terrain.

6.3 EVAPOTRANSPIRATION

Evapotranspiration describes the process of water movement from the surface to the atmosphere. *Evaporation* is an abiotic process that accounts for water loss from the water surfaces (e.g., lakes, ponds) and from unvegetated soil or paved surfaces. *Transpiration* consists of water loss from plant surfaces, either from intercepted precipitation on plant surfaces or from the translocation of subsurface water through the roots, stems, and leaves of the vegetation.

Measuring and estimating evapotranspiration is difficult, and indirect methods are commonly used. That is, variables other than evapotranspiration are measured and used to make inferences about evapotranspiration. While direct estimates of evapotranspiration are preferred for different kinds of crops, forests, and soils, this is often expensive and time-consuming.

When characterizing evapotranspiration, it is important to distinguish between the *potential evapotranspiration* (PET) and the *actual evapotranspiration* (AET). PET is the maximum possible transpiration by plants with unlimited soil moisture. For a given plant community, PET is determined by climatic variables such as temperature, solar radiation, humidity, and wind speed. Because water is often limiting, AET is a better estimate of water loss to the atmosphere. AET depends on PET, as well as soil moisture conditions and the type of crop (or vegetation) and its stage of growth. Estimating AET on a daily basis is useful for determining crop irrigation needs.

6.3.1 Pan Evaporation

Pan evaporation is considered to be the simplest way to estimate PET. The *Class A evaporation pan* has a cylindrical shape with a diameter of 120.7 cm and is filled with water to a

³ TRMM, <http://trmm.gsfc.nasa.gov/>

FIGURE 6.5 Class A evaporation pan showing animal exclusion cage, anemometer for wind speed determination, and water level measurement device. Credit: http://upload.wikimedia.org/wikipedia/commons/e/e5/Evaporation_Pan.jpg

depth of 25 cm (Figure 6.5). The pan is placed on a level (wooden) base and should be enclosed to prevent water loss from animals such as livestock, birds, and bats. Control of debris, mosquitos, and algae within the pan is also important. Water loss due to evaporation, E_p , is expressed as a change in water depth each day, $E_p = dh/dt$. Measurements are not possible when the water surface is frozen or when large precipitation events overtop the pan.

An empirical *pan coefficient* is commonly employed to determine lake evaporation as well as AET. In these applications, the lake evaporation or AET is found as the product of the pan coefficient, C_p , and the pan evaporation rate, $AET = C_p E_p$.

6.3.2 Watershed Studies

A common procedure for determining AET over large areas uses a *water balance equation*, $AET = P - Q - \Delta S/\Delta t$, where P is the measured average precipitation over the

FIGURE 6.6 Weighing lysimeter showing the plant-containing soil monolith, load cell, water drainage through monolith, and overland flow from monolith.

watershed, Q is the measured total discharge (surface and groundwater) from the watershed, and $\Delta S/\Delta t$ is the change in water storage within the watershed. Note that measurement errors directly affect the AET estimate, so that precision is essential in the determination of the water balance components.

6.3.3 Weighing Lysimeters

Direct measurements of AET for specific crops over time can be obtained using *weighing lysimeters*, which are large soil monoliths that are placed on top of load cells (Figure 6.6). Weighing lysimeters are expensive but provide accurate, time-varying estimates of evapotranspiration. Daily changes in load are used to account for water loss from the soil monolith during the life cycle of the crop. AET is determined using the water balance equation, except that P is the sum of precipitation and irrigation inputs, Q is the sum of overland flow and deep seepage out of the lysimeter, and $\Delta S/\Delta t$ is found using the change in load (mass) of the lysimeter.

A novel approach for determining landscape-scale evapotranspiration uses groundwater levels in monitoring wells to record changes in soil moisture content. This approach, termed a *geological weighing lysimeter*, relies on fluid pressures within isolated geologic units in place of the traditional load cell. This technique has been demonstrated in a large number of regions around the world, but requires a suitable geologic unit.

6.3.4 Enclosures

Another method for determining evapotranspiration uses gas flux measurements from enclosed crops. A transparent tent is placed over the target vegetation, and air is blown

FIGURE 6.7 Eddy covariance station used to measure turbulent gas (e.g., water vapor) movement within the atmospheric boundary layer. Credit: www.campbellsci.com/news-2010-q3/ec150-ec155

through the tent. Evapotranspiration is determined by measuring the humidity and flow rate of the incoming and outgoing air. Care must be taken, however, to ensure that temperatures and gas concentrations within the enclosure are consistent with outdoor conditions.

6.3.5 Eddy Covariance

The eddy covariance technique measures vertical turbulent fluxes within the atmospheric boundary layer to find the water loss to the atmosphere (Figure 6.7). An added benefit is the ability to determine other gaseous exchanges, such as CO_2 and CH_4 . The method requires a large, horizontal, homogenous expanse of vegetation to ensure uniform conditions over the area.

6.3.6 Indirect Approaches

The *Penman–Monteith* equation estimates evapotranspiration using daily mean temperature, relative humidity, wind speed, and solar radiation. The *Blaney–Criddle* method is an alternative method that only requires air temperature at a site and is more commonly used in the western United States, where relative humidity is frequently low. For both methods, soil moisture availability and crop stage are additional factors that must be considered when trying to estimate AET.

6.3.7 Remote Sensing

Remote sensing of evapotranspiration losses is also possible using an *energy budget*. In this method, the incoming short-wave energy from the sun is offset by short-wave reflection, long-wave emission, surface conduction, and latent heat losses from evapotranspiration. Both short-wave and long-wave components can be monitored remotely, and surface conduction can be estimated, leaving the evapotranspiration loss as the residual: $\text{ET} = (\text{SW} + \text{LW} + G)/\delta$, where ET is the estimated evapotranspiration rate, SW is the net incoming short-wave radiation, LW is the net incoming long-wave radiation, G is the net transfer of sensible heat from the subsurface to the ground surface, and δ is the latent heat of evaporation.

6.4 SURFACE FLOW

Surface flow consists of *overland flow* (e.g., flow across the ground surface that is not contained in a channel, including *sheet*, *rill*, and *gully* flow, Figure 6.8), *lotic* flow (e.g., fast moving water in defined channels), and *lentic* flow (e.g., slow flow in wetlands, lakes, and reservoirs).

Quantifying overland flow can be challenging due to its disseminated and ephemeral nature. Berms can be used to intercept overland flow, concentrating and routing it to a control structure (described below). Water within a defined channel is often easier to measure because it is more concentrated, although shallow, braided channels can be challenging. Measuring flows in lentic systems can also be challenging because internal circulation is slow and varies with depth and location.

6.4.1 Topographic and Bathymetric Maps

Topographic maps provide detailed geomorphic information (e.g., slope, aspect) about elevations within the system. Features such as stream channels, wetlands, and lakes can be determined, as well as artificial structures such as reservoirs, highways, and developed areas. These maps provide a starting point for determining the size and nature of the watershed contributing to surface water flow.

While published maps and Digital Elevation Models are available for most areas, more detailed maps may be required for some purposes. In these cases, *photogrammetric* and *LIDAR* tools can be used to develop high-resolution topographic maps.

Bathymetric maps display the topography of the bed of large water bodies, such as a wetland, lake, or reservoir. In these systems, lines of equal elevation are used to show the bottom contours. The bathymetric map can be used to determine the relationship between

FIGURE 6.8 Overland flow showing sheet (or saturation-excess) flow, as well as concentrated flow in rills and gullies.

the elevation, area, and volume of water of the system. Estimation of the area within each contour interval, A , provides a starting point for estimating the water storage volume, V , by integration: $V = \int A(z) dz \approx \sum A_i \Delta z$, where z is the elevation. The summation provides a useful approximation for small changes in elevation, Δz .

Depth profilers using *echo-sounders* (sonar) with concomitant *Global Positioning System* locations can be used to map the shape of the feature. For wadeable systems, survey transects can be run across the feature to generate a profile which can be interpolated to create the bathymetric map. The bathymetry of an artificial reservoir can also be taken from topographic surveys created before the feature was filled. Changes in bathymetry over time may occur due to sediment accumulation or dredging.

6.4.2 Control Structures

Engineered structures often provide the most accurate method for determining flow rates. This is because a simple geometry and known flow hydraulics can be imposed that reduces uncertainties in the flow measurement. One simple control structure would be an empty container (e.g., barrel, reservoir) that is filled over time. The flow rate into the container, Q , would be $Q = A \Delta h / \Delta t$, where A is the cross-sectional area of the container, and $\Delta h / \Delta t$ is the rate of change of water level over time in the container.

Another type of control structure is the *weir* that consists of an upstream ponding basin and a weir blade (Figure 6.9). Discharge from the weir is directly related to the stage in the weir basin. The weir *bulkhead* (or dam) is constructed using a concrete, timber, or metal structure. A weir *notch* is placed in the bulkhead to allow water to pass. The weir *crest* is the edge or surface over which the discharged water flows. Types of outlets include triangular (or v-notch), rectangular, and trapezoidal (or cipolletti). A *nappe* forms as water spills over the crest. The nappe can be classified as either *submerged* or *free*. A submerged nappe forms when the crest is flooded, whereas a free nappe forms when the water discharges freely into air.

A *sharp-crested* weir is constructed so that the flowing water passes over a vertical, knife-edge blade. This design minimizes friction across the weir blade and provides the greatest accuracy. A *broad-crested* weir consists of a crest across which water flows for

FIGURE 6.9 General components of a weir.

FIGURE 6.10 General components of a Parshall flume.

some distance before falling over the downstream edge. Spillways of dams are often constructed in the shape of a broad-crested weir.

Weirs may not provide accurate estimates when the weir blade becomes blocked by ice or floating debris, such as leaves and branches. Another source of error arises when the weir basin fills with sediments.

Flumes are another type of device for estimating discharge. Flumes require no upstream stilling pond and allow sediment to pass unimpaired through the structure. Ice, leaves, and other debris may still affect readings if they block the flume outlet. *H-type* flumes developed by the U.S. Department of Agriculture are useful for measuring discharge in sediment-laden streams. A small drop is required downstream of H-type flumes, which can be difficult to achieve in level channels. Another popular flume design is the *Parshall* flume, which uses a constriction in the width and depth of the channel (Figure 6.10). No drop is needed downstream of the structure, allowing its use in level channels.

Rather than having to construct a control structure, a *culvert* may already exist to route water under roads. Culverts are often round or rectangular, providing a regular section for measuring discharge. There are four combinations of two general conditions, upstream flooded (or open) and downstream flooded (or open).

The simplest flow condition occurs when both the upstream and downstream conditions are flooded. These are fully submerged conditions that are consistent with flow through a pipe. In this case, the velocity is estimated using the difference in elevation between the upstream and downstream water levels, along with the culvert length, roughness, and diameter. When both the upstream and downstream conditions are open, then channel flow conditions exist. In this case, the discharge can be determined using Manning's equation (described below). Necessary information includes the culvert roughness, hydraulic radius, and slope. The accuracy of this approach is degraded by debris or other obstructions within the culvert.

6.4.3 Rating Curves

Rating curves—also called a *stage–discharge relationship*—are used to relate river *stage* to *discharge* so that measurements of water levels can be used to estimate stream discharge. Creating the rating curve requires that periodic measurements of stream discharge be obtained, and related to the river stage at the time of measurement. Sufficient flow measurements over a range of stages (low, medium, and high) should be collected so that the full range of anticipated discharges can be predicted. Also, repetitive measurements should be collected to ensure that channel flow conditions do not change over time due to scouring or sedimentation within the channel.

Stream discharge can be determined using field measurements of water velocity within the channel. The water velocity is usually not constant in a channel, with the maximum velocity commonly occurring at or near the surface in the middle of the channel, with slower velocities near the bottom and along the banks of the channel. The actual distribution of channel velocities can vary greatly, however, due to bends in the river or obstructions such as woody debris or rocks.

Because water velocity can be highly variable within a channel, multiple measurements of water velocity are needed at different points within the channel. The stream discharge, Q , is calculated using the sum of discharges within specific sections within the channel, $Q = \sum_{i=1}^n Q_i$, where $Q_i = v_i A_i$ is the flow in each section, v_i is the water velocity in each section, and A_i is the channel section cross-sectional area. To reduce measurement error, an ideal channel section should be straight, with few obstructions, and with uniform depth and velocity. A minimum of 10 subsections is then used to estimate the total flow, with approximately equal flows in each subsection, if possible. That is, faster, deeper parts of the channel should have more measurements than shallow, calm sections.

Rather than collecting field measurements of water velocities, *Manning's equation* provides an empirical relationship to estimate the mean channel water velocity for conditions where engineered structures and flow measurements are not available, $v = (\alpha/n)R^{2/3}S^{1/2}$, where v is the average channel velocity, $\alpha = 1$ in metric units and 1.49 in English units, n is the *Manning roughness coefficient*, which increases with increasing channel roughness, $R = A/P$ is the *hydraulic radius*, equal to the ratio of the channel cross-sectional area, A , to the channel *wetted perimeter*, P , and S is the *energy gradient*. The total stream discharge is found using $Q = vA$. The energy gradient can be approximated using the regional channel slope (taken from topographic maps). The hydraulic radius can be approximated for a wide, shallow stream using the channel depth.

6.5 GROUNDWATER

Groundwater traditionally refers to subsurface water located in saturated geologic materials. The upper boundary of the saturated zone lies at or near the *water table*, which is the elevation of water in a well tapping the uppermost part of the saturated zone.

The saturated zone may extend above the water table due to *capillary rise* in small pores. The capillary rise is caused by *surface tension forces*, consisting of both *cohesive forces* between water molecules and *adhesive forces* between the water and mineral surfaces. The zone of saturation above the water table is called the *capillary fringe*.

FIGURE 6.11 Subsurface hydrology showing unconfined (surficial) and confined aquifers.

6.5.1 Types of Aquifers

Aquifers are defined as geologic units that transmit useful quantities of water to wells. An *unconfined aquifer* refers to an aquifer bounded above by the water table and is the uppermost aquifer if more than one aquifer is present. Contour lines of water table elevations can be drawn just like topographic contours.

In some geologic regions, multiple aquifers may be present, with layers of lower permeability separating each of the aquifers (Figure 6.11). The lower aquifers are referred to as *confined aquifers*. A *confining layer* (or *aquitard*) of lower permeability separates confined aquifers from overlying aquifers.

Water levels in confined aquifers do not correspond to the water table; instead, they are termed *piezometric surfaces*. This is because water levels in these wells rise above the top of the aquifer. *Flowing* or *artesian* wells occur when the piezometric surface is higher than the ground surface. Contour lines of equal water-level elevations, called *equipotentials*, can be drawn for each aquifer. Figure 6.12 illustrates how *piezometers* (small-diameter wells

FIGURE 6.12 Piezometers can be installed in different soil horizons to monitor the vertical change in hydraulic head at a site.

used for monitoring water levels) can be installed at different depths for the purpose of monitoring the vertical distribution of hydraulic head within a profile.

Drilling logs and *borehole surveys* can be used to determine the locations of aquifers and confining layers. In fractured rock, *drill cores* or *downhole telev viewers* can be used to identify water-yielding intervals. Water quality measurements can also be used to identify different hydrogeologic units.

6.5.2 Hydraulic Properties

Pores, or *voids*, within the saturated zone are entirely filled with water. The volume of water per unit volume of solids is referred to as the *porosity*, n . The porosity of geologic materials can be found by extracting samples of the media, making sure that they are fully saturated, and then measuring the water lost by drying in an oven. The volume of water lost per unit volume of sample is their porosity.

The ability of geologic materials to conduct water is called the *hydraulic conductivity*, K . A similar term is the *permeability*, k , which is a more general term that can be used for determining the movement of any fluid. The relationship between the two is found using $K = (\gamma/\mu)k$, where γ is the *specific weight* of the fluid used to measure the fluid pressure, and μ is the *dynamic viscosity* of the moving fluid. For a system in which freshwater is used to measure both the oil and water pressure, then the ratio of conductivities is equal to the ratio of their viscosities; the permeability is approximately the same for both.

The source of water pumped from an unconfined aquifer is water draining from pores as the water table falls. In this case, not all of the water drains because of water held by capillary forces within the capillary fringe. The volume of water drained per unit area of aquifer per unit decline of water table is called the *specific yield*, S_y , of the aquifer and is usually less than the porosity, $S_y < n$.

Water does not drain from a confined aquifer as the piezometric surface is lowered because the air–water interface is higher than the top of the aquifer. In this case, the water source is the slight expansion of water due to the small compressibility of water and the aquifer itself. The *specific storage*, S_s , is used to describe the water released from a confined aquifer.

Two additional hydraulic parameters are used for confined aquifers, the *transmissivity*, T , and *storativity*, S . The transmissivity is the product of the *aquifer thickness*, b , and the hydraulic conductivity of the aquifer, $T = bK$. Similarly, the storativity is the product of the thickness and the specific storage, $S = bS_s$. Like the specific yield, the storativity represents the volume of water drained per unit area of aquifer per unit decline in water level, but is much smaller, $S_y \gg S$.

Vertical flow between aquifers through the confining layer is termed *leakage*. The *hydraulic conductance*, $C = K'/b'$, is used to account for this leakage and is a function of the hydraulic conductivity of the confining layer, K' , and the thickness of the layer, b' .

Slug tests are commonly used to determine the hydraulic conductivity by rapidly adding or removing a known volume of water (or slug) and noting the resulting change in water level over time. The advantage of this test is that only a single borehole is required, yet the hydraulic properties are generally biased toward those in the vicinity of the borehole and may not accurately represent regional behavior.

Aquifer hydraulic properties are best estimated using *aquifer tests*. A well is pumped at a constant rate and nearby *observation wells* are monitored for their *drawdown*, which is the decline in water levels as a cone of depression forms around the pumping well.

Required data include the pumping rate, Q ; the distance from the pumping well, r ; and the drawdown record as a function of time, $s(t)$. These data are interpreted using graphical or computer techniques to determine the aquifer hydraulic properties. If drawdown data are collected with sufficient frequency, then the time rate of change of drawdowns can be determined, ds/dt , and analyzed using *derivative curve techniques*.

Alternatively, *periodic* (or *sinusoidal*) aquifer tests can also be used to determine aquifer hydraulic properties. In this approach, a periodic pumping rate is used in conjunction with the observed responses in observation wells to determine the lag and attenuation of the pumping signal. These values are then used to infer hydraulic properties. The primary advantages of the periodic approach are the minimization of formation water removed (which may be contaminated and require expensive treatment), as well as the minimization of background interference from regional disturbances.

6.5.3 Flow and Transport

The *hydraulic head*, h , is a variable used to determine the magnitude and direction of water flow in the subsurface; water moves from high to low head. For example, water moves from zones with high water tables in an unconfined aquifer toward lower areas. If a stream is lower in elevation than the surrounding water table, then water is moving from the aquifer toward the stream. In a confined aquifer, water also moves from higher to lower head. And water moves between aquifers across the confining layer in the direction of higher to lower head.

Monitoring regional hydraulic heads require a sufficiently dense network of monitoring wells to account for natural heterogeneities in aquifer properties as well as variations in aquifer recharge, discharge, and pumping. Corrections to hydraulic head due to barometric and tidal influences are also needed.

The magnitude of water movement is a function of the *hydraulic gradient*, ∇h , or the change in hydraulic head with distance, $\nabla h = [\partial h/\partial x, \partial h/\partial y, \partial h/\partial z]$ in three dimensions, or $\nabla h = dh/dx$ in one dimension. To simplify the analysis of groundwater flow, vertical flow within an aquifer is often ignored, as is horizontal flow within a confining layer.

The hydraulic gradient between two wells, $\nabla h = \Delta h/\Delta x$, is found by taking the difference in water surface elevation between the two wells, Δh , divided by the distance between the two, Δx . Water levels in four different wells are the minimum required to find the three-dimensional hydraulic gradient *vector*.

The water *flux*, or *darciian flux*, is the rate of water movement and is governed by *Darcy's law*: $q = -K\nabla h$. Note that K incorporates the fluid and geologic properties, whereas ∇h incorporates the driving force. The equation contains a minus sign because flow is in the opposite direction of the hydraulic gradient.

Anisotropy refers to geologic media that have greater hydraulic conductivity in one direction than another. In this case, the hydraulic conductivity must be treated as a *tensor* rather than a *scalar*.

A general conservation equation can be written for groundwater flow, $K [\partial^2 h/\partial x^2 + \partial^2 h/\partial y^2 + \partial^2 h/\partial z^2] = S_y \partial h/\partial t$, for unconfined aquifers, and $T [\partial^2 h/\partial x^2 + \partial^2 h/\partial y^2] = S \partial h/\partial t$ for confined aquifers without leakage.

These equations are used in computer models to predict the water table and piezometric surface in areas where field observations are lacking, or for evaluating alternative management strategies. Calibration of these models to field data is a critical part of the modeling effort and is complicated by unknown variations in subsurface properties

(e.g., faults, fractures), as well as limited understanding of discharge and recharge behavior. Field-testing strategies to reduce these uncertainties should be an integral part of evaluating model performance.

The pore-water velocity, v , is of interest when examining transport of pollutants. Unlike in surface water, the water velocity is not the same as the water flux. This is because the porosity affects the water velocity by limiting the cross-sectional area available for flow. That is, water flowing through a medium with higher porosity moves slower than the same amount of water flowing through lower porosity.

As noted previously, the water velocity is equal to the darcian flux, q , divided by the porosity, n , $v = q/n$. (Note that the two velocities are equal when the porosity equals one.) Field-testing strategies to determine aquifer porosity usually relies on core samples, or on cross-hole tracer tests. In general, however, preferential flow that bypasses the bulk of the porosity leads to more rapid migration of tracers and pollutants. The *effective porosity*, n_e , is a measure of the voids that dominate fluid flow and is less than the bulk porosity, $n_e < n$. Environmental tracers that have migrated over longer distances and time are likely to be better indicators of preferential flow patterns than artificial tracer tests conducted over shorter distances and time.

6.6 SOIL WATER

Between the ground surface and the saturated zone lies a region of partially saturated geologic media, which is called the *unsaturated* or *vadose zone* (Figure 6.13). This region

FIGURE 6.13 Subsurface hydrology showing unsaturated (vadose) zone.

contains *soil water*, which is bound by capillary forces to soil surfaces. Many pores contain air because they are not fully saturated with water.

6.6.1 Infiltration

Soils naturally absorb precipitation as long as their saturation and permeability are not limiting. One goal of soil management is to determine the maximum rate of soil infiltration over time and to find ways to increase and maintain this rate. Typically, the maximum rate of water uptake occurs at the beginning of a precipitation (or irrigation) event, and declines over time. This occurs because the hydraulic gradient that drives water flow decreases over time as the soil becomes saturated.

Field measurements of infiltration rates can be used to provide estimates of soil hydraulic properties, especially the saturated and unsaturated hydraulic conductivities and diffusivity. Two types of methods are commonly used to determine infiltration rates, *infiltrimeters* (also called *permeameters*) and *rainfall simulators*. Infiltrimeters are surface or borehole tools that apply water at the soil surface, much like the way surface irrigation might occur. Rainfall simulators generate water droplets that mimic natural rainfall conditions, and better reproduce the effects of raindrop impact on the soil surface.

The *double-ring infiltrimeter* is a simple method for determining soil infiltration rates for surface-saturated conditions (Figure 6.14). The purpose of the outer ring is to ensure that vertical water movement into the inner ring is maintained. Two methods are used to determine the water infiltration rate. For the *falling-head method*, the rate of water-level decline in the inner ring is used. For the *constant-head method*, water is added to maintain a uniform level in both rings, and the amount of water required to maintain the inner ring is measured. The constant-head method yields a higher infiltration rate than the falling-head method. One property of the double-ring method is that the water depth is greater than would occur during most rainfall events, but may be consistent with conditions during flood or furrow irrigation.

FIGURE 6.14 Double-ring infiltrimeter used to measure the maximum rate of water infiltration in soils. Water levels in both inner and outer rings are maintained at constant levels. Flow into soil from outer ring is divergent, and not measured. Flow into the soil through the inner ring is measured and is assumed vertical.

Alternatively, a *disk permeameter* can be employed to maintain a more stable and natural hydraulic potential at the soil surface. Both small positive and negative potentials can be maintained to ensure that infiltration curves more closely resemble those anticipated under natural rainfall conditions.

The *borehole permeameter* is useful for determining water movement from shallow boreholes into unsaturated soils. Rather than examining vertical infiltration from surface applications, this method relies on the infiltration through the borehole walls, which is primarily horizontal near the walls. Care must be taken, however, to remove any smearing of clays that may form on the borehole wall during its installation.

Infiltrimeters and permeameters do not account for surface disturbances associated with raindrop impact. During a rainstorm, the kinetic energy of falling raindrops can disturb the soil surface, resulting in clogging of pores, and an associated decrease in the rate of infiltration.

Rainfall simulators are commonly used to generate water droplets to simulate natural rainfall conditions. The simulator consists of a sprinkler head that sprays water over an area with a well-defined drop size and energy content. The infiltration rate is found by subtracting the measured runoff from the application rate.

6.6.2 Percolation

Although infiltration refers to the movement of water into soil across the soil surface, *percolation* refers to the movement throughout the unsaturated zone. Water can be removed from the soil surface by evaporation, and from deeper in the soil column by plant root uptake for transpiration. Water that moves downward past the root zone is termed *deep percolation*. Deep percolation continues to move downward until it reaches the saturated zone, where it contributes to groundwater *recharge*.

Percolation rates can be measured by installing *horizontal collection pans* that intercept percolating water as it moves downward. The rate can also be estimated by measuring the soil-water content using *time domain reflectometers* or the matric tension using *tensiometers* or *psychrometers*, and then using these observations to estimate the unsaturated hydraulic conductivity, $K(\psi)$, where ψ is the *matric tension*, or negative pressure head. The unsaturated hydraulic conductivity is independently determined from laboratory or field measurements. The flow rate is determined by assuming a unit vertical hydraulic gradient, $dh/dz = 1$, so that $q = K(\psi)$.

6.6.3 Hydraulic Properties

The *water content*, θ , is the volume of water per unit volume of soil and is less than or equal to the porosity, $n \geq \theta \geq 0$. The *relative saturation*, Θ , is the ratio of the soil water content to the porosity, $\Theta = \theta/n$, so that $1 \geq \Theta \geq 0$.

The *matric* or *soil-water tension*, ψ , is a measure of the force which binds water to the soil surface. Water films near the mineral surface are bound more tightly than water at a greater distance. For example, the height of fluid rise in a capillary tube is greater in smaller diameter tubes, $\psi = (2\sigma \cos\alpha)/r$, where σ is the solid-liquid-air interfacial (surface) tension, α is the solid-liquid contact angle, and r is the pore radius. As a result, the matric tension decreases as larger pores are filled with water.

The relationship between the soil-water content and the matric tension is described using the soil-water *retention* or *characteristic curve*, $\theta(\psi)$. Certain tensions are especially important and are referred to as

Saturation (SAT): The water content when the pores are entirely filled with water. Saturation corresponds to matric potentials of zero (or at positive pressures). At saturation, the volumetric water content equals the porosity. The saturated water content is determined by oven drying the sample and finding the weight gain after immersion.

Field Capacity (FC): The water content held after rapid gravitational drainage has occurred, corresponding to matric tensions between 100 and 333 mbar.

Wilting Point (WP): The amount of water held when plant roots can no longer extract water from the soil. This tension is commonly assumed to be 15 bars.

Air Dry (AD): The amount of water held by soil when it is exposed to the atmosphere, a function of the relative humidity (moist air causes soils to be wetter than soils left in dry air).

Oven Dry (OD): The matric tension that corresponds to a soil that has been in an oven until the weight stabilizes, assumed to be approximately 10 kbar.

Plant Available Water (AW): The difference between the field capacity and the wilting point, $AW = FC - WP$.

Each soil has to be characterized to define its characteristic curve due to unique variations in pore and particle size distributions. The curve can be determined using *porous plates*, *psychrometry*, *hanging columns*, or *centrifuge methods*.

A prominent feature of these curves is their *hysteresis*, that is, wetting curves have a different shape than drying curves. This leads to *scanning curves* that trace the water saturation as the matric tension is reversed.

The *unsaturated hydraulic conductivity*, $K(\psi)$, is a measure of the ability of water to move through unsaturated soils held at a constant saturation. Wet soils display a higher $K(\psi)$ than dry soils because more of the pores are filled with water and contribute to fluid flow. The *relative conductivity*, K_r , is defined using $K_r = K(\psi)/K$, so that $1 \geq K_r \geq 0$ where $K_r = 1$ for fully saturated conditions ($\psi = 0$). The relationship between K_r and matric potential, ψ , is called the *relative permeability curve* and can be determined using *Tempe cells*, *hanging columns*, or *centrifuge methods*.

The slope of the retention curve, $d\theta/d\psi$, is called the *specific water capacity curve*, C . This function is used to determine the *soil-water diffusivity*, $D(\psi) = K(\psi)/C(\psi)$, which is used to describe dynamic flow behavior in unsaturated soils. The diffusivity can be found using the same methods as used for determining the unsaturated conductivity.

6.7 WATER QUALITY

The need for water to sustain human and ecosystem health drives efforts to measure and understand water quality behavior in all aspects of hydrology, from atmospheric precipitation (e.g., acid rain), to surface water (e.g., fish health), groundwater (e.g., toxic chemicals), and soil water (e.g., organics and metals that might accumulate in crop tissue).

This section takes a broad view of water quality; one that focuses on the *physical*, *chemical*, and *biological* integrity of water resources. By integrity, we mean the suitability of the water for designated uses such as fishing, swimming, and water supply.

6.7.1 Physical

Physical water quality refers to the ability of the channel habitat to support native plants and animals. Most streams support natural riparian and hyporheic zones, floodplains, and riverine wetlands (Figure 6.15). These provide key feeding areas, refugia, and substrate for the entire life cycle of the resident aquatic species. Disruption of the habitat by dams, channeling, riparian encroachment, and loss of wetland habitat can alter the natural flow rhythms that support a healthy ecosystem (Figure 6.16).

The *channel structure* refers to the structural and hydraulic properties of the channel. For example, a *pool-and-riffle habitat* refers to an alternating sequence of calm, deep segments with fast, shallow segments. The *stream-bank condition* is another important feature, in that banks may collapse due to disturbance or excessive stream velocity, altering the natural refugia that stream banks provide. The amount and type of large woody debris and leaf litter are important attributes that favor specific ecologic communities. The natural sinuosity (or tortuosity) of a stream channel also affects channel hydraulics and bank condition. Characterizing the type of channel structure requires stream surveys that map the important channel components.

Benthic sediments affect not only hyporheic flows but also fish nesting behavior and plant establishment. Cobbles and gravels provide habitat for macroinvertebrates, while coarse sediments with few fines allow water to migrate through channel sediments, maintaining benthic oxygen concentrations, and moderating stream temperatures. Increasing fine sediments may adversely affect native biological productivity, and may favor the establishment of invasive species. Surveys of benthic sediments using *pebble counts* or *particle size distributions* can be used to characterize stream conditions.

FIGURE 6.15 Sandy Creek, a stream in good physical condition. Note natural riparian vegetation and stream substrate.

FIGURE 6.16 Tanyard Branch, a stream in poor physical condition. Note lack of riparian vegetation and artificial substrate.

Riparian zones and *wetlands* help to sequester upland sediment and nutrient inputs, and also moderate hydraulic disturbances such as droughts and floods. Riparian zones and forested wetlands also moderate stream temperatures by providing a canopy that buffers the daily and seasonal temperature cycles. Water temperatures can be measured manually using a thermometer, or using *thermistors* or *thermocouples* that provide electronic outputs.

6.7.2 Chemical

The chemical condition of water includes those dissolved and suspended components that favorably or adversely affect the integrity for designated uses. In many cases, the desirable conditions should mimic natural conditions, that is, the absence of synthetic chemicals, or within a normal range of natural concentrations.

Many of the chemical water quality measurements can be obtained manually in the field, using *peristaltic pumps* that collect *discrete* or *composite* water samples, or using sensors connected to display units (Figure 6.17) or *dataloggers* to control sensors that provide data. Other measurements must be performed using laboratory equipment.

Samples for laboratory analysis should be collected so that a good representation of hydrologic conditions is achieved. For example, the *DH-48 integrated sampler* is used for collecting surface water from across the full depth and width of a stream. Wells should be thoroughly purged using *bailers* or *peristaltic pumps* to ensure that fresh groundwater is sampled. *Soil suction samplers* are useful for extracting pore waters. Regardless of the method employed, standard methods for collecting data should be used.

pH is a measure of the proton, or *hydronium*, H_3O^+ , *activity*, or *concentration*. pH is commonly measured using a glass *ion selective electrode* or a *pH indicator* that changes color with pH. pH is related to the *alkalinity* and *acidity*. Alkalinity is determined for water samples with a pH greater than 4.5, whereas acidity is determined for samples less

FIGURE 6.17 Example of a portable water quality probe that monitors multiple water quality parameters, including temperature, specific conductance, pH, dissolved oxygen, turbidity, and water depth.

than 4.5. For alkalinity, acid is titrated with the water sample to lower the pH to 4.5, whereas a base is titrated to raise it to 4.5 for acidity. Acid mine drainage may have high acidities, whereas carbonate waters are likely to have high alkalinities.

Although plants manufacture their own oxygen through photosynthesis, respiration by aquatic animals requires sufficient oxygen in the water to maintain their metabolic processes. Oxygen dissolves in water in small amounts, on the order of 10 mg/L (ppm), but is a function of water temperature and atmospheric pressure. Colder water contains higher concentrations than warmer water, and water at higher elevations has lower concentrations than at sea level (when both are at the same temperature). Dissolved oxygen concentrations are measured using *membrane galvanic sensors* or *luminescent probes*.

Dissolved oxygen concentrations may fall to *anoxic* levels (<0.5 mg/L) if respiration rates are high, or in geologic conditions where reducing conditions dominate. In these cases, the *redox* or *oxidation–reduction potential* (ORP) can be monitored using an ORP probe, which can be combined with the pH sensor.

The *electrical conductivity* is a measure of the dissolved solids in solution. Increasing concentrations of dissolved solids leads to increasing conductivities. A common unit for conductivity is $\mu\text{S}/\text{cm}$ (S is Siemen, equivalent to the older unit, mho) and is also reported as *specific conductance* when the conductivity is temperature compensated. The conductivity probe consists of two electrodes a fixed distance apart. The probe is immersed in water, and the electric current and voltage are monitored between the electrodes. The conversion from specific conductance to dissolved solids concentration should be calibrated using the types of ions likely to be present in the water sample.

Turbidity is a measure of the clarity of water. Higher concentrations of *suspended* solids, and *dissolved* and *particulate* organic matter can increase the water turbidity. Turbidity is commonly measured using a portable *nephelometric turbidimeter*, which determines the amount of scattering from a light source. The amount of *filterable solids*

FIGURE 6.18 Example of a portable water-quality testing device for determining nutrient concentrations.

can be found by filtering the water samples through a fine medium. *Centrifuging* can also be used to concentrate the heavier solids from the water, and then oven dried to obtain the total solids. For deeper water bodies such as lakes and reservoirs, a *Secchi disk* can be lowered below the water surface. The depth at which the disk is no longer visible is called the *Secchi depth*.

Nutrients, primarily nitrogen and phosphorus, contribute to lake and estuary *eutrophication*. Multiple forms of these nutrients might be present, such as sorbed to sediments, as part of organic molecules (e.g., amino acids) both living and dead, and in multiple inorganic forms (especially for nitrogen, which could be found as nitrate, ammonium, and so on). Field estimation of nutrients using ion selective electrodes is possible, but *colorimetric* techniques (e.g., the Murphy–Riley technique for phosphorus) are likely to be more reliable (Figure 6.18). Laboratory estimates of nutrients also use colorimetry as well as *chromatography*.

Samples for *inorganic* (e.g., heavy metals) and *organic* (e.g., fuels, pesticides) analysis are normally collected in the field, stabilized, and promptly returned to a laboratory for further analysis. The use of special sampling techniques and equipment is critical for many constituents, especially for those at very low concentrations.

6.7.3 Biological

A wide range of organisms can survive in both the surface and subsurface environments. While most of these organisms are desirable, such as native fishes and plankton, others are not.

Water-borne pathogens and invasive species can be disruptive to humans and ecosystems. Microbial pathogens include viruses, bacteria, fungi, and protozoa. Sampling requires collection and laboratory culturing and analysis. Invasive species determination requires field surveys and traps to determine the presence or absence of the species.

FIGURE 6.19 Example of the use of biotic indicators with chemical water quality measurements.

Besides pathogens, other measures of stream health have been established that utilize an *index of biological integrity* (IBI), which is an effort to use aquatic surveys to determine the status of ecosystem health (Figure 6.19). Various indicators can be used, including algae, macroinvertebrates, and fish. These indicators are usually geographically specific and are commonly limited to specific times of the year when the target index is most effectively estimated. IBIs rely on the preference of some organisms for natural, or undisturbed, conditions, while other organisms are more tolerant of pollution and disturbance. The advantage of biological indicators over water chemistry lies in their long-term presence that reacts to occasional disturbances, which may not be observed using standard chemical sampling.

This chapter provides a broad perspective on emission testing of new and in-use vehicles, particularly in the United States. Under a mandate from the U.S. Congress, The U.S. Environmental Protection Agency (US EPA or EPA) sets emissions standards for vehicles. These standards mainly differ among engine and/or vehicle classes, year of manufacturing. Once EPA sets emission standards manufacturers are required to produce engines that meet those standards within a given timeframe of the corresponding implementation schedule.

The Clean Air Act (CAA) requires every engine and motor vehicle within the chain of commerce in the United States to meet a set of emission standards and conformity requirements. Anyone wishing to sell an engine or vehicle within the United States must demonstrate compliance with the CAA and all applicable EPA regulations. Upon adequate representation of conformity by the manufacturer and possibly confirmatory testing by EPA, EPA may issue a certificate of conformity that provides authorization for production and sales within the United States (CA-ARB, 2002).

The certification process begins when a manufacturer submits an application for certification to EPA for a group of vehicles or engines having similar design and emission characteristics. EPA requires manufacturers to provide detailed information to show that they have met all of the applicable requirements to qualify for the certificate of conformity. The application for certification describes those vehicles or engines

specifically covered by the certificate of conformity. The certificate is a license to produce and sell the vehicle and covers only those vehicles or engines specifically described in the application.

All of EPA's emission regulations specify test procedures to measure engine or vehicle emission levels. EPA uses the test results to determine compliance with the applicable emission standards.

The number and types of tests vary according to the regulated sector. Certification testing is a form of compliance testing that is required as a condition of certification and is generally performed prior to issuing a certificate. In-use testing occurs after the vehicles or engines have been certified, generally on privately used vehicles or engines. Production line (or assembly line) testing audits emission levels of vehicles or engines that are in production, but not yet in service, to confirm that the manufacturer is building compliant vehicles (CA-ARB, 2002).

7.1 TESTING FOR REGULATORY COMPLIANCE

Vehicle testing is usually performed in laboratory environment under simulated real-world driving conditions. Drive train is placed on a dynamometer mechanism where the circular motion of the drive train is transferred to spinning steel cylinders of the dynamometer. A dynamometer is a machine that measures the torque and power produced by an engine. It applies various loads to an engine and is usually connected to a computer that can analyze and calculate all the aspects of engine operation measured.

Dynamometers are particularly useful in designing and refining engine technology. They can help identify how an engine or its drive train needs to be modified or tuned to achieve more efficient power transfer.

There are two types of dynamometers. Engine dynamometer measures engine performance only. The engine is removed from the vehicle and mounted onto a special frame for this type of dynamometer. It is coupled directly to the engine flywheel and measures performance independent of the vehicle's drive train—such as its gearbox, transmission, or differential.

The second type of dynamometer is called chassis dynamometer, which measures the power from the engine through a vehicle's driven wheels. The drive train is mounted on rollers, and the vehicle is fixed to the ground to prevent jumping when it is driven during testing. As the vehicle is driven in gear, it turns the rollers without moving. The power output and emissions are measured using various techniques.

7.1.1 The Federal Test Procedure

One of the fundamental assumptions underlying on-road emissions inventory development is that driving behavior can be captured and reproduced in a laboratory setting. The Federal Test Procedure or FTP was developed in the late 1960s and early 1970s as a model of a typical commute in an urban area. The FTP was neither Federal nor typical. It is actually the composite of several trips to and from the then headquarters of the California Air Resources Board in Downtown Los Angeles.

When first utilized, the FTP (also referred to as CVS72), was a two mode or two-bag test. The term "bag" refers to the Tedlar bags in which exhaust is stored for analysis. The first mode of the test is referred to as a "cold start." Cold start refers to a physical turn of the

ignition when the engine is actually at ambient temperature after several hours of turn off. Cold starts are associated with excessive cranking or starting emissions of a vehicle. The cold-start mode is followed by a cold transient model for 505 s in duration with a maximum speed of 56.7 miles/h and an average speed of 25.6 miles/h. The maximum acceleration and deceleration rates of 5.6 and 5.2 miles/h/s were mitigated to 3.3 miles/h/s because of the limitations of the belt-driven dynamometers used at that time (CA-ARB, 2002).

Mode two, or bag two, of the FTP is referred to as the “hot stabilized” portion of the test. With a maximum speed of 34 miles/h and an average speed of 16, bag two is slower than bag one because bag one contains freeway driving. Again the maximum and minimum acceleration and deceleration rates of 5.4 and 8.0 miles/h/s were clipped at plus or minus 3.3 miles/h/s. Taken together, the two modes of the CVS72 comprise a driving cycle, which is 1372 s in duration with an average speed of 19.6 miles/h (CA-ARB, 2002).

The CVS75 cycle added a third mode to the test. Upon completion of bag two, the vehicle is switched off and allowed to sit or soak for 10 min after which the vehicle is restarted and mode one of the test is repeated. This is referred to as the hot-start portion of the test. The acceleration, deceleration, cruise, and idle cycle of this cycle are illustrated in Figure 7.1.

The laboratory setup includes instrumentation that can control engine in such a way that the drive train will mimic this driving cycle. Also included in the setup are instrumentation for emission collection and analysis. Figures 7.2 and 7.3 illustrate the schematic and actual setup of a laboratory set up for the FTP Test.

The parameters of LA4 cycle used in FTP are summarized in Table 7.1. The FTP test data for new vehicles are used by EPA to develop emissions models such as the MOBILE model and its successor MOVES model.

7.1.2 Testing for Inspection and Maintenance

Vehicles registered in specific classifications of nonattainment areas are periodically required to go through testing for compliance with Inspection and Maintenance

TABLE 7.1 FTP Parameters

Drive Cycle	LA4 Cycle
Average speed	19.6 mph
Maximum speed	56.7 mph
Average maximum speed	N/A
Percent idle	19.0
Stops per mile	2.41
Maximum acceleration	1.48 m/s ²
Average maximum acceleration	N/A
Cycle length	7.5 miles

**FIGURE 7.4** IM240 drive cycle used in several I&M programs.

(I&M) programs. While the FTP is used for testing new vehicles, authorized emission-testing stations with chassis dynamometer facilities use a test cycle for shorter duration. Most commonly used driving cycle for I&M programs is IM240 Drive Cycle (Figure 7.4).

7.1.3 Emission Testing with On-Board Portable Emissions Monitoring Systems

Although the FTP presents a standardized method to assess the emissions performance of new vehicles, the driving schedule used in the FTP test does not reflect real-world driving conditions. Dynamometer tests are often used in regulatory procedures to check compliance of new vehicles with emission standards or to inspect in-use vehicles. The data obtained from driving cycles are also used to develop emission estimation models, such as EMFAC7F, MOBILE6 (also in MOVES), and UC Riverside's modal emissions models (Roughail et al., 2000; Frey, 2003).

Remote sensing (RS) is another method for measuring vehicle emissions. RS uses infrared (IR) and, in some cases, ultraviolet (UV) spectroscopy to measure the concentrations of pollutants in exhaust emissions as an on-road vehicle passes a sensor on the roadway. There are several applications of remote sensing in mobile emissions determination. These include monitoring of emissions to evaluate the overall effectiveness of inspection and maintenance programs; identification of high emitting vehicles for inspection or enforcement purposes; and development of emission factors (Roughail et al., 2000).

The major advantage of remote sensing is that it is possible to measure a large number of on-road vehicles (e.g., thousands per day). The major disadvantage of remote sensing is that it only gives an instantaneous estimate of emissions at a specific location. There are constraints on the siting of remote sensing devices (RSDs) that make it impractical to use remote sensing as a means for measuring vehicle emissions at many locations of practical interest, such as close to intersections or across multiple lanes of heavy traffic. Furthermore, remote sensing is more or less a fair weather technology (Roughail et al., 2000).

On-board emissions measurement is widely recognized as a desirable approach for quantifying emissions from vehicles since data are collected under real-world conditions at any location traveled by the vehicle. Variability in vehicle emissions as a result of variation in facility (roadway) characteristics, vehicle location, vehicle operation, driver, or other factors can be represented and analyzed more reliably than with the other methods. This is because measurements are obtained during real-world driving, eliminating the concern about nonrepresentativeness that is often an issue with dynamometer testing, and at any location, eliminating the siting restrictions inherent in remote sensing.

Once such device in use, OEM-2100, is capable of testing electronically controlled light-duty passenger vehicles and light trucks 1996 and newer with on-board diagnostics (OBD). The unit includes a durable touch-screen computer and comes standard in powder-coated aluminum housing.

The system connects to the vehicle via three interfaces. The vehicle cigarette lighter provided electrical power to the PEMS units; the vehicle OBD port provided access to the engine data stream; and the PEMS sample line and exhaust probe were inserted into the tailpipe. Exhaust gas and particulate concentrations were reported by their respective analyzers. The Portable Emission Measurement Systems (PEMS) in use captured HC, CO, CO₂, and NO_x emissions from the gasoline-fueled vehicles on a second-by-second basis, correlating the emissions captured with engine-operating characteristics such as engine RPM, fuel flow, ignition timing advance, throttle position, mass air flow, and vehicle speed (Hart 2002; USEPA, 2003). These operating characteristics were gathered from each test vehicle's engine control unit via the on-board diagnostics—OBD II—port. Global positioning system (GPS) units were used concurrently with PEMS, providing positional data, and cross-referencing speed and acceleration data with that gathered by the PEMS unit. The PEMS units were powered by each vehicle's 12 V system (via the cigarette lighter or auxiliary power ports). Processing the emissions data were managed by the PEMS on-board computer, and stored to the PEMS hard disk.

For example, PEMS were used in a study to measure differences in vehicle emissions between HOV and GP facilities. Several hundred miles of on-road emissions data were collected with vehicles instrumented with PEMS operated in HOV and GP lanes during

FIGURE 7.5 Setup of a portable emission monitor system for field emissions measurement study.

peak hours in the metropolitan Washington, DC area (Krimmer and Venigalla, 2006). Illustrated in Figure 7.5 is the OEM-2100 setup for this study.

However, on-board emissions measurement has not been widely used because it has been prohibitively expensive (Frey, 2003).

7.1.4 Testing for Special Purpose Emissions Studies

Whether the testing is done for regulatory compliance (FTP, IM240, remote sensing, etc.), or for testing on-road traffic and transportation strategies using portable emissions monitors, and emissions testing is generally an expensive proposition. In addition to requiring expensive equipment, acquiring and maintaining such systems also requires skilled staff and high maintenance costs. A few public universities have laboratory facilities to facilitate design and execution of various types of emissions testing studies.

For example, the Center for Environmental Research and Technology (CE-CERT) in Burns College of Engineering at University of California, Davis has state-of-the-art laboratory equipment to facilitate various types of emissions studies such as heavy-duty chassis and engine dynamometers, a light-duty chassis dynamometer, a portable emissions laboratory, and a chemical analysis laboratory (CE-CERT, 2011). Figure 7.6 shows the heavy-duty chassis dynamometer and mobile emissions laboratory at CE-CERT.

- 8.3 Surfaces
 - 8.3.1 Characteristics of surfaces

In addition to mechanical and physical properties of materials, other factors that determine the performance of a manufactured product include the dimensions and surfaces of its components. *Dimensions* are the linear or angular sizes of a component specified on the part drawing. Dimensions are important because they determine how well the components of a product fit together during assembly. When fabricating a given component, it is nearly impossible and very costly to make the part to the exact dimension given on the drawing. Instead, a limited variation is allowed from the dimension, and that allowable variation is called a *tolerance*.

The surfaces of a component are also important. They affect product performance, assembly fit, and aesthetic appeal that a potential customer might have for the product. A *surface* is the exterior boundary of an object with its surroundings, which may be another

object, a fluid, or space, or combinations of all these. The surface encloses the object's bulk mechanical and physical properties.

This chapter discusses dimensions, tolerances, and surfaces—three attributes specified by the product designer and determined by the manufacturing processes used to make the parts and products. It also considers how these attributes are assessed using measuring and gaging devices. A closely related topic is inspection, which is covered in Chapter 42.

8.1 DIMENSIONS, TOLERANCES, AND RELATED ATTRIBUTES

The basic parameters used by design engineers to specify sizes of geometric features on a part drawing are defined in this section. The parameters include dimensions and tolerances, flatness, roundness, and angularity.

8.1.1 Dimensions and Tolerances

ANSI (American National Standards Institute, Inc., 1982) defines a *dimension* as “a numerical value expressed in appropriate units of measure and indicated on a drawing and in other documents along with lines, symbols, and notes to define the size or geometric characteristic, or both, of a part or part feature.” Dimensions on part drawings represent nominal or basic sizes of the part and its features. These are the values that the designer would like the part size to be, if the part could be made to an exact size with no errors or variations in the fabrication process. However, there are variations in the manufacturing process, which are manifested as variations in the part size. Tolerances are used to define the limits of the allowed variation. Quoting again from the ANSI standard (American National Standards Institute, Inc., 1982), a *tolerance* is “the total amount by which a specific dimension is permitted to vary. The tolerance is the difference between the maximum and minimum limits.”

Tolerances can be specified in several ways, illustrated in Figure 8.1. Probably the most common is the *bilateral tolerance*, in which the variation is permitted in both positive and negative directions from the nominal dimension. For example, in Figure 8.1a, the nominal dimension = 2.500 linear units (e.g., mm, in.), with an

FIGURE 8.1 Three ways to specify tolerance limits for a nominal dimension of 2.500: (a) bilateral, (b) unilateral, and (c) limit dimensions.

TABLE 8.1 Definitions of Geometric Attributes of Parts

<i>Angularity</i> —The extent to which a part feature such as a surface or axis is at a specified angle relative to a reference surface. If the angle = 90°, then the attribute is called perpendicularity or squareness.	<i>Cylindricity</i> —The degree to which all points on a surface of revolution such as a cylinder are equidistant from the axis of revolution.
<i>Circularity</i> —For a surface of revolution such as a cylinder, circular hole, or cone, circularity is the degree to which all points on the intersection of the surface and a plane perpendicular to the axis of revolution are equidistant from the axis. For a sphere, circularity is the degree to which all points on the intersection of the surface and a plane passing through the center are equidistant from the center.	<i>Flatness</i> —The extent to which all points on a surface lie in a single plane.
<i>Concentricity</i> —The degree to which any two (or more) part features such as a cylindrical surface and a circular hole have a common axis.	<i>Parallelism</i> —The degree to which all points on a part feature such as a surface, line, or axis are equidistant from a reference plane or line or axis.
	<i>Perpendicularity</i> —The degree to which all points on a part feature such as a surface, line, or axis are 90 from a reference plane or line or axis.
	<i>Roundness</i> —Same as circularity.
	<i>Squareness</i> —Same as perpendicularity.
	<i>Straightness</i> —The degree to which a part feature such as a line or axis is a straight line.

allowable variation of 0.005 U in either direction. Parts outside these limits are unacceptable. It is possible for a bilateral tolerance to be unbalanced; for example, 2.500, +0.010, −0.005 dimensional units. A *unilateral tolerance* is one in which the variation from the specified dimension is permitted in only one direction, either positive or negative, as in Figure 8.1b. *Limit dimensions* are an alternative method to specify the permissible variation in a part feature size; they consist of the maximum and minimum dimensions allowed, as in Figure 8.1c.

8.1.2 Other Geometric Attributes

Dimensions and tolerances are normally expressed as linear (length) values. There are other geometric attributes of parts that are also important, such as flatness of a surface, roundness of a shaft or hole, parallelism between two surfaces, and so on. Definitions of these terms are listed in Table 8.1.

8.2 CONVENTIONAL MEASURING INSTRUMENTS AND GAGES

Measurement is a procedure in which an unknown quantity is compared with a known standard, using an accepted and consistent system of units. Two systems of units have evolved in the world: (1) the U.S. customary system (U.S.C.S.), and (2) the International System of Units (or SI, for Systeme Internationale d’Unites), more popularly known as

the metric system. Both systems are used in parallel throughout this book. The metric system is widely accepted in nearly every part of the industrialized world except the United States, which has stubbornly clung to its U.S.C.S. Gradually, the United States is adopting SI.

Measurement provides a numerical value of the quantity of interest, within certain limits of accuracy and precision. *Accuracy* is the degree to which the measured value agrees with the true value of the quantity of interest. A measurement procedure is accurate when it is absent of systematic errors, which are positive or negative deviations from the true value that are consistent from one measurement to the next. *Precision* is the degree of repeatability in the measurement process. Good precision means that the random errors in the measurement procedure are minimized. Random errors are usually associated with human participation in the measurement process. Examples include variations in the setup, imprecise reading of the scale, round-off approximations, and so on. Nonhuman contributors to random error include temperature changes, gradual wear and/or misalignment in the working elements of the device, and other variations.

Closely related to measurement is gaging. *Gaging* (also spelled *gauging*) determines simply whether the part characteristic meets or does not meet the design specification. It is usually faster than measuring, but scant information is provided about the actual value of the characteristic of interest. The video clip on measurement and gaging illustrates some of the topics discussed in this chapter.

Video Clip

Measurement and Gaging. This clip contains three segments: (1) precision, resolution, and accuracy; (2) how to read a vernier caliper; and (3) how to read a micrometer.

This section considers the variety of manually operated measuring instruments and gages used to evaluate dimensions such as length and diameter, as well as features such as angles, straightness, and roundness. This type of equipment is found in metrology labs, inspection departments, and tool rooms. The logical starting topic is precision gage blocks.

8.2.1 Precision Gage Blocks

Precision gage blocks are the standards against which other dimensional measuring instruments and gages are compared. Gage blocks are usually square or rectangular. The measuring surfaces are finished to be dimensionally accurate and parallel to within several millionths of an inch and are polished to a mirror finish. Several grades of precision gage blocks are available, with closer tolerances for higher precision grades. The highest grade—the *master laboratory standard*—is made to a tolerance of ± 0.00003 mm (± 0.00001 in.). Depending on degree of hardness desired and price the user is willing to pay, gage blocks can be made out of any of several hard materials, including tool steel, chrome-plated steel, chromium carbide, or tungsten carbide.

Precision gage blocks are available in certain standard sizes or in sets, the latter containing a variety of different-sized blocks. The sizes in a set are systematically determined so they can be stacked to achieve virtually any dimension desired to within 0.0025 mm (0.0001 in.).

For best results, gage blocks must be used on a flat reference surface, such as a surface plate. A *surface plate* is a large solid block whose top surface is finished to a flat plane. Most surface plates today are made of granite. Granite has the advantage of being hard, non-rusting, nonmagnetic, long-wearing, thermally stable, and easy to maintain.

Gage blocks and other high-precision measuring instruments must be used under standard conditions of temperature and other factors that might adversely affect the measurement. By international agreement, 20°C (68°F) has been established as the standard temperature. Metrology labs operate at this standard temperature. If gage blocks or other measuring instruments are used in a factory environment in which the temperature differs from this standard, corrections for thermal expansion or contraction may be required. Also, working gage blocks used for inspection in the shop are subject to wear and must be calibrated periodically against more precise laboratory gage blocks.

8.2.2 Measuring Instruments for Linear Dimensions

Measuring instruments can be divided into two types: graduated and nongraduated. *Graduated measuring devices* include a set of markings (called *graduations*) on a linear or angular scale to which the object's feature of interest can be compared for measurement. *Nongraduated measuring devices* possess no such scale and are used to make comparisons between dimensions or to transfer a dimension for measurement by a graduated device.

The most basic of the graduated measuring devices is the *rule* (made of steel, and often called a *steel rule*), used to measure linear dimensions. Rules are available in various lengths. Metric rule lengths include 150, 300, 600, and 1000 mm, with graduations of 1 or 0.5 mm. Common U.S. sizes are 6, 12, and 24 in., with graduations of 1/32, 1/64, or 1/100 in.

Calipers are available in either nongraduated or graduated styles. A nongraduated caliper (referred to simply as a *caliper*) consists of two legs joined by a hinge mechanism, as in Figure 8.2. The ends of the legs are made to contact the surfaces of the object being measured, and the hinge is designed to hold the legs in position during use. The contacts point either inward or outward. When they point inward, as in Figure 8.2, the instrument is an *outside caliper*, and is used for measuring outside dimensions such as a diameter. When the contacts point outward, it is an *inside caliper*, which is used to measure the distance between two internal surfaces. An instrument similar in configuration to the caliper is a *divider*, except that both legs are straight and terminate in hard, sharply pointed contacts. Dividers are used for scaling distances between two points or lines on a surface, and for scribing circles or arcs onto a surface.

A variety of graduated calipers are available for various measurement purposes. The simplest is the *slide caliper*, which consists of a steel rule to which two jaws are added, one fixed at the end of the rule and the other movable, shown in Figure 8.3. Slide calipers can be used for inside or outside measurements, depending on whether the inside or outside jaw faces are used. When in use, the jaws are forced into contact with the part surfaces to be measured, and the location of the movable jaw indicates the dimension of interest. Slide calipers permit more accurate and precise measurements than simple rules. A refinement of the slide caliper is the *vernier*

FIGURE 8.2 Two sizes of outside calipers (Courtesy of L.S. Starrett Co.).

caliper, shown in Figure 8.4. In this device, the movable jaw includes a vernier scale, named after P. Vernier (1580–1637), a French mathematician who invented it. The vernier provides graduations of 0.01 mm in the SI (and 0.001 in. in the U.S. customary scale), much more precise than the slide caliper.

FIGURE 8.3 Slide caliper, opposite sides of instruments shown (Courtesy of L.S. Starrett Co.).

FIGURE 8.4 Vernier caliper (Courtesy of L.S. Starrett Co.).

The *micrometer* is a widely used and very accurate measuring device, the most common form of which consists of a spindle and a C-shaped anvil, as in Figure 8.5. The spindle is moved relative to the fixed anvil by means of an accurate screw thread. On a typical U.S. micrometer, each rotation of the spindle provides 0.025 in.

FIGURE 8.5 External micrometer, standard 1-in. size with digital readout (Courtesy of L.S. Starrett Co.).

of linear travel. Attached to the spindle is a thimble graduated with 25 marks around its circumference, each mark corresponding to 0.001 in. The micrometer sleeve is usually equipped with a vernier, allowing resolutions as close as 0.0001 in. On a micrometer with metric scale, graduations are 0.01 mm. Modern micrometers (and graduated calipers) are available with electronic devices that display a digital readout of the measurement (as in the figure). These instruments are easier to read and eliminate much of the human error associated with reading conventional graduated devices.

The most common micrometer types are (1) *external micrometer*, Figure 8.5, also called an *outside micrometer*, which comes in a variety of standard anvil sizes; (2) *internal micrometer*, or *inside micrometer*, which consists of a head assembly and a set of rods of different lengths to measure various inside dimensions that might be encountered; and (3) *depth micrometer*, similar to an inside micrometer but adapted to measure hole depths.

8.2.3 Comparative Instruments

Comparative instruments are used to make dimensional comparisons between two objects, such as a workpart and a reference surface. They are usually not capable of providing an absolute measurement of the quantity of interest; instead, they measure the magnitude and direction of the deviation between two objects. Instruments in this category include mechanical and electronic gages.

8.2.3.1 Mechanical Gages: Dial Indicators *Mechanical gages* are designed to mechanically magnify the deviation to permit observation. The most common instrument in this category is the *dial indicator* (Figure 8.6), which converts and amplifies the linear

FIGURE 8.6 Dial indicator: top view shows dial and graduated face; bottom view shows rear of instrument with cover plate removed (Courtesy of Federal Products Co., Providence, RI).

FIGURE 8.7 Dial indicator setup to measure runout; as part is rotated about its center, variations in outside surface relative to center are indicated on the dial.

movement of a contact pointer into rotation of a dial needle. The dial is graduated in small units such as 0.01 mm (or 0.001 in.). Dial indicators are used in many applications to measure straightness, flatness, parallelism, squareness, roundness, and runout. A typical setup for measuring runout is illustrated in Figure 8.7.

8.2.3.2 Electronic Gages Electronic gages are a family of measuring and gaging instruments based on transducers capable of converting a linear displacement into an electrical signal. The electrical signal is then amplified and transformed into a suitable data format such as a digital readout, as in Figure 8.5. Applications of electronic gages have grown rapidly in recent years, driven by advances in microprocessor technology. They are gradually replacing many of the conventional measuring and gaging devices. Advantages of electronic gages include (1) good sensitivity, accuracy, precision, repeatability, and speed of response; (2) ability to sense very small dimensions—down to $0.025\text{ }\mu\text{m}$ ($1\text{ }\mu\text{in.}$); (3) ease of operation; (4) reduced human error; (5) electrical signal that can be displayed in various formats; and (6) capability to be interfaced with computer systems for data processing.

8.2.4 Fixed Gages

A fixed gage is a physical replica of the part dimension to be assessed. There are two basic categories: master gage and limit gage. A *master gage* is fabricated to be a direct replica of the nominal size of the part dimension. It is generally used for setting up a comparative measuring instrument, such as a dial indicator; or for calibrating a measuring device.

A *limit gage* is fabricated to be a reverse replica of the part dimension and is designed to check the dimension at one or more of its tolerance limits. A limit gage often consists of two gages in one piece, the first for checking the lower limit of the tolerance on the part dimension, and the other for checking the upper limit. These gages are popularly known as *GO/NO-GO gages*, because one gage limit allows the part to be inserted, whereas the other limit does not. The *GO limit* is used to check the dimension at its maximum material condition; this is the minimum size for an internal feature such as a hole, and it is the maximum size for an external feature

FIGURE 8.8 Snap gage for measuring diameter of a part; difference in height of GO and NO-GO gage buttons is exaggerated.

such as an outside diameter. The *NO-GO limit* is used to inspect the minimum material condition of the dimension in question.

Common limit gages are snap gages and ring gages for checking outside part dimensions, and plug gages for checking inside dimensions. A *snap gage* consists of a C-shaped frame with gaging surfaces located in the jaws of the frame, as in Figure 8.8. It has two gage buttons, the first being the GO gage, and the second being the NO-GO gage. Snap gages are used for checking outside dimensions such as diameter, width, thickness, and similar surfaces.

Ring gages are used for checking cylindrical diameters. For a given application, a pair of gages is usually required, one GO and the other NO-GO. Each gage is a ring whose opening is machined to one of the tolerance limits of the part diameter. For ease of handling, the outside of the ring is knurled. The two gages are distinguished by the presence of a groove around the outside of the NO-GO ring.

The most common limit gage for checking hole diameter is the *plug gage*. The typical gage consists of a handle to which are attached two accurately ground cylindrical pieces (plugs) of hardened steel, as in Figure 8.9. The cylindrical plugs serve as the GO and NO-GO gages. Other gages similar to the plug gage include *taper gages*, consisting of a tapered plug for checking tapered holes; and *thread gages*, in which the plug is threaded for checking internal threads on parts.

Fixed gages are easy to use, and the time required to complete an inspection is almost always less than when a measuring instrument is employed. Fixed gages were a

FIGURE 8.9 Plug gage; difference in diameters of GO and NO-GO plugs is exaggerated.

fundamental element in the development of interchangeable parts manufacturing (Historical Note 1.1). They provided the means by which parts could be made to tolerances that were sufficiently close for assembly without filing and fitting. Their disadvantage is that they provide little if any information on the actual part size; they only indicate whether the size is within tolerance. Today, with the availability of high-speed electronic measuring instruments, and with the need for statistical process control of part sizes, use of gages is gradually giving way to instruments that provide actual measurements of the dimension of interest.

8.2.5 Angular Measurements

Angles can be measured using any of several styles of *protractor*. A *simple protractor* consists of a blade that pivots relative to a semicircular head that is graduated in angular units (e.g., degrees, radians). To use, the blade is rotated to a position corresponding to some part angle to be measured, and the angle is read off the angular scale. A *bevel protractor* (Figure 8.10) consists of two straight blades that pivot relative to each other. The pivot assembly has a protractor scale that permits the angle formed by the blades to be read. When equipped with a vernier, the bevel protractor can be read to about 5 min; without a vernier the resolution is only about 1 degree.

High precision in angular measurements can be made using a *sine bar*, illustrated in Figure 8.11. One possible setup consists of a flat steel straight edge (the sine bar), and two precision rolls set a known distance apart on the bar. The straight edge is aligned with the part angle to be measured, and gage blocks or other accurate linear measurements are made to determine height. The procedure is carried out on a surface plate to

FIGURE 8.10 Bevel protractor with vernier scale (Courtesy of L.S. Starrett Co.).

achieve most accurate results. The height H and the length L of the sine bar between rolls are used to calculate the angle A using

$$\sin A = \frac{H}{L} \quad (8.1)$$

8.3 SURFACES

A surface is what one touches when holding an object, such as a manufactured part. The designer specifies the part dimensions, relating the various surfaces to each other. These *nominal surfaces*, representing the intended surface contour of the part, are defined by lines in the engineering drawing. The nominal surfaces appear as absolutely straight lines, ideal circles, round holes, and other edges and surfaces that are geometrically perfect. The actual surfaces of a manufactured part are determined by the processes used to make it. The variety of processes available in manufacturing result in wide variations in surface characteristics, and it is important for engineers to understand the technology of surfaces.

Surfaces are commercially and technologically important for a number of reasons, different reasons for different applications: (1) aesthetic reasons—surfaces that are smooth and free of scratches and blemishes are more likely to give a favorable impression to the customer, (2) surfaces affect safety, (3) friction and wear depend on surface characteristics, (4) surfaces affect mechanical and physical properties; for example, surface flaws can be points of stress concentration, (5) assembly of parts is affected by their surfaces; for example, the strength of adhesively bonded joints (Section 31.3) is increased when the surfaces are slightly rough, and (6) smooth surfaces make better electrical contacts.

Surface technology is concerned with (1) defining the characteristics of a surface, (2) surface texture, (3) surface integrity, and (4) the relationship between manufacturing processes and the characteristics of the resulting surface. The first three topics are covered in this section; the final topic is presented in Section 8.5.

8.3.1 Characteristics of Surfaces

A microscopic view of a part's surface reveals its irregularities and imperfections. The features of a typical surface are illustrated in the highly magnified cross section of the surface of a metal part in Figure 8.12. Although the discussion here is focused on metallic surfaces, based on the process capability for the particular manufacturing operation, as defined in Section 42.2. The tolerance that should be specified is a function of part size; larger parts require more generous tolerances. The table lists tolerance for moderately sized parts in each processing category.

The manufacturing process determines surface finish and surface integrity. Some processes are capable of producing better surfaces than others. In general, processing cost increases with improvement in surface finish. This is because additional operations and more time are usually required to obtain increasingly better surfaces. Processes noted for providing superior finishes include honing, lapping, polishing, and superfinishing (Chapter 25). Table 8.2 indicates the usual surface roughness that can be expected from various manufacturing processes.

TABLE 8.2 Surface Roughness Values Produced by the Various Manufacturing Processes^a

Process	Typical Finish	Roughness Range ^b	Process	Typical Finish	Roughness Range ^b
<i>Casting</i>			<i>Abrasive</i>		
Die casting	Good	1–2 (30–65)	Grinding	Very good	0.1–2 (5–75)
Investment	Good	1.5–3 (50–100)	Honing	Very good	0.1–1 (4–30)
Sand casting	Poor	12–25 (500–1000)	Lapping	Excellent	0.05–0.5 (2–15)
<i>Metal forming</i>			Polishing	Excellent	0.1–0.5 (5–15)
Cold rolling	Good	1–3 (25–125)	Superfinish	Excellent	0.02–0.3 (1–10)
Sheet metal draw	Good	1–3 (25–125)	<i>Nontraditional</i>		
Cold extrusion	Good	1–4 (30–150)	Chemical milling	Medium	1.5–5 (50–200)
Hot rolling	Poor	12–25 (500–1000)	Electrochemical	Good	0.2–2 (10–100)
<i>Machining</i>			Electric discharge	Medium	1.5–15 (50–500)
Boring	Good	0.5–6 (15–250)	Electron beam	Medium	1.5–15 (50–500)
Drilling	Medium	1.5–6 (60–250)	Laser beam	Medium	1.5–15 (50–500)
Milling	Good	1–6 (30–250)	<i>Thermal</i>		
Reaming	Good	1–3 (30–125)	Arc welding	Poor	5–25 (250–1000)
Shaping and planing	Medium	1.5–12 (60–500)	Flame cutting	Poor	12–25 (500–1000)
Sawing	Poor	3–25 (100–1000)	Plasma arc cutting	Poor	12–25 (500–1000)
Turning	Good	0.5–6 (15–250)			

^aCompiled from American National Standards Institute, Inc. (1978, 1986) and other sources.

^bRoughness range values are given, in μm ($\mu\text{in.}$). Roughness can vary significantly for a given process, depending on process parameters.

9.1 INTRODUCTION

Mass properties—weight, center of gravity, and inertias—are critical performance parameters for any vehicle such as an aircraft, spacecraft, land vehicle, or ship as well as any subsystem or component. In spite of the excellent computer models that are available, the only way to ensure that the mass properties are accurate is to measure those properties. This leads to the questions that every engineer must consider in order to understand or develop a mass properties measurement plan.

- What should be measured?
- When should measurements be made?
- What measurement accuracy is required?
- What measurement equipment is available?

The mass properties of a moving object have a tremendous impact on how it performs during its intended operations and how it behaves during an emergency situation. For example, the weight and center of gravity (CG) of a land vehicle impacts its operability, economy, safety, and even its marketability. For marine vehicles, weight and CG location determines its draft, list, trim, handling, and its inherent ability to remain stable in a seaway. In the case of aircraft, missiles, and rockets, the vehicle's weight, CG, and moment of inertia (MOI) have a profound effect on the stability and controllability of the vehicle and its economy of operation.

Neglecting the mass properties of a vehicle has historically resulted in dire consequences, often with a significant loss of life. Planes have crashed due to instability and controllability problems. Cars have had a greater propensity to overturn during high-speed turns and have been the subject of expensive recalls and even model cancellations due to the neglect of mass properties. Ships have capsized due to insufficient stability when loads have shifted or when heavy seas have been encountered. In fact, entire product development programs have been canceled due to problems with mass properties. Therefore, the impact of mass properties is critical to the proper operation, economy, and safety of a moving object and this is why the accurate measurement of mass properties is an essential element of a successful product development program.

9.1.1 Scope

This article deals mainly with the mass properties measurement of individual objects and vehicles where precise mass properties measurement and management is necessary to meet strict engineering and performance requirements. The techniques, methods, tools,

and approach described here are primarily aimed at the application of mass properties measurement to vehicles and vehicle subsystems, rather than to production line or bulk measurements. Information on these other weight measurement methods and requirements can be found in National Institute of Standards and Technology (2011; <http://www.nist.gov>). The mass properties addressed herein are weight and mass, centers of gravity, moments of inertia, and products of inertia.

9.1.2 Other Resources

There are many organizations that can serve as valuable resources to the field of mass properties measurement. These include numerous governmental and independent professional societies that support the development of standards and practices for the measurement of physical properties. These organizations may offer valuable standards, recommended practices, training, educational resources, and publications. These organizations include

- *The Society of Allied Weight Engineers, Inc. (SAWE, Inc.):* An international organization based in the United States and dedicated to the promotion, practice, education, and innovation in the field of mass properties engineering. The SAWE's primary emphasis is on military and commercial aerospace, shipbuilding, land vehicle, and allied industries. Founded in 1939, the SAWE is a nonprofit organization. More information can be found at <http://www.sawe.org>.
- *National Institute of Standards and Technology (NIST):* A nonregulatory federal agency within the U.S. Department of Commerce dedicated to the promotion of U.S. innovation and industrial competitiveness by advancing measurement science. More information can be found at <http://www.nist.gov>.
- *International Bureau of Weights and Measures, or Bureau Internationale des Poids et Mesures (BIPM):* An international organization established in 1875 to ensure worldwide unification and coordination of measurement and the establishment of standards and scales for the measurement of physical quantities. The BIPM is based in France. More information can be found at <http://www.bipm.org>.
- *National Physical Laboratory:* The national measurement standards laboratory for the United Kingdom that was established in 1900 and is devoted to the development and application of physical measurement techniques. More information can be found at <http://www.npl.co.uk>.

9.1.3 Terms

As with any engineering field, mass properties engineering has many specific terms that are unique or that may not be familiar to all readers. A partial list follows

Bifilar Pendulum: A two wire suspension system to support an object so its moment of inertia can be determined by measuring the period of rotational oscillation when it is displaced through a small angle about a vertical axis.

Center of Gravity (Center of Mass; CG): The point at which the distributed mass of a body can be acted upon by a force without inducing any rotation of that body.

Displacement: (1) The weight of a ship or floating body in terms of the weight of the fluid displaced. Usually stated in terms of metric tons or long tons (2240 lbs).
 (2) The position of an object or CG of an object relative to a datum stated in linear units (i.e., inches or millimeters).

Fixture: A structure that supports and locates an object on the mass properties measurement assembly.

Mass: The measure of the quantity of matter in a body; a body's resistance to change in motion.

Moment of Inertia (MOI): The rotational inertia or resistance to change in direction or speed of rotation about a defined axis.

Longitudinal Center of Gravity (LCG): Normally measured from a datum and along the longitudinal axis of the object or vehicle.

Payload: The object or vehicle that is mounted in the mass properties measurement assembly for measurement. Also called unit under test (UUT) or test object.

Product of Inertia (POI): A measure of a body's dynamic (or coupled) imbalance resulting in a precession when rotating about an axis other than the body's principal axis.

Rangeability: The ratio between load capacity and accuracy for a measurement instrument such as a scale.

Tare: The weight (or other mass property) of a container or fixture in an empty state without any payload.

Transverse Center of Gravity (TCG): Normally measured from a datum and along the transverse axis of the object or vehicle.

Trifilar Pendulum: A suspension system using three wires to support an object to measure its MOI by timing rotational oscillations about a vertical axis.

Vertical Center of Gravity (VCG): Normally measured from a baseline up along the vertical axis of the object or vehicle.

Weight: The force that presses the object down on a scale due to the acceleration of gravity.

9.2 MASS AND WEIGHT

Before attempting to measure the mass properties of an object, it is vital to understand exactly what you will be measuring, and what you need to measure. The first thing that must be understood is the difference between mass and weight.

Mass is related to weight through Newton's second law:

$$W = Mg \quad (9.1)$$

where W is the weight of the object (gravity force); M is the mass of the object; and g is the acceleration of gravity.

Mass is the quantity of matter in an object, whereas weight is the force that presses the object down on a scale due to the acceleration of gravity. The mass of an object is a fixed quantity; its weight varies as a function of the acceleration of gravity. The mass properties

of an object are related to mass, not weight. For instance, mass properties do not change as a space vehicle leaves the attraction of Earth's gravity.

9.2.1 Measurement Systems

The two most prevalent measurement systems used internationally are the metric or SI system and the English or Imperial system. The engineer performing the measurement and the end user of the data must be made clearly aware of which system is being used. This is especially important in international collaboration projects or in any situation where mixed units might be used.

In 1999, the Mars Climate Orbiter crashed as a result of confusion over the system of units. The software program that controlled the thrusters was supplied with thrust data in pound-seconds but interpreted it as if it were Newton-seconds, resulting in an underestimation of the thruster impulse. This is only one of many thousands of errors that have occurred as a result of the conflict between Metric and English units (Boynton, 2001).

Many of these errors are the result of a misunderstanding regarding the difference between mass and weight. If you place an object on a scale in Europe, you will read its mass (generally expressed in kilograms). However, if you place an object on a scale in the United States, you will read a value equal to the force exerted by the acceleration of gravity (generally expressed in pound-force [lbf]). In reality, most scales (and all those used for commerce) are calibrated to read the weight of a given mass in a standard gravitational field, not the local gravitational field. Since you are really trying to use the scale to measure mass, when you weigh yourself on an American bathroom scale, it should read 6.22 slugs rather than 200 lbf.

Traditionally, a dimensionally inconsistent correction factor is used to convert from one set of units to the other. The expression $1 \text{ kg} = 2.205 \text{ lb}$ is not actually valid. It is like comparing apples to oranges. Mass does not equal force. This traditional conversion factor is based on the value of standard gravity.

The various measuring systems are fundamentally mass–length–time systems with force being a defined or derived term. The U.S. systems are fundamentally force–length–time systems with mass being defined or derived. Table 9.1 shows the two most commonly used systems of measurement.

If different names are used for weight and mass, then the problem of distinguishing between the two is minimized. The Metric SI system uses the word Newton for weight and the word kilogram for mass. The Newton is defined as the force required to accelerate a 1 kg mass by 1 m/s^2 . Since the standard value for g is 9.80665 m/s^2 , if an object weighs 9.80665 N, its mass is 1 kg.

In the English system, the aerospace industry has created a unit of mass called the slug. A 1 lb force is required to accelerate a 1 slug mass at 1 ft/s^2 . Since the standard value for g is 32.17405 ft/s^2 , if an object weighs 32.17405 lbf on Earth, then its mass is 1 slug.

TABLE 9.1 Dimensionally Correct Measuring Systems

System	Mass	Length	Time	Weight	g
SI (metric)	Kilogram (kg)	Meter (m)	Second (s)	Newton (N)	9.80665 m/s^2
US (foot)	Slug	Foot (ft)	Second (s)	Pound (lbf)	32.17405 ft/s^2

Unfortunately, not all systems of units adequately differentiate between mass and weight. In the United States, the word pound is commonly used for both mass and weight, resulting in endless confusion and errors in calculating mass properties and dynamic response. Officially, pound refers to mass (National Institute of Standards and Technology, 2011). However, the common usage of the word pound is the value you read on a scale, which is actually pound-force (lbf). If the term pound is used to describe a mass whose measured weight is 1 lb (force), this quantity must be divided by the acceleration of gravity in appropriate units to convert it to proper mass dimensions if it is to be used in mass properties calculations. Similarly, in metric countries the terms kilogram and gram are often used, incorrectly, to describe force as well as mass. To avoid confusion and uncertainty, an analysis of fundamental dimensions will confirm if correct units of measurement are being applied correctly to achieve desired results.

Throughout this article, both SI and English systems are used in the examples and in equations. Although SI is the preferred system, legacy projects in the United States still use English exclusively or some mix of the two systems (National Institute of Standards and Technology, 2011). The important thing is to understand the system being used and consistently use and report the correct units for the mass properties measurement being performed.

9.3 MEASUREMENT METHODOLOGY

9.3.1 Steps in Making a Mass Properties Measurement

As described in Boynton and Wiener (1998), there are nine steps required to measure the mass properties of an object:

1. Define the particular mass properties you need to measure and the required measurement accuracy.
2. Choose the correct type of measuring instrument. This choice will be driven by the availability of existing equipment, accuracy required, cost, and suitability for the measurement environment.
3. Define the coordinate system on the test object to be used as the mass properties reference axes. Any object has an infinite number of values for CG location, MOI, and POI, depending on where the reference axes are assigned. The axes may be related to the geometric centerline of the vehicle, a line of thrust, or may depend on the attachment interface to another stage of the vehicle, object, or structure.
4. Define the position of the test object on the mass properties measuring machine. There are an infinite number of ways a payload can be mounted on a mass properties machine. While the mass properties of the payload are fixed, the measured data will be dependent on its orientation relative to the measurement coordinate system (referring to basic position, not how accurate this position is). For example, a rocket can be mounted on the machine with its nose up or its nose down. The fins can be parallel to the X -axis of the machine or the Y -axis (or for that matter can be oriented at any angle). To avoid confusion, you need to make a drawing or sketch of the position of the payload on the machine so you can interpret the measured data correctly.

5. Determine the dimensional accuracy of the object being measured. This can be the limiting factor on accuracy. For example, you cannot measure the CG of a cylindrical object with an accuracy of 0.005 in. (0.127 mm) if the outer surface of the object has a runout (out of round) of 0.020 in. (0.508 mm).
6. Design the fixture required to mount the test object at a precise location relative to the measuring instrument. This will require a means of determining the location of the measurement axis of the instrument as well as a means of accurately supporting the test object on the instrument. Verify the position of the object on the instrument.
7. Take the mass properties measurement. Several orientations of the test object on the measurement instrument may be needed to meet specified requirements.
8. Reduce data to account for differences between test object configuration and that of the operational vehicle.
9. Report the mass properties data, both raw data and reduced data, including a sketch showing the orientation of the payload and definition of the measurement coordinate system.

9.3.2 Data and Frames of Reference

Whenever a measurement of the physical properties of an object is taken, it is important that the data be properly interpreted for use by someone who was not involved in the measurement. Therefore, the context of the physical measurement must be clearly and concisely communicated to the user of the information. This context is provided by data or frames of reference that are an established form of coordinate system, or set of axes, that serves to locate one specific point on an object relative to another. Typically, the definition of a specific unique point on a three-dimensional object requires location relative to three different planes and a common reference point.

There is no one correct datum or frame of reference for the measurement of physical properties. They are an adopted convention that can vary significantly from one profession to another, one technical discipline to another, one industry to another, and even one country to another.

9.3.2.1 Choosing the Frame of Reference Often there are two different vehicle frames of reference: the body frame, defined by the structure of the vehicle, and the inertial frame, defined by the mass properties of the vehicle. It is important to understand the difference between these two frames of reference (SAWE Members, 2007).

The body frame is a reference system that is related to the physical structure of the vehicle. This frame is easy to define for an ideal vehicle shape, but may be hard to locate on a real vehicle, because of loose manufacturing tolerances and other practical problems.

The inertial frame is a reference system defined by the principal axes of the vehicle. This can be crudely calculated, but it is necessary to make measurements of the real vehicle to accurately determine the location of this inertial frame relative to the body frame. Measurements are made on a mass properties instrument that determines CG location, moments of inertia, and (if necessary) products of inertia. These measurements define the inertial frame relative to the body frame within the tolerance limitations of both the structure and the measuring instruments.

9.3.2.2 Interpreting the Data The following are some general characteristics of mass properties data that must be observed when deciding on the orientation and coordinate system to be used for mass properties measurements.

Moment of inertia can only be positive, so there is never any uncertainty regarding sign. However, you should determine whether this magnitude should be expressed about the geometric centerline of the vehicle or about its CG, about an axis parallel to the geometric centerline or rotated so the data is about the principal axes. In most cases, there will not be a big difference in these three magnitudes. This can lead to confusion, since it will not be immediately obvious that the wrong data is being presented. Mass properties instruments are commercially available which report MOI and CG relative to the instrument centerline and also relative to the payload datum and coordinate system.

Center of gravity coordinates can be positive or negative. You should determine whether your positive axis agrees with the definition of axes used by the recipient of your data. Furthermore, CG distance can be expressed along a coordinate system defined by the geometry of the vehicle or along the principal axes. It is recommended that you provide a sketch that clearly shows the axes and their algebraic signs.

Product of inertia can also be positive or negative. Since this quantity is derived by multiplying the incremental masses by two different distances, the POI sign is even more prone to error than the sign of the CG data. What usually happens is not that the sign is wrong, but that the mass properties engineer and the recipient of his data are using different coordinate systems.

Moment of inertia is expressed about an axis. CG coordinates can be expressed as a distance along an axis or as an unbalance moment about an axis (CG along X corresponds to the CG unbalance moment about Y or Z). POI is relative to two axes (or it can be a tilt angle in a plane defined by two axes).

Six types of information are required to establish a mass properties reference system:

1. The location of the reference axes origin
2. The mathematical symbols or names used to define the reference axes
3. The zero point along each axis
4. The direction of positive values along each axis
5. The positive direction for rotation about each axis
6. A zero rotation angle reference about each axis

9.3.2.3 Standard Coordinate Systems

Aircraft Coordinate System The standard coordinate system defined by the geometric shape of an aircraft is a right-hand rule system as depicted in Figure 9.1. The X , or roll axis, is a line from the nose (or more commonly from a point forward of the nose) of the aircraft to the tail. The Y , or pitch axis, is a line from one wing tip to the other, and the Z , or yaw axis, is a vertical line through the CG of the aircraft. This standard convention is designated as A by Society of Allied Weight Engineers (2006). Measurements are positive when going toward the tail from the origin on the X -axis, to the right (when looking forward) on the Y -axis, and up on the Z -axis.

Spacecraft Coordinate System The geometric coordinate system for satellites, reentry vehicles, or any other space flight object that orbits the Earth is a right-hand rule system

FIGURE 9.1 SAWE standard A, aircraft coordinate system.

as shown in Figure 9.2. In this standard convention commonly referred to as *S*, the positive *X*-axis points in the direction of motion during orbital flight, the *Z*-axis points toward Earth. The *Y*-axis runs transversely, perpendicular to the *Z*-axis. The origin of the *S* coordinate system can coincide with the nominal CG of the vehicle or may be located at a well defined hard point, a specific point on the vehicle which can be accurately measured and identified. If the vehicle has thrusters, their centerlines usually pass through the nominal CG and the intersection of thruster centerlines is the origin.

From the origin, points aft on the *X*-axis are considered positive, points to the right, or starboard, of the origin on the *Y*-axis are typically positive, and points down the *Z*-axis are positive.

Ship Coordinate System The forward standard coordinate system is a left hand rule system for marine vehicles as shown in Figure 9.3. This coordinate system is used with framing conventions originating at the forward perpendicular (FP) and ending at the stern.

FIGURE 9.2 SAWE standard coordinate system for spacecraft (*S*).

FIGURE 9.3 Standard ship coordinate system.

The X-axis is oriented at the baseline along the centerline of the ship. Longitudinal dimensions are measured along or parallel to this axis with the origin at the forward perpendicular. Locations aft of the origin are positive. The Y-axis runs transversely port and starboard. Transverse dimensions are measured along or parallel to this axis with the origin on centerline. Locations to port are positive. The Z-axis runs vertically and dimensions are measured along or parallel to this axis. Locations above the baseline are positive.

The weight moment of inertia of a marine vehicle is calculated relative to a reference origin about the longitudinal X-axis for roll, transverse Y-axis for pitch, and vertical Z-axis for yaw. The reference origin is located at the marine vehicle's center of gravity. A bow up rotation is positive for pitch, a bow to port rotation is positive for yaw, and a port side up rotation is positive for roll (Society of Allied Weight Engineers, 1996).

Other Coordinate Systems The reference scheme for wheeled vehicles is generally a right-hand rule datum as shown in Figure 9.4:

- Longitudinal station (X), forward of the datum is negative and aft of the datum is positive.
- Lateral buttline (Y), right-hand side of vehicle centerline is positive, looking forward.
- Vertical waterline (Z), up above water line 0.0 is positive.

The location of the datum varies between manufacturers and design firms. The reference system shown also may change for ground vehicle dynamic analysis.

9.3.3 Choosing a Mass Properties Instrument

A wide variety of mass properties measuring instruments is available. The choice of which one to use, in part, depends on what properties you want to measure, the accuracy required, the degree of automation required, and budgetary restrictions. If you are measuring center of gravity, you need to determine whether you need to measure along a single axis, or along more than one axis (some CG instruments are only capable of a single axis measurement). In addition, you need to choose the size of the instrument. This is usually

FIGURE 9.4 Standard wheeled vehicle coordinate system.

governed by the weight or physical size of the largest object you need to measure (Society of Allied Weight Engineers, 2006).

Since CG sensitivity decreases as the size of the instrument gets larger, the selection of an instrument may involve a trade-off between cost and current and future capacity needs. This can result in the selection of too large an instrument, resulting in limited accuracy for the present requirements.

9.3.3.1 Properties to Measure There are instruments available that measure only one mass property, and many instruments that can measure two or more mass properties. Using a combined function instrument often eliminates the effort, cost, and risk involved in moving the test item to another instrument or fixture.

The requirements for what properties to measure will help define the instruments needed for the measurement:

Need to Measure Both CG and MOI: In order to measure MOI, you will need an instrument with a gas or oil-bearing rotary table.

Need to Measure Both CG and Weight: Multiple-point weighing instruments have this capability. These instruments are available with load-cell technology or with the more accurate force-cell technology.

Need to Measure Both CG and POI: If you have a requirement to measure dynamic imbalance (POI) as well as CG, then a spin balance machine would be a good solution, particularly if your goal is to balance the test object for minimum POI and CG offset about a particular axis. Some spin balance machines are available with a separate static CG feature. This improves CG measurement accuracy over what would normally be available with a spin balance machine.

Need Maximum CG Accuracy: Instruments with a gas-bearing rotary table and force restoration moment measuring technology are the most accurate.

Need an Explosion Proof Design: Most types of mass properties measurement equipment are available with this option.

Need to Measure CG of Objects Weighing More than 25,000 lbf: Three-point reaction force machines have been made to measure objects as heavy as the space shuttle. Gas-bearing rotary table machines are currently limited to about 25,000 lb (11,340 kg) because of practical problems and cost involved in building gas bearings larger than this.

9.3.3.2 Instruments and Methods A summary of instruments and their principles and characteristics is shown in Table 9.2.

9.3.4 Fixtures

The major source of error in most mass properties measurements is the inability to accurately define the position of the object being measured relative to the measurement axis of the instrument. This is usually accomplished using a precision fixture that supports and locates the object. As described in Society of Allied Weight Engineers (2006), mass properties fixtures must perform three basic functions

1. The fixture must support the payload in a repeatable manner relative to the mass properties instrument.
2. The fixture must provide a means to precisely relate the payload coordinate system to the mass properties instrument coordinate system.
3. The fixture must secure the payload to the mass properties instrument rigidly to minimize all modes of deflection during measurement.

9.3.4.1 Fixture Interfaces There are four basic types of object-to-fixture interfaces

1. *Attachment Point Interface* where the fixture emulates the actual interface between the object and a mating part. This is suitable for rocket/missile stages.
2. *Hard Point Interface* where a system of hard points or rings built into the object being measured is used for inspection, alignment and assembly reference.
3. *Adjustable Interface* where the object has no well-defined hard points and a sophisticated (and time-consuming) method must be used to determine the position of the axes. The fixture is then adjusted to move the object so its axes are coincident with the machine axes.
4. *Calculated Interface* where the object is placed in approximately the correct position, a measurement is made with the object in this position, electronic probes or other means sense the position of the object relative to the machine, and the data are then corrected mathematically so it is expressed relative to the object axes.

Cylinders and other objects having an axis of revolution, such as cones, ellipsoids, and stepped cylinders, can usually be supported on a V-block when measured horizontally, as shown in Figure 9.5. Some objects that are not cylindrical can be mounted in rings so they can be treated as cylinders.

More information on fixtures and fixture design guidelines may be found in Society of Allied Weight Engineers (2006).

TABLE 9.2 Summary of Instruments' Principles and Characteristics

Measurement System Function	Typical Weight Capacities	Operating Principle and Features	Characteristics (R = Range/Sensitivity)
Mass only	1 kg to hundreds of tons	Single purpose. Calibrated in mass or weight units	Wide range of capacities, styles, accuracy and prices. Spring scales: low accuracy and cost Strain gage type: $R = 1/2000$ – $1/10,000$, medium cost, capacities 500 g–50,000 kg Force restoration: up to $R = 1/12,000,000$, highest cost, capacities to 6,000 kg
CG (moment) only	120–500 g	Single sensitive axis, force restoration transducer	High sensitivity for small to medium parts. Requires separate weight measurement to determine CG offset distance
CG (moment) only	1–15 kg	Manually operated rotary table LVDT transducer	Rugged. Not well suited for tall parts. Requires separate weight measurement to determine CG offset distance
Mass and CG	5–10,000 kg	Multi-point weight and CG table	Medium to high capacity, modest accuracy, fast operation. Measures both weight and two axes CG location simultaneously. Well suited to high volume measurements
MOI only	100 g–120 kg	Torsion pendulum with low tare collets for mounting payloads	Manually operated small instruments have very low tare and high accuracy (to 0.01%); Measures MOI about instrument centerline only. Tolerates small CG offset moment
MOI only	250–6,000 kg	Gas-bearing table with torsion pendulum	Large manually operated instruments have good accuracy (to 0.1%) and relatively low cost. Can report only MOI about instrument centerline. Tolerates moderate CG offset moment

(continued)

TABLE 9.2 (Continued)

Measurement System Function	Typical Weight Capacities	Operating Principle and Features	Characteristics (<i>R</i> = Range/Sensitivity)
CG and MOI	5–10,000 kg	Gas-bearing rotary table force restoration transducer for CG; torsion pendulum for MOI	Wide range of capacities available High accuracy. Typical <i>R</i> for CG = 1/30,000 One instrument covers wide range of payloads. Requires separate weight measurement to determine CG offset distance
CG, MOI, POI, static and dynamic balancing	5–6,000 kg	Gas-bearing rotary table. Spin balance 2-plane force measurement for POI. Dynamic CG torsion pendulum for MOI. Force restoration transducer for static CG	Spin speeds from 20 to 800 RPM for POI and dynamic CG measurement. Static and dynamic balancing. Static CG and MOI comparable to above instrument Requires separate weight measurement to determine CG offset distance

FIGURE 9.5 Generic V-block fixture.

9.3.4.2 Defining the Instrument Axes High accuracy mass properties machines have a mounting table that rotates, making it easy to determine the measurement axes with great precision. The measurement axis is simply the center of rotation of the object-mounting table. Often the object can be dial indicated to align the object with this axis.

CG instruments that use the two-, three-, or four-point weighing method do not have a rotating mounting plate and, therefore, have no well-defined measurement axis. This constitutes a major source of error and is one of the reasons why the three-point reaction force method of CG measurement is less accurate than the rotating table method.

9.3.4.3 Work Reversal Method Whether a fixture is generic or custom designed for a unique payload, its relationship to the instrument coordinate system must be accurately established. If the fixture has been properly designed, its location will be highly repeatable on the mass properties instrument. It is often more cost effective to let the instrument determine the location of the fixture datum relative to the instrument than it is to attempt manufacturing to extremely close tolerances. One of the simplest and most effective means to do this is called work reversal.

Figure 9.6 shows how work reversal is used to determine the true CG offset of a cylinder from its centerline, as well as the V-block centerline offset from the instrument centerline. It is important to note that the part used for this test must be cylindrical and well within the allowable CG tolerance. The CG location of the payload, or a mass model, is measured. The part is then rolled 180° in the fixture and remeasured. Half the difference between the two measurements is the CG offset from the cylinder centerline, while half the sum of the two measurements is the fixture centerline offset from the instrument zero.

The same method can be used to determine the end stop location using a mass model with a known length. The average CG location, as measured from both ends, must be located at a distance equal to half the length of the part.

FIGURE 9.6 Finding V-block offset by work reversal.

9.4 WEIGHT AND MASS MEASUREMENT

Weight and mass measurement can be as simple as stepping on a bathroom scale or as complicated as using multiple load cells to weigh an aircraft. In most cases, the method and instruments must be chosen carefully to achieve the needed accuracy. The sources of error or uncertainty must also be understood.

9.4.1 Types of Scales

Although spring and balance scales are still used, nearly all precision scales currently in use have electronic digital displays and computer interface capability. The most common scales still use strain gage load cells with typical accuracy of one part in 2000 (0.05%). These scales lend themselves to computer interfacing at relatively low cost. Pulsed DC power supplies and linearization circuits have allowed accuracies to one part in 5000 (0.02%) at slightly higher cost (Society of Allied Weight Engineers, 2006).

The next level of price with improved rangeability comes with new ceramic capacitive strain gages. These scales can be made with accuracies up to 0.002%. Transducer stiffness is comparable with strain gage beam cells. These transducers have one drawback: they can be damaged if a hard object is dropped on the scale, since the ceramic spring is brittle and cannot withstand shock. Some newer scales using this technology incorporate spring shock dampers to eliminate this problem.

The biggest innovation has been the application of force restoration technology to weight measurement. This technology has been in use since the late 1950s in both electronic and pneumatic process control transducers. The newest generation of electronic force rebalance transducers can achieve accuracies on the order of one part in 10,000,000 (0.00001%) in laboratory balances.

In the more common bench scale ranges up to 25 lb (11.34 kg), the accuracy can approach 0.0001%. In the larger sizes, 75–13,000 lb (34–5,897 kg), accuracies are typically 0.004–0.002%. At this time, the load range available is from micrograms to 13,000 lb (5,897 kg).

These scales are highly programmable to accommodate many weighing conditions: stability (i.e., animal weighing), parts counting on weight basis, selectable units of measurement, and so on. They are fully compatible with computer interfacing. The major disadvantages are price, and slow response time. The slow response time is due to the use of a closed loop rebalance circuit. The slow response time also limits them from being used for dynamic measurements.

9.4.1.1 Force Restoration Principle In a scale that is designed with the force restoration principle, when a load is applied, the transducer deflects. A current driven restoring force is applied through a closed loop control system until the unloaded geometry is restored. The applied current is then related to the applied force. Since the loaded geometry after the restoring force is applied is the same as the unloaded geometry, the transducer is inherently linear like the time honored balance beam scale. This is unlike the strain gage load cell that relies on the deformation of the sensitive spring element to generate an output. High accuracy mass properties measuring instruments for static CG and moment measurement use this force restoration technology.

9.4.1.2 Corner Loading Error When a scale manufacturer quotes the accuracy of his scale, usually he is referring to the accuracy when an object is placed on the platform so that its CG is in the center of the scale. If you place the object off-center, then a moment will be created which tends to tip the platform of the scale. On many scales this will introduce an error. Depending on the internal mechanism in the scale, this error can be as large as 0.5%. High quality scales use parallel beam flexing and other compensating mechanisms, so that this effect can be as small as 0.001%. You can test the scale you are using by first placing a test weight in the center of the scale and measuring its weight. Then you move the weight to each of the corners of the scale and remeasure the weight. You may be surprised at how large the change is. This type of error is the major limiting factor when using two or more scales to determine CG. Placing an object on two scales simultaneously introduces side forces on the scales. Since the CG position is determined by small differences in weight measurement, huge CG errors can result from this side load (corner loading) effect.

9.5 CENTER OF GRAVITY MEASUREMENT

9.5.1 Repositioning Methods of CG Measurement

A basic method of CG measurement is the free-pivot method where the test object is balanced on a pivot and allowed to tilt. The test object is moved relative to the pivot of the instrument until a balance is obtained. Some means is then required to measure the final position of the object. This method of CG measurement is inexpensive, very time-consuming, and generally the least accurate of all methods.

9.5.1.1 Broom Handle Method The simplest method of measuring CG is to balance the object on a round rod. This method only works if the object has a low profile with a rigid surface that will not be indented if its entire weight is supported on a narrow rod, and the surface of the object is flat and smooth.

Since the total CG of the test object lies above the pivot axis, the object can tip in either direction when the pivot point is near its CG. This deadband results in an error in

FIGURE 9.7 Hanging pivot method of CG measurement.

CG location. The magnitude of this error is proportional to the amount of angular tilt of the test object, which is permitted. Reducing this tilt will decrease the magnitude of this error. However, the small amount of travel makes the instrument extremely tedious to operate; there is no advance warning that the balance point is being reached and extremely fine adjustments of the test part position must be added to prevent overshooting this very narrow point.

9.5.1.2 Hanging Pivot Method If an object is suspended from a knife-edge, the CG of the object will lie below the center of pivot of the knife-edge. In this method, the position of the test object is moved relative to this pivot point until a balance condition is achieved (see Figure 9.7).

Hanging systems such as this one where the test object CG is always below the pivot point have the disadvantage that their sensitivity is low. Shifting the lateral CG of the test object results in only a small change in the level condition of the instrument. The amount of tilt, which results from a CG offset, is a function of the CG height difference between the object and the knife-edge. Reducing this distance increases sensitivity. However, it also increases measurement time, since the object rocks back and forth at a slower rate when sensitivity is increased. Each time the item is moved, the operator must wait for the system to settle again. In this respect, this method is like using the old beam balance scales.

The sensitivity of the instrument is directly dependent on the accuracy of the means used to detect the level of the instrument. Even the smallest error in the position of the bubble level relative to the structure of the instrument results in a large error in measured CG location.

Since there is no readout to indicate how far to move the object, the process is strictly trial and error. The initial cost of this method is the lowest of any type of CG measuring technique, but often the labor required to make a measurement more than offsets the cost, causing this method to be in fact, the most expensive of all techniques.

Once you have obtained an accurate balance, you must relate the final position of the object to the pivot axis of the knife-edge using something such as a transit and a coordinate measuring machine (Boynton and Wiener, 1998).

9.5.2 Multiple-Point Weighing Method

The multiple-point weighing method can be used for the combined measurement of weight and CG. In this method, a test platform is supported by three (or more) load cells as shown in Figure 9.8. The CG location is calculated from the relationship between force measurements at these points. In the past, the accuracy of this method has been limited by the dynamic range of load cells, so that these instruments were not suitable for projectile and missile measurements. The introduction of force rebalance technology to CG measurement has reduced force measurement uncertainty by a factor of 30. When this technology is applied to the multiple-point weighing method, accuracy improvement is great enough so that this method now becomes acceptable for many applications (Society of Allied Weight Engineers, 2006). Weight is the sum of the transducer readings

$$W = A + B + C \quad (9.2)$$

where A , B , and C are force readings on the three force transducers.

To determine CG, one takes moments about A where X and Y are the CG measurement coordinates. If all the transducers outputs are set to zero when fixturing is in place, Equations (9.3)–(9.7) are used to determine the CG location of the test part (see Figure 9.9). In practice, tare readings are subtracted from the part measurements and the values represent the net A , B , and C forces required to support the part weight and CG offset moment.

$$\sum M_x = (B + C)L - WX = 0 \quad (9.3)$$

$$\sum M_y = \frac{CD}{2} - \frac{BD}{2} - WY = 0 \quad (9.4)$$

FIGURE 9.8 Multipoint weight and center of gravity principle.

FIGURE 9.9 Free-body diagram of the multipoint weight and center of gravity principle.

$$= \frac{D}{2}(C - B) - WY \quad (9.5)$$

$$X = \frac{(B + C)L}{W} \quad (9.6)$$

$$Y = \frac{(C - B)D}{2W} \quad (9.7)$$

Each force transducer supports an equal load when the payload CG is centered. However, with this type of instrument, each force transducer should be capable of supporting the full weight of the payload to allow for CG offset. Since sensitivity and accuracy of force transducers are inversely related to their capacity, sensitivity of this weight–CG configuration is quite limited. An alternative configuration, the piggyback design, shown in Figure 9.10, uses one large high sensitivity weight platform to support the payload and two high sensitivity force transducers to measure CG offset moments. The payload CG is

FIGURE 9.10 Weight CG “piggyback” arrangement.

supported over a flexible hanger support, which transfers the load to the weight platform. If the CG is not directly over the support, the unbalance moment is supported by the sensitive moment transducers, which are located at a known distance from the support. This configuration combines high CG sensitivity with high load capacity. It is best suited for a dedicated product in a high production environment.

The disadvantage of these methods is that leveling errors cannot be readily detected or corrected, and the datum is not as well defined as on a rotary table.

9.5.3 CG by MOI Method

In the MOI method for finding an object's CG, the test object is mounted on an inverted torsion pendulum (moment of inertia instrument, see Figure 9.13), and successive moment of inertia measurements made for at least three positions of the test object. The CG location can then be calculated from the small change in the MOI, which results from moving the principal axis of the object.

Center of gravity is determined on a torsion pendulum by making use of the parallel axis theorem. If the moment of inertia of the object about axis *A–A* through its CG is I_A , then the moment of inertia through axis *B–B* is

$$I_B = I_A + d^2M \quad (9.8)$$

where M is the mass of the object and d is the distance between axis *A–A* and axis *B–B*. Note that the minimum measured moment of inertia of an object occurs when the axis of measurement coincides with the CG of the object.

In practice, the CG (along one axis only) can be determined by mounting the object in a V-block fixture on an MOI instrument and taking several MOI measurements with different object positions. The position that results in the smallest measured MOI is one where the CG is coincident with the axis of measurement. This can be a tedious procedure and is prone to position measurement errors. A better method is to measure MOI at three known positions and calculate CG from this data using methods described in Boynton (1977) and Boynton and Bell (1981).

If the displacements between the three measurement positions are made small, then the sensitivity of this method is abysmal. Accuracy of better than 0.1 in. (2.54 mm) is difficult to obtain. If the displacements are made large relative to the radius of gyration of the test object, then the accuracy improves from a theoretical standpoint. However, torsion pendulums do not operate successfully with large CG offsets, due to the gravity pendulum error, so that the increased measurement error partially offsets the gain in sensitivity, and the accuracy of measurement is still worse than other methods.

9.5.4 Spin Balance Method

In this method, the test object is rotated and force transducers sense the reactions on the bearings that support the part during rotation (see Figure 9.11). These forces are due to both gravity and centrifugal force (the higher the spin speed, the less significant the gravity force is). The CG location of the part may then be separated from the dynamic unbalance of the part using calculations that involve the magnitude of the bearing forces and their phase relationship. Spin balance machines rotate the test

FIGURE 9.11 The spin balance method of CG measurement is expensive and has limited accuracy.

item at speeds ranging from 20 to 10,000 RPM, and measure the reaction forces acting against the bearings in the machine due to dynamic unbalance (a combination of CG offset and product of inertia).

At first analysis, it might appear that it does not make any difference whether CG is measured in a static or a dynamic mode. However, there are a number of considerations that make the spin method of CG measurement unsatisfactory. If one needs to measure the longitudinal CG of a long test object (e.g., 10 m long rocket), then static measurement is the only practical way. Spinning such a test object would require tremendous power and generate high winds in the test laboratory. If you are measuring the CG of a partially filled fuel tank, then the fuel will ride up the sides of the tank if you spin it, because of the centrifugal force. This results in an erroneous CG measurement. If the test object has extended solar panels, then centrifugal forces may damage or deflect them. For objects with a large CG offset, the force limits of the transducers will be exceeded if you spin the part. If a part has a very large product of inertia unbalance, CG measurement will be more accurate in the static mode, since the small CG forces do not have to be separated from the larger POI forces. Finally, and perhaps the most important consideration, when an irregularly shaped object is spun, aerodynamic forces cause large variations in the measured CG offset, severely limiting measurement accuracy.

9.6 MOI MEASUREMENT

The moment of inertia is the rotational inertia of an object about a defined axis. MOI for a rotational body is analogous to mass for a body in linear motion. The moment of inertia can be measured by hanging an object from a wire, twisting it to start it oscillating, and then timing the period of oscillation. If more accuracy is desired, an inverted torsion pendulum instrument is required.

9.6.1 Hanging Wire Torsion Pendulum

Although hanging wire pendulums are usually not accurate enough for satellite and missile measurements, they are useful for measuring the MOI of large objects such as an aircraft.

This method consists of hanging an object from a wire, twisting it to start it oscillating, and then timing the period of oscillation. Although it might appear to be a simple device, the structure required to support the upper end of the wire can be very expensive, and some accurate means is required to time the period of oscillation. One problem with the hanging wire method is that the object swings from side to side and rocks up and down rather than rotating smoothly about an axis, making it difficult to acquire accurate time period data.

It is essential that the center of gravity of the object be aligned horizontally with the wire. Otherwise, the moment the object is released, there will be a couple generated and the motion of the pendulum will be sideways as well as torsional. In addition, the payload will tip to bring the CG directly under the wire.

A single hanging (steel) wire has a torsional stiffness (k) that is proportional to the fourth power of the diameter

$$k = \frac{1,178,000d^4}{L} \text{ in.-lb/radian} \quad (9.9)$$

where L is the length of wire and d is the diameter (in.) of wire.

The equation of motion for this pendulum is

$$I = Ct^2 = \frac{kt^2}{4\pi^2} \quad (9.10)$$

where t is the time for one complete period of oscillation and C is a calibration constant.

However, the actual period of oscillation will not follow this formula because the wire stretches under load, and there will be both a swinging pendulum effect and a rocking pendulum. Typical measurement uncertainty with this method is about 3%.

9.6.2 Bifilar Suspension

A frequently used method of determining the inertia of an object about one axis is the bifilar pendulum method. This is a relatively inexpensive measurement method and is easy to set up for many regular shaped objects. This method avoids some of the problems associated with a single wire pendulum such as the need to make numerous wire diameter measurements.

The general arrangement of the bifilar suspension method is shown in Figure 9.12. Since both suspension wires must be spaced equally from the center of gravity of the test object, and since both wires must be of equal length, this method may be difficult to set up for irregular shaped objects.

The equation governing this inertia is

$$I = \frac{Wd^2t^2}{16\pi^2L} \quad (9.11)$$

FIGURE 9.12 MOI measurement (in this case yaw) using bifilar suspension method.

where W is the weight of the object, d is the distance between the suspension wires, t is the time in seconds, and L is the length of the wires. To get the inertia in mass units, I must be multiplied by gravitational acceleration, g .

Typical measurement uncertainty for the bifilar method is about 2%, with experienced individuals routinely achieving 1% by selecting cord spacing and lengths and averaging numerous measurements.

9.6.3 Inverted Torsion Pendulum

Modern moment of inertia instruments consist of an inverted torsion pendulum that oscillates in a rotational sense and a means of measuring the exact period of oscillation of the torsion pendulum. Instead of hanging from a torsion rod or wire, the test object rests on a precision rotary table attached to the top of the instrument. Low friction bearings support the table and payload while constraining the motion of this torsion member to pure rotation (see Figure 9.13). Air bearings provide the best performance.

The measurement of the moment of inertia of the test part is based on the change in the natural frequency of oscillation of the torsion pendulum resulting from the addition of the test part mass. This change in natural frequency is compared with the change in natural frequency that occurs when a calibration mass of known moment of inertia is placed on the instrument.

In this process, the object is secured to the table with its CG aligned with the axis of the bearing. The part is rotated and released. It will then oscillate about the fixed axis of the instrument and the total time for one complete oscillation can be displayed on a digital period counter. The total combined moment of inertia of the test object, its fixture, and the instrument itself can be calculated from the formula

$$I_x = Ct_x^2 \quad (9.12)$$

where I_x is equal to the total moment of inertia, C is the calibration constant of the instrument (a function of its torsional stiffness), and t_x is the period of oscillation in seconds. Then the test object is removed from the instrument, and the tare moment of inertia of the instrument and the fixture is determined by measuring the oscillation

FIGURE 9.13 MOI measurement using inverted torsion pendulum.

time without the test object.

$$I_o = Ct_o^2 \tag{9.13}$$

The moment of inertia of the test object is then the difference between the total inertia and tare inertia.

$$I = I_x - I_o = \text{net moment of inertia of object} \tag{9.14}$$

In order to establish the value of the calibration constant, C , of the instrument, MOI calibration standards are measured. MOI calibration standards are precision weights of simple geometry, known mass, and known physical dimensions.

The calibration procedure is identical with the procedure for measuring the moment of inertia of an object of unknown MOI, except that in the computation, the inertia is a known quantity and the value of the calibration constant is the unknown, which must be solved for.

Because the weight of the object is supported by the air bearing, these instruments are linear over a wide range of test part weight and moment of inertia. Only a single calibration measurement is required to establish the value of the calibration constant used for all measurements.

9.6.4 Combined CG and MOI Measurement

For combined CG and MOI measurements, a spherical gas-bearing instrument, as shown in Figure 9.14, is used. In this type of instrument, the test object (and fixture) is supported by a spherical gas bearing (Society of Allied Weight Engineers, 2006). An overturning moment restraint is provided by a hollow tube, which extends from the base of the

FIGURE 9.14 Basic elements of a spherical gas bearing type of instrument.

spherical bearing. The lower end of this hollow tube is attached to a second (cylindrical) gas bearing, which is connected through a moment rebalance transducer to the rigid instrument base structure. For maximum accuracy, the overturning moment produced by a displacement of the test object CG from the center of rotation of the table is sensed using this force restoration transducer. Measuring this moment and dividing by the test object weight yields the CG displacement from the center.

A torsion rod extends downward from the upper surface of the bearing (the rotary table) to a clamping mechanism at the bottom of the rod. When this clamp is released, the spherical bearing is free to turn about the vertical axis for CG measurement and when clamped, the machine is converted to a torsion pendulum for MOI measurement.

When the rotary table concept is implemented with a spherical gas bearing, the resulting instrument is capable of higher accuracy than any other method. Instrument CG measurement uncertainty is typically ± 0.001 in. (0.0254 mm), and moment of inertia measurement uncertainty is 0.1%.

9.7 POI MEASUREMENT

The product of inertia is a measure of an object's dynamic imbalance and is used to determine rotational stabilities of the object.

9.7.1 MOI Method of Measuring POI

This POI measuring method uses a torsion pendulum to determine POI by making use of the mathematical relationship between POI and MOI of an object. Special fixtures must be constructed to move the object to a number of positions while keeping both the object and the fixture CG near the center of oscillation. The moment of inertia of the object is measured in each orientation. The tare MOI of the fixtures must then be measured and subtracted from the measurements with the object. The net MOI of the object in the different orientations is then used to determine the POI of the object. The calculations are quite complex, so a computer is used.

The axes of minimum and maximum MOI correspond to the axes where the POI is zero. The POI is a maximum at an angle of 45° from these principal axes.

If the test part was fixtured so that it could be rotated through an angle C about a horizontal axis (i.e., the Z-axis) and MOI measured about numerous axes in the X-Y plane, including the X and Y axes, the MOI would be found to vary sinusoidally. If the angle C ranges over 180° , the maximum and minimum values of MOI can be seen in a plot of MOI versus C (Figure 9.15).

The axes about which the maximum and minimum MOIs are measured are the principal axes. For all other axes, the moment of inertia I_{Axy} , about an axis (A) in the X-Y plane at an angle C from the +X-axis, and the product of inertia P_{xy} are related through the equation

$$I_{Axy} = I_{yy}\sin^2 C + I_{xx}\cos^2 C - P_{xy}\sin^2 C \quad (9.15)$$

Solving this equation for P_{xy} forms the basis for the MOI method of POI determination

$$P_{xy} = \frac{I_{yy}\sin^2 C + I_{xx}\cos^2 C - I_{Axy}}{\sin^2 C} \quad (9.16)$$

FIGURE 9.15 Minimum and maximum POI values located on principal axes.

POI in a single plane requires three MOI measurements about axes that go through the CG. These measurements are

1. MOI about the yaw axis (I_{xx})
2. MOI about the pitch axis (I_{yy})
3. MOI about an axis at 45° between pitch and yaw (I_{aa}). Note: Any angle C may be used but 45° provides the most accuracy.

These three measurements permit calculating the POI in the pitch/yaw plane using the equation:

$$P_{xy} = \frac{(I_{yy} - I_{xx})}{2 - I_{aa}} \quad (9.17)$$

For the general case, the total number of MOI measurements needed for POI calculations is nine; three in each of three mutually perpendicular planes. The intersections of these planes must be at the CG, so the MOI about each of these axes will be common to two planes, thus reducing the total number of measurements to six: three about the X , Y , and Z axes, and three about axes at 45° between the X - Y , Y - Z , and Z - X axes. If vacuum data are required, the same six MOI measurements must also be repeated in a helium atmosphere (Boynton et al., 1991).

9.7.2 Spin Balance Method

Product of inertia is generally measured using a spin balance machine. In this type of machine, the object is rotated at a fixed speed, and the reaction forces against the upper and the lower spindle bearings are measured. Product of inertia is then calculated automatically by the machine's computer, using formulas that involve the vertical spacing between the upper and the lower bearings, and the height of the payload CG above the mounting surface of the machine. The CG offset of the part may be separated mathematically from the dynamic unbalance of the part.

When the test object spins, there are two forces acting through the CG of the object: gravity forces acting downward and centrifugal forces acting horizontally (the higher the spin speed, the less significant the gravity force is). The magnitude of the downward gravity force is equal to the weight of the object in pounds (M_1). The magnitude of the horizontal centrifugal force is

$$F_1 = M_1 \times R_1 \times S^2 \quad (9.18)$$

where M_1 is the mass of unbalance in slugs, R_1 is the radius of CG in feet, and S is the speed in radians per second.

Converting the mass into weight and the speed into RPM

$$F_1 = \frac{W_1 \times R_1 \times (\text{RPM})^2}{35,207} \quad (9.19)$$

where W_1 is the weight of unbalance mass in lbs, R_1 is the radius of CG of unbalance in inches, RPM is the speed of rotation in RPM, and 35,207 is the constant to transform units.

The horizontal forces applied to the bearings of the balancing machine will depend on the geometry of the balancing machine and the type of unbalance. If neither a CG offset nor a POI unbalance is present in the rotating test object, then the horizontal forces on the bearings will be zero. A POI (with no CG offset) results in equal forces being applied 180° out of phase on the two bearings (the couple due to the product of inertia is offset by an equal couple on the bearings of the balancing machine). A CG offset will cause a different force to be applied to each bearing. In order to evaluate the accuracy of a balancing machine in measuring CG, it is necessary to know the relative values of POI and CG offset. For a flywheel, POI is usually small, and a balancing machine will be able to accurately measure CG offset. For a tall rocket, for example, the reverse is true.

If the goal of the measurement is to ballast the test object for minimum POI and CG offset about a particular axis, then the measurement becomes much more accurate. As the unbalance is reduced in successive iterations, the residual unbalance can be measured on a more sensitive scale. As the magnitude of POI is reduced, the CG sensitivity improves and as the CG offset is reduced, POI sensitivity improves.

To calculate the CG offset from the measured bearing forces, we can make use of the fact that the sum of the moments around each transducer must be zero (since the system is stable). Independent calculations can be made at the X and Y axes, and the resultant of these two calculations determined to yield the magnitude and angle of the CG offset.

Two transducers are required to separate POI from CG offset. In order to separate the unbalance due to POI from the unbalance due to CG offset, it is necessary to use a force transducer on each of the spindle bearings in the balancing machine. Then both CG offset and product of inertia are obtained in a single measurement.

9.8 MEASURING LARGE VEHICLES

9.8.1 General Process

Measuring mass properties of complex vehicles such as ships and aircraft is more complicated than measuring an individual component. This increased complexity is a result not only of the sheer size of the objects but also from the numerous potential configurations of the vehicles. Therefore, the task of measuring large complex vehicles is twofold: first, measuring the vehicle in its current configuration; second, determining the vehicle's standard operating condition. Once the mass properties of the vehicle in a standard operating condition are known, it is possible to calculate the mass properties of any conceivable configuration. Depending on the quantity of variable items on the vehicle, the vehicle may be placed in the standard operating condition prior to the measurement or a comprehensive survey of all variable items may be performed. The resultant answer is more accurate if the vehicle is measured in the standard operating condition, but in many cases such an effort is impractical. For most ships this is the case.

In most cases, only the weight and center of gravity of large vehicles can be measured directly. Other mass properties are normally calculated from component databases or derived from performance testing.

9.8.2 Weighing Ships

Ships are too large to be weighed in the conventional sense. The determination of a ship's weight and center of gravity involves calculations using observed measurements and

calculated volumetric properties (hydrostatics). The primary method for measuring the weight and CG of a ship is the inclining experiment. This experiment provides the displacement of the ship (the weight of the ship in terms of weight of water displaced) and the vertical, longitudinal, and transverse centers of gravity. A ship's MOI and POI cannot be measured and are calculated values.

9.8.2.1 The Inclining Experiment Archimedes' principle states that the weight of a floating object equals the weight of the fluid displaced by that object. This principle is used in the inclining experiment. The ship's drafts (the distance from the keel to the waterline) are recorded, and water samples are taken to determine the water density. Once this information is collected the ship's weight can be calculated by consulting the ship's hydrostatics table, which provides calculated displaced volume for the ship at various drafts. These volumes can be mathematically adjusted for the ship's trim and list and longitudinal flexing of the hull (hogging or sagging).

Once the displaced volume of the ship is known, the weight (displacement, Δ) is determined by multiplying this volume by the density of the water as determined from the samples. The longitudinal center of gravity is determined by locating the center of gravity of the displaced water (also known as the center of buoyancy) as the ship will find equilibrium such that this center is vertically aligned with the center of gravity of the ship.

The vertical center of gravity of a ship cannot be determined by merely reading the ship's drafts because the ship's static attitude is not a function of the vertical center of gravity. In order to determine the vertical center of gravity, the ship is inclined slightly by moving a known weight across the deck of the ship. Moving this weight creates a heeling moment, which induces a list on the ship. By measuring the angle of list (θ), the weight of the movable weight (w), and the distance the weight is moved (d), the distance between the ship's metacenter (KM), and vertical center of gravity (KG) can be determined (see Figure 9.16). The measure of initial stability is called the metacentric height (GM) and can be calculated by

$$GM = \frac{wd}{\Delta \tan \theta} \quad (9.20)$$

The distance from the ship's keel to its vertical center of gravity (KG) can be calculated from the equation

$$KG = KM - GM \quad (9.21)$$

where KM is a property of the ship's geometry which is usually listed for each draft in the ship's hydrostatics table.

Inclining Procedure The basic procedure for an inclining experiment as outlined below has not changed greatly in the past century except for improved instrumentation and data processing:

Inventory or Deadweight Survey: This survey is performed either before or after the inclining experiment. This survey consists of inspecting every compartment of the ship for weights that are not part of the lightship condition (ship without

FIGURE 9.16 Diagram of ship inclining experiment method to measure vertical center of gravity.

consumable loads) and recording their weight and CG. The survey also includes recording missing lightship items.

Draft Readings: In calm water, the ship's draft (the distance from the keel to the waterline) is recorded in several locations (often six; port and starboard at three locations along the ship's longitudinal axis) and water samples are taken to determine the water density.

Weight Movements: As shown in Equation 9.20, a measure of the ship's stability, GM , can be calculated by moving a known weight a known distance athwartships, and recording the resultant list angle. In actuality, a series of weight movements are done and angle measurements taken for each movement. The angle of inclination is normally less than 3° .

Tangent Readings: For each weight movement, the angle of heel is recorded through pendulums or inclinometers. The tangents of the angles are plotted against the heeling moment, and the slope of the fitted line is used to determine the GM :

$$GM = \frac{\text{Slope}}{\Delta} \quad (9.22)$$

Correction to Standard Loads: From the draft readings and the weight movements, the ship's weight and CG is known for the as-inclined condition. The dead-weight survey data are used to calculate the lightship weight and CG, and then standard loads are added to determine the weight and CG of each standard condition. These standard conditions are tracked as part of the normal ship weight control process.

9.8.2.2 Sources of Uncertainty in Ship Measurement The weight of a ship is not directly weighed; therefore, the uncertainty of the result is dependent on more factors than a conventional weighing. These sources of uncertainty can be broken down into factors affecting the accuracy of the draft readings and deadweight survey. Sources of uncertainty in the former include building tolerances, measuring the ship's drafts, uncertainties in the water density profile, and uncertainties in the ship's hydrostatic calculations. Sources of uncertainty in the deadweight survey are largely related to data recording and estimates of the weights of the variable items, but also include uncertainties due to the build tolerances and calculated capacities of tanks. Liquid loads on a ship can be a significant portion of the total weight; thus the uncertainty of the loads is often dominated by the uncertainty of the liquids.

Greater detail on the uncertainties associated with an inclining experiment or a dunnage survey can be found in Shakshober and Montgomery (1967), Tellet (2005), and Cimino and Tellet (2007).

9.8.3 Weighing Aircraft

Unlike ships, the mass properties of an aircraft are determined directly by the use of calibrated scales and dimensional readings of the complete vehicle. The two main mass properties of interest are the weight of the aircraft and its horizontal center of gravity. These measurements should be performed on all new aircraft and after each major upgrade or overhaul that impacts the vehicle's configuration. This information is critical to the safe and efficient performance of the aircraft. There are many cases in which the mass properties of the plane have been neglected and damage to the plane has occurred during loading, or even the worse the plane suffered a loss of control during takeoff and crashed with serious consequences.

9.8.3.1 Weighing Preparation Proper premeasurement preparation is essential to obtaining an accurate and precise weight and CG for the aircraft. The craft should be as close as possible to its basic configuration with no fuel or load items such as bombs, munitions, crew members, or equipment not having a fixed position onboard the aircraft. All liquid reservoirs and tanks should be empty or filled to normal capacity. The hydraulic fluid reservoir and all other reservoirs containing contents required for the normal operation of the aircraft should be full. All waste tanks should be empty. An aircraft should never be weighed with partially filled tanks or reservoirs.

All fuel should be drained in accordance with manufacturer's instructions. Any fuel remaining in the system after draining should be considered part of the empty aircraft weight. If it is not feasible to drain the fuel, the fuel tanks should be topped off and the weight of the fuel and its moment subtracted from those of the weighed aircraft. Engine lubricating oil should also be treated similar to fuel.

All permanent ballast must be properly installed and any temporary ballast removed from the aircraft prior to weighing.

A complete inventory of all onboard equipment should be conducted before weighing identifying each piece of onboard equipment and its weight and location.

The aircraft to be weighed should be in a clean condition. All dirt, grease, and moisture should be eliminated and sufficient time should be provided for the aircraft to dry prior to weighing. The aircraft should also be positioned in a closed hangar with no blowers or ventilation systems impinging on any surface of the aircraft. The slope of the floor should

be as level as possible, not exceeding 0.25 in./ft (21 mm/m). Further information on the preparations required prior to weighing an aircraft can be found in United States Air Force (2008) and Federal Aviation Administration (2007).

9.8.3.2 Weighing Equipment and Procedures There are two types of scales used to weigh an aircraft. In the first type, scales are onto which the aircraft is rolled so the weight can be read at each wheel. In some cases, scales are portable and can be used in any hangar; and in other cases, large scales are permanently installed flush with the floor. In both instances, the aircraft is rolled onto the scale surfaces, and weight of the aircraft is read directly on an electronic readout. This type of weighing completely eliminates the need for jacks and the risk of side loads which can be present. The second type employs electronic load cells that are attached to axle jacks or wing jacks. When the aircraft is raised and leveled, the weight is measured by the load cells and transmitted electronically to a readout device. Other accessories that are used during weighing are a spirit level, leveling bars, plumb bobs and chalk lines, steel measuring tapes, and hydrometers for measuring the density of fuel or oil. Figure 9.17 shows the arrangement of an aircraft weighing using three load cells.

The basic weighing procedure using platform scales is as follows:

1. Zero the scale.
2. Tow aircraft onto the scales.
3. Level the aircraft.
4. Read the scales and make dimensional measurements for CG calculations.
5. Remove the aircraft from the scales.

The basic weighing procedure to be followed when electronic load cells are employed is as follows:

1. Level the aircraft.
2. Position the jacks below jack pads or designated lifting points.
3. Remove all chocks and release brakes.
4. Jack the aircraft in accordance with jacking instructions using all jacks simultaneously.

FIGURE 9.17 Weighing an aircraft using three load cells.

5. Level the aircraft.
6. Read the scales for weight and make dimensional measurements for CG determination.
7. Lower the aircraft and remove the jacks and load cells from the aircraft.

More detailed information on the process for weighing an aircraft may be found in United States Air Force (2008).

9.8.3.3 CG Determination The horizontal CG of an aircraft is determined by dividing the total horizontal moment by the total weight of the vehicle. When the plane is at a level attitude, a plumb line is dropped from a datum point (an easily identifiable physical location usually specified by the manufacturer from which measurements can be made) to the floor below. A chalk line is then drawn through the point parallel to the longitudinal axis of the aircraft. A lateral line is then drawn between the actual weighing points (main wheels) and the point is marked along the longitudinal line at the weighing point for the other (nose or tail) weighing point. These lines and marks allow accurate measurements between the datum and the weighing points to determine their moment arms. The CG is then determined by adding the weight and moment of each weighing point to arrive at the total weight and moment. Dividing the total moment by the total weight results in the CG relative to the datum.

The location of the CG may be expressed in terms of distance from the datum point or as a percentage of the leading edge mean aerodynamic cord (MAC) which is located a specified distance from the datum by the manufacturer. For a more detailed description of determining the CG of an aircraft refer to United States Air Force (2008) and Federal Aviation Administration (2007).

9.8.3.4 Sources of Uncertainty in Aircraft Weighing The main sources of uncertainty in the weighing of an aircraft are inaccuracies in the inventory of the equipment onboard, inaccuracies in the scales being used, or human error in the performance of the weighing activity. The only other major source of uncertainty involves the aircraft and its interaction with its surroundings. Every precaution should be taken to ensure that the aircraft is not acted upon by any force that will induce any loading, horizontal or vertical, on the aircraft being measured. This is the reason for the closed hangar and turning off blowers or ventilation fans described in the preparation for weighing. The scale used should be calibrated, exercised, and zeroed in strict accordance with the manufacturer's instructions to ensure its accuracy and repeatability. It is good engineering practice to perform the weighing at least twice to reduce the chance for error.

9.9 SOURCES OF UNCERTAINTY

As in all engineering fields, there are uncertainties in the measurement of mass properties that must be considered. The previous sections have touched on the relative accuracies of specific instruments or methods. Following are some specific sources of uncertainty that should be considered in any mass properties measurement.

9.9.1 Weight Uncertainties

The mass of an object is fixed and is the same whether the object is on the Earth or in outer space. Weight, on the other hand, is a force that depends on several factors that are related to the location of the scale. With the advent of force restoration technology, it is possible to measure an object at different locations on the Earth and observe significantly different values for weight.

The force a mass exerts on a scale is affected by four factors:

1. The gravitational mass attraction to the Earth at a particular location, which is in part related to the altitude and latitude of that location.
2. The gravitational mass attraction to the sun and moon at the particular location, which may reach 0.003% of the acceleration of Earth's gravity at certain dates during the year when the sun and moon align.
3. The centrifugal force due to the rotation of the Earth, which varies from zero at the North Pole to a maximum value at the equator.
4. The buoyancy of the object as it floats in a sea of air. This can be compensated for by determining the enclosed volume and calculating the weight of the displaced air (the density of which can vary due to the weather).

These factors combine to result in a change in the weight of an object of almost 1% over the surface of the Earth, and about 0.2% over the contiguous United States. If a mass weighs 100 lb (45.36 kg) at one location in the United States, it could weigh 99.8 lb (45.35 kg) somewhere else in the United States. To get around this problem, mass is used (rather than weight) to standardize and calibrate scales. To calibrate a scale, a standard calibration mass is placed on the scale. The scale is then adjusted until it reads the appropriate standard weight. The standard weight is the weight the mass would have at standard gravity (32.17405 ft/s^2 or 9.80665 m/s^2).

The traditional "Scales of Justice" balance beam compares one mass against another mass; therefore, the measurement does not vary with changes in gravitational field strength.

A problem occurs when a scale is calibrated at one location and then moved to another location to weigh an object. For large scale capacities, it is often not possible to bring a calibration weight to the new site, either because this weight is not available, or because of the problems of shipping a calibration mass weighing many thousands of pounds. Therefore, it is necessary to correct for the change in the acceleration of gravity between the site where the scale was calibrated and the site where the object is being measured. The National Geodetic Information Center in Rockville, MD (<http://www.ngs.noaa.gov/GRAV-D/>) has data on the weight correction required for many locations on Earth. If these data are not available, then another method to determine the correction is to calibrate a small scale at the first site and ship this scale to the new site, together with its calibration weight. The small calibration weight is then remeasured. If, for example, the measured value of this small weight is 0.05% high, then the acceleration of gravity is 0.05% higher at this new location, and the measurement of the large object must be divided by 1.0005 to correct for this change in the acceleration of gravity.

The following sections discuss in detail the factors affecting weight measurement (Boynton, 2001).

9.9.2 Factors Affecting Weight Measurement

Measured weight is affected by factors from gravity variations as well as influences from local external factors such as environment and test setup.

9.9.2.1 Gravity Effects

Latitude Correction: The most significant variable in determining the acceleration of gravity is the latitude. The acceleration of gravity varies from 9.780 m/s^2 (32.087 ft/s^2) at the equator to 9.832 m/s^2 (32.257 ft/s^2) at the poles (a difference of 0.53%). The value of g is the smallest at the equator (due to the centrifugal force and the bulging of the Earth).

The radius of the Earth is approximately 22 km (13.67 miles) more at the equator than at the North or South Pole, due to the bulge in the Earth, which resulted from centrifugal forces while the Earth was cooling. In addition, the centrifugal force due to the Earth's rotation counteracts the centripetal force due to the attraction of gravity.

The force is

$$F_{\text{cen}} = \frac{m_2 v^2}{R} \quad (9.23)$$

where m_2 is the mass of object being weighed, R is the distance to Earth's rotational axis, and v is the speed (zero at poles; 463 m/s at equator)..

The local value for g at sea level can be calculated using the formula

$$g = 9.80613(1 - 0.0026325 \cos 2L) \quad (9.24)$$

where L is the latitude in degrees and g is in m/s^2 .

Altitude Correction: For locations on the surface of the Earth, the gravitational attraction is inversely proportional to the square of the distance to the mass center of the Earth. Therefore, gravity decreases as you increase altitude (Boynton, 2001).

At sea level,

$$g = \frac{Gm_1}{r^2} \quad (9.25)$$

where G is the universal gravitational constant, $6.67259 \times 10^{-11} \text{ nm}^2/\text{kg}^2$, m_1 is the current accepted mass of Earth in $\text{kg} = 5.9736 \times 10^{24} \text{ kg}$, and r is the mean radius from the center of Earth's mass = 6,378,100 m.

At an altitude h

$$\begin{aligned} g_h &= \frac{Gm_1}{(r+h)^2} \\ &= \frac{Gm_1}{(r^2 + 2rh + h^2)} \\ \frac{g}{g_h} &= \frac{(r^2 + 2rh + h^2)}{r^2} \\ &= 1 + \frac{2h}{r} + \frac{h^2}{r^2} \end{aligned} \quad (9.26)$$

$\frac{h^2}{r^2}$ is extremely small, so we assume $\frac{g}{g_h} = 1 + \frac{2h}{r}$ and thus

$$g_h = \frac{g}{\left(1 + \frac{2h}{r}\right)} \quad (9.27)$$

In addition, the centrifugal force increases as the radius increases, resulting in a further decrease in the acceleration of gravity. This centrifugal effect depends on the latitude. The decrease in g due to rotation is zero at the poles and reaches a maximum of about 1.567×10^{-4} m/s per kilometer of altitude at the equator.

The altitude correction is a relatively small number. If the altitude is increased by 3000 m, then the measured weight decreases by 0.11%. However, high accuracy scales can detect changes in measured weight as small as that which results from an increase in elevation of only 40 m, so the scale should be calibrated at the same altitude as the measurement.

Tidal Variation: An object on the surface of the Earth is attracted to every celestial body. Most of these masses are too far away to have any significance on weight, but the sun and the moon do have a significant effect. If you have a scale with an accuracy of 0.003% or better, you will notice that the weight of an object varies as a function of the time of day. This effect is most pronounced during spring and fall when the sun and moon align.

Correcting for Variations in the Acceleration of Gravity

Method 1: Recalibrate the scale at a new location. Once you have performed a calibration using a mass which is traceable to NIST at a specific location, you have automatically corrected for the acceleration of gravity at the location. No mathematical manipulation of the data will be necessary to correct for latitude or longitude.

Method 2: Correct for the acceleration of gravity by using a small scale and calibration weight. If you have a means of calibrating your scale at one location, but you then need to move your scale to another location and you are unable to bring a large calibration mass to this location, you can accurately determine the correction necessary by the following procedure, which uses an additional small scale and small calibration mass.

1. Calibrate the small scale at the first location. From this point on you may adjust the zero of this scale but not the span.
2. When you arrive at the second location, place the small calibration weight on the small scale and note the measured weight. If the acceleration of gravity is lower at the new location, then the measured weight of the small calibration mass will be low.
3. Use your large scale to measure the unknown object. Then multiply the large scale reading by a correction factor equal to the true mass of the small calibration weight divided by the small scale reading in step 2.

Method 3: Correct for acceleration of gravity by knowing the altitude and latitude of the location where the scale was calibrated and where the final measurement will

take place. In some instances, you will have no means of calibrating a scale. It may have been calibrated at the factory only. In this case, you will need to know the acceleration of gravity at the location where the scale was calibrated and also at the location where you will be making your measurements.

Although anomalies in the Earth's crust will affect local gravity, gravity is mainly a function of latitude and altitude. Gravity at a particular location can be calculated with a precision of about 0.002% using the following formula

$$M = \frac{(g_c)(\text{Measured mass})}{g_m} \quad (9.28)$$

where M is the true mass, g_c is the acceleration of gravity where scale (or load cell) was calibrated, and g_m is the acceleration of gravity where the measurement was made.

Method 4: Correction for acceleration of gravity by using information available from the National Geodetic Information Center. Values for the acceleration of gravity at specific locations can be purchased from the National Geophysical Data Center. The true mass can be calculated by using the formula given in Method 3.

9.9.2.2 Other Effects

Buoyancy: If an object is immersed in a fluid or gas, the object experiences a buoyant force equal to the weight of the fluid or gas it displaces (Archimedes' principle). This explains why a balloon rises. When an object is weighed in air, there is an upward force introduced which reduces the measured weight. For large lightweight objects, this effect can be quite significant. Air has an average density of about 1.20 kg/m^3 (0.0749 lb/ft^3). If an object has a volume of 1 m^3 , then 1.2 kg must be added to the measured mass of the object to yield the true mass. This correction is particularly important for space vehicles whose mass is measured in the Earth's atmosphere.

To complicate this analysis, the scale was originally calibrated using a standard mass. This mass has volume and also experiences an upward force due to buoyancy. Therefore, for very accurate measurements, the calibration adjustment of the scale must be corrected for the buoyancy of this weight. This effect is very small. Usually, a calibration mass is made of solid metal and has a density of 8000 kg/m^3 . Therefore, its buoyancy error is about 1 part in 6666 (or 0.015%).

Method to correct for buoyancy, using calculated air density

1. Calibrate the scale and adjust its output to read the exact value of the calibration weight.
2. Determine the density of the calibration weight (brass = 8570 kg/m^3 ; stainless steel = 7870 kg/m^3 ; cast iron = 7100 kg/m^3).
3. Measure the weight of the object.
4. Determine the volume of the air displaced by the object (often not an easy task).
Note: If openings allow air to enter a space, then this space is not part of the volume of air displaced.
5. Determine the approximate density of the object by dividing the measured weight by the volume of air displaced.

6. Determine the density of the air by using the following formula

$$\rho = \frac{(0.020582h + 0.348444p - 0.00252t \times h)}{(t + 273.15)} \quad (9.29)$$

where p is the atmospheric pressure in mbar (hPa), h is the relative humidity in %, t is the temperature in degrees Celsius, and ρ is the air density in kg/m^3 .

7. Perform the buoyancy correction using the formula

$$\text{True mass} = \text{measured mass} \times \left[\frac{1 - (\rho/s)}{1 - (\rho/u)} \right] \quad (9.30)$$

where s is the density of calibration weight in kg/m^3 , u is the density of unknown in kg/m^3 , and ρ is the density of air in kg/m^3 .

One can also correct for buoyancy effects by weighing two objects of identical mass but different volumes. The difference in measured weight will be

$$w_1 - w_2 = \delta(v_2 - v_1) \quad (9.31)$$

$$\rho = \frac{w_1 - w_2}{v_2 - v_1} \quad (9.32)$$

This value for ρ can then be used in the formula in step 7 mentioned in Section 9.2.2.

Condensation: In areas with high humidity, sudden changes in temperature can produce condensation on the object being measured, which adds to the weight of the object. This most commonly occurs when an object is brought from an air conditioned space to a non air conditioned one. Condensation can be minimized by allowing an object's temperature to equalize before weighing it.

Electrostatic Attraction: It is remarkable how dramatic this effect can be if you are weighing a large lightweight object such as a Mylar decoy reentry cone. If the object is covered by a clear plastic draft shield during measurement, the attraction between object and shield can be as much as 2% of the weight of the object.

Magnetic Attraction: If the object you are weighing contains permanent magnets, there will be an attraction to any magnetic material near or on the scale. There will also be a small attraction force to the magnetic north of the Earth. It may be necessary to demagnetize the object before weighing it. Generally, you can detect magnetic errors by repositioning the object on the weighing pan of the scale. If the readings are very sensitive to position on the pan, then the problem may be magnetic attraction (but it might also be the corner loading error of the scale). Using a compass is also a good way to test for magnetic attraction.

Drafts or Air Currents: Generally, this effect will be quite obvious, since drafts will introduce a random variation in the readings. However, there are some instances where drafts can produce a relatively steady downward or upward force. These effects can be minimized by making sure that the object is at the same temperature as the surrounding air, by avoiding direct sunlight or bright lights, and by turning off any source of airflow in the immediate test area.

9.9.3 Sources of MOI Uncertainty

9.9.3.1 Coincident CG It is important that the center of gravity of the test part and fixture be positioned as close as possible to the rotational axis of the torsion pendulum. Otherwise, measurement error will increase for a number of reasons.

One source of error is the so-called gravity pendulum effect that occurs because the axis of rotation of the torsion pendulum can never be made exactly vertical. If a part is oscillated about an axis which does not fall on its center of gravity, then the force of gravity acting through the center of gravity will tend to bring the center of gravity to its low point (i.e., the direction in which the axis of rotation of the torsion pendulum is tilted), resulting in a change in the effective calibration constant of the instrument. This effect can be minimized by leveling the table and repositioning the test part, so that its center of gravity lies close to the rotational axis of the instrument.

A second source of error with offset center of gravity is the classical axis translation error. Mathematically, this increase is equal to the test part mass times the square of the offset distance. Since this increase can be exactly calculated, it can be subtracted from the measured moment of inertia; therefore, it does not constitute an uncertainty. For small offsets (less than 1% of the radius of gyration), this effect is negligible. For larger offsets, instruments are available which measure both CG and MOI. The software then automatically reports the MOI about the center of oscillation and about the CG. To utilize this feature, the test part must be weighed.

9.9.3.2 Effect of Air Mass For large lightweight objects, the measured mass properties are often different from the calculated values. In particular, measured moment of inertia can be 10–20% larger than calculated. Inexact analysis (e.g., neglecting to input the MOIs of small parts into the model) often contributes up to 5% or more to this discrepancy. A second consideration is that air has significant mass and alters the mass properties in two ways.

The first way is when air is trapped inside the payload. This will increase its mass by an amount equal to the unoccupied volume in the payload times the density of air (0.0749 lb/ft^3 [1.2 kg/m^3]). The other air effect is when air is dragged or pushed along by any protrusions on the outer surface of the payload. This can dramatically increase moment of inertia. For example, the roll moment of inertia of a missile flying in air is much larger than the roll MOI of the missile in a vacuum.

How you handle this difference depends on whether the payload operates in the vacuum of space or in air. If the payload flies in a vacuum, then measured values must be decreased to eliminate the effect of air mass. The best way of doing this is to make a second measurement in helium and then extrapolate the value in vacuum (Boynton et al., 1991).

9.9.3.3 Minimum MOI that can be Measured Moment of inertia instruments have amazing dynamic ranges. An MOI instrument that is designed to measure objects weighing up to 3000 lb (1361 kg) can often detect the change in MOI due to the addition of an object weighing 0.1 lb (0.05 kg). However, accuracy is reduced when the MOI of an object is smaller than the tare MOI of the instrument. The error is primarily due to the inherent 0.1% limitation accuracy of the instrument.

As an extreme example, if a payload has a MOI of 10 lb-in^2 and the instrument has a tare MOI of $10,000 \text{ lb-in}^2$, then a 0.1% uncertainty in tare is 10 lb-in^2 . When the payload

is mounted, the uncertainty in the gross measurement ($10,010 \text{ lb-in}^2$) is 0.1% of the gross or 10.01 lb-in^2 . The sum of these ($10 + 10.01 = 20.01$) is the total uncertainty in the net payload MOI so the final answer would be payload MOI = $10 \pm 20.01 \text{ lb-in}^2$, which is a more than 200% uncertainty. For this reason, the ratio of gross to net should be kept to a minimum. A ratio greater than two dramatically reduces the accuracy of the measurement.

Another source of uncertainty is thermal expansion and contraction of the instrument and fixture during the time between tare and object MOI measurement. Reducing short-term temperature change can increase the usable range of an instrument. Improved accuracy can be achieved by simply shutting off the heating or air conditioning system during the interval of time between tare and object measurement.

9.9.3.4 Damping Air-bearing MOI instruments themselves have very small losses, and the effect of this damping can generally be ignored. For payloads which introduce significant damping due to air turbulence while oscillating, the actual period of oscillation is greater than the undamped natural period by an amount determined by the damping ratio, z . If the torsion pendulum is being used as an instrument to measure moment of inertia, then the measured moment of inertia will be greater than the true value. This error can be eliminated if the following equation is used in place of Equation 9.12. The quantity z^2 is the error.

$$I = Ct^2(1 - z^2) \quad (9.33)$$

In order to make use of this equation, the value of the damping ratio, z , must be determined. This is accomplished by noting the rate at which the amplitude of oscillation decays. If we define the logarithmic decrement as the natural logarithm of the ratio of any two successive amplitudes, then the log decrement, d , of the starting amplitude, a_0 , as compared to the peak amplitude, a_n , after n cycles have elapsed is given by the equation:

$$d = \frac{\ln(a_0/a_n)}{n} \quad (9.34)$$

For small values of z , the logarithmic decrement, d , can be related to z by the following relationship

$$d = 2\pi z \quad (9.35)$$

If we now count the number of oscillations of our torsion pendulum, n , for a decay in peak amplitude of 10:1, we may combine the above equations and solve for the error resulting from damping. It should be noted that this effect is in addition to the increase in MOI due to entrained air.

Percentage of error due to damping = $100z^2$

$$\text{Percentage of error} = \frac{100(\ln 10^2)}{(2\pi n)^2} \quad (9.36)$$

$$\text{Percentage of error} = \frac{13.41}{n^2} \quad (9.37)$$

10.1 INTRODUCTION

Force is one of the ubiquitous physical phenomena. From the strong nuclear forces holding subatomic particles together to the weak forces holding the Earth in orbit around the sun and the solar system around the galactic center, forces are an influence in everything we see and do.

Aristotle (1934) is credited with an approach that considered the natural phenomena with a combination of observation and philosophical reasoning. He postulated that the relative proportion of “Earth,” the heaviest element, and “Fire,” the lightest element, determined the natural motion of a body. Earth tended toward the center of the universe, whereas Fire would like to rise upwards away from the center. Terrestrial objects move upwards or downwards toward their natural place in accordance with their composition of the four elements. His observations were constrained by the technology available at the time. For example, a vacuum was thought to be impossible, but if it did theoretically exist, then motion in a vacuum would be infinitely fast. The ideal speed of an object moving with terrestrial motion (upwards or downwards) was directly proportional to its weight.

Given the inability to observe a system where friction played only a negligible part, it was thought that the natural state of things was to be at rest. Forced or unnatural motion required the constant application of force to sustain the motion. Some philosophical thinking was applied to a situation such as the flight of a spear through the air. After an initial impetus, the constant force was thought to be provided by the air as the spear passed through it. The motion of heavenly bodies was considered to be different. The sun, moon, and stars were embedded in crystal spheres that rotated with an unchanging circular motion, with the planets embedded in spheres within spheres to account for their apparently erratic motion.

While we now think that the Aristotelian physics contains some shortcomings, but from a purely practical point of view, it has some resonance. Pushing a cart loaded with bags of rice to the market place requires the expenditure of a constant force to keep the cart moving.

In the seventeenth century, Galileo Galilei (1953) experimented with cannon balls and inclined slopes to theorize that acceleration due to gravity did not depend on the weight of the object and that the force of friction was responsible for slowing down the motion which would otherwise remain constant.

With the publication of Sir Isaac Newton’s “*Principia Mathematica*” (Newton, 1685) in 1687, a mathematical explanation of the laws of motion was proposed that would last for almost 300 years. Newton realized that the same force of gravity was responsible for items falling toward the Earth, and the motion of the moon around the Earth. Newton provided the means to calculate and predict the motion of bodies both terrestrial and celestial based of the forces experienced between the objects. Newton’s reasoning was so compelling that when inconsistencies in the orbit of the planet Mercury were observed that could not be fully explained by the Newtonian model, astrophysicists predicted the presence of an unobserved new planet that would account for the discrepancies. No such planet was found, but Albert Einstein (1916) sensationally added a correction to his theory of general relativity that precisely accounted for the observed motion.

So, force is a measurement of the interaction between objects. It is a vector quantity with both magnitude and direction. If a body is at equilibrium, the sum of forces acting

upon the body is zero. The derived SI unit of force is named in honor of the aforementioned Sir Isaac Newton with 1 N being the force required to accelerate a mass of 1 kg by 1 m/s/s.

In general, force is calculated using the following formula:

$$F = ma \quad (10.1)$$

where F is force in Newton, m is the mass of the object in kilogram, and a is its acceleration in meters per second per second.

Because it is not practical to accelerate a mass by 1 m/s² to produce a standard force of 1 N, we tend to use a more readily available and predictable acceleration factor to produce a known force on a transducer, that is, the acceleration due to gravity. This modifies Equation (10.1) to become

$$F = mg \quad (10.2)$$

Local gravity is relatively easy to determine and so when a known mass is applied in any geographical location, the force in Newton is easily determined also. Using such masses, force transducers can be calibrated so that wherever in the world they are used, they will report the correct force.

10.2 FORCE TRANSDUCERS

A transducer is a device that senses a physical parameter and reports it quantitatively as an output of a different type. In the case of a force transducer, the output is most commonly electrical, meaning a change in resistance, capacitance, or voltage, for example. These changes are usually quite small, so associated instrumentation is required to interpret the output quantity and convert it to a display for the operator or user to see.

Force transducers take many forms, with some of the more common forms listed in Table 10.1, along with their approximate ranges and accuracies.

The majority of force measurement devices used in industry fall into the first category, with the others satisfying more specialist applications. This chapter will accordingly emphasize the strain gauge load cell devices, with briefer descriptions of the other transducer types.

In the seventeenth century, British physicist Hooke (1678) stated “*Ut tensio, sic vis*,” roughly translated: “as the extension, so the force,” implying that there is a linear relationship between extension and applied force, and although originally derived for springs, can be applied to most elastic materials. Put another way, when a material is placed under tension, applied force (the stress) is proportional to the amount by which the material deforms (the strain), provided that the elastic limit is not exceeded. This observation is defined by the following equation:

$$F = -kx \quad (10.3)$$

TABLE 10.1 Common Force Transducers along with Their Typical Uncertainties and Temperature Characteristics (Institute of Measurement and Control, 1996)

Device Type	Typical Range of Rated Capacities	Typical Total Uncertainty (% fso)	Temperature Sensitivity and Operating Range (% fso per °C)
Strain gauge load cells			
Semiconductor gauges	1 N to 10 kN	0.2–1%	0.2–0.5% (–40°C to +80°C)
Thin film gauges	0.1 N to 100 N	0.02–1%	0.02% (–40°C to +80°C)
Foil gauges	5 N to 50 MN	0.02–1%	0.0015% (–40°C to +80°C)
Piezoelectric crystal	1.5 mN to 120 MN	0.3–1%	0.02% (–190°C to +200°C)
Hydraulic	500 N to 5 MN	0.25–5%	0.02–0.1% (5–40°C)
Pneumatic	10 N to 500 kN	0.1–2%	0.02–0.1% (5–40°C)
LVDT, capacitive, tuning-fork, vibrating wire, optical	10 mN to 1 MN	0.02–2%	0.02–0.05% (–40°C to +80°C)
Magneto-elastic	2 kN to 50 MN	0.5–2%	0.03–0.05% (–40°C to +80°C)
Gyroscopic	50–250 N	0.001%	0.0001% (–10°C to +40°C)
Force balance	0.25–20 N	1 part in 10 ⁶	0.0001% (–10°C to +40°C)

where F is the restorative force, x is the displacement, and k is a force (or spring) constant. Put another way

$$E = \text{stress/strain} \quad (10.4)$$

where stress is the force applied to the specimen, and strain is the relative elongation of the specimen from its original length.

Here, E is also known as Young's Modulus (1807), represented as the gradient of the stress/strain curve within the initial linear region. This is an extremely useful value to determine, because it gives a clear indication of how much the material will deform under applied tensile loading. A bungee rope, for instance, must have a low enough Young's Modulus to guarantee the jumper will achieve a long, thrilling jump without the rope jarring when the slack is taken up, but a high enough Young's Modulus to ensure the rope is sufficiently stiff to bring the jumper springing back skywards prior to hitting the ground.

A common stress/strain curve is shown in Figure 10.1. The trace shown in Figure 10.1 is typical of an Aluminum metal plate specimen and shows the linear region, where Hooke's law is obeyed, followed by a plastic deformation phase indicated by a steady decline in gradient toward the ultimate tensile strength (UTS) point, and then specimen break.

Most force transducers consist of a sensing element and an elastic element. The sensing element is the strain gauge, vibrating element or optical sensor, and so on. The elastic element is the bulk medium upon which the sensing element is placed and is designed to operate within the linear region of the stress/strain curve. This ensures that the load cell returns to its zero load position with minimal error.

It is called the elastic element because it is designed so that when a force is applied, it deforms such that the sensing element can report a measurement, and after the applied force

FIGURE 10.1 Typical stress/strain curve for aluminum plate metal (Courtesy of Mecmesin Ltd).

is removed, the element returns to its original dimensions. They can be designed to allow measurement in tension and compression or in compression only. Static torque sensors are also constructed using the same principles, although the designs are more complex. Load cells come in many shapes and sizes, but materials tend to remain the same. Steel and aluminum are the most common and are used for their properties as well as their relative abundance. Choice of material depends largely upon the design criteria: aluminum has better thermal stability, whereas stainless steel has better mechanical stability. Figure 10.2 shows some of the common forms (Institute of Measurement and Control, 1996).

(d) Ring 1 kN to 1 MN. (e) S-beam (bending or shear) 200 N to 50 kN. (f) Double-ended beam (simplified) 500 N to 50 kN. (h) Shear beam 1–500 kN. (i) Double-bending beam 100–10 N. (j) Tension cylinder 50 kN to 50 MN.

10.3 UNIVERSAL TESTING MACHINES

Load cells are commonly used in materials and product testing applications. This type of testing requires a method of controlling the sometimes complicated test routines. Universal test machines often fulfill this purpose and are available from many manufacturers.

Universal testers provide a means to hold a sample and place it under a compressive or tensile load. They can be simple motorized machines, whereby the speed and direction are controlled using manual controls, hand operated machines where the operator uses a wheel or pump control to increase the force on the sample, right up to high end computer controlled test stands that can run sophisticated multistage test programs. They are available with hydraulic actuation or electromechanical control using electric motors driving a ball screw arrangement, for a wide range of forces from 500 N up to 30 MN. They will perform complex calculations such as Young's modulus and create and print reports. When used in conjunction with other instrumentation, such as extensometers, even more sophistication is possible. With the ever growing library of international test methods, universal testers are required to provide more functionality and more calculations. Figure 10.3 shows just a few of the range of available universal test machines.

Portable force measurement is catered for by a plethora of hand-held instrumentation, from simple gram gauges to advanced force gauges that allow data storage and transmission as well as peak and trough calculations. Some will allow simple control functions for operating some test stands so that no computer is necessary.

Force measurement in this form is used in all industries, from medical and pharmaceutical to food, automotive, and electronics sectors. Both the finished products and the raw materials they are made of are tested for either quality control or to determine basic material properties. Figure 10.4 shows some examples of force measurement applications in industry, including replacement joint testing, PCB component pull off testing and food testing.

10.4 THE STRAIN GAUGE SENSOR

Although the then Lord Kelvin first reported on the relationship between strain on a metal and its electrical resistance in 1856 (Thomson and William, 1856), it was not until 1936 that a practical implementation of a bonded strain gauge (Simmons, 1942) was realized, by the eccentric Edward E Simmons, Jr. The invention, which consisted of wires glued to the surface of the object whose stress or strain was to be measured, had an enormous impact on the engineering world and was of great importance during the World War II (Dietrich and Jane, 1986).

In 1952, with the advent of etching technology for electrical components, the first strain gauges were developed using etched metal foil instead of wire (Jackson, 1990). The benefits of this technique are that the resistance of the strain gauge can be more accurately and repeatably achieved, and also a much finer pattern can be achieved thus increasing the length of resistor in a smaller space allowing for smaller sensors. This revolutionized the strain gauge industry, and now most strain gauges are of the metal foil type (Figure 10.5). They are manufactured by photo-etching the resistors from a metal coating on a substrate. The substrate has a dual purpose; that of a backing for the strain gauge and as a resistive barrier between the gauge and the item whose strain we want to measure. The gauge on its substrate is adhesively bonded to the component so that strain on the component is transferred efficiently to the gauge. The bonding process is a challenging one given the tolerances that need to be achieved and this is a specialist task, which is highly valued.

As is well known (Young and Freedman), electrical resistance per unit length, L , of a metal wire is inversely proportional to its cross-sectional area:

$$R = \rho L/A \quad (10.5)$$

FIGURE 10.5 A typical strain gauge, complete with mounting guide marks.

FIGURE 10.6 (a) Metal wire resistor and (b) metal wire resistor under strain.

where R is the resistance, ρ is the resistivity of the material, and A is the cross-sectional area.

Figure 10.6 shows the most basic form of strain gauge, which is a wire of known length, L , and cross-sectional area, A . When an external force is applied to the wire, which causes strain, ϵ (i.e., it is stretched or compressed), its cross-section is also deformed and so a corresponding change in the wire's resistance, R , can be measured.

By differentiating Equation (10.1) and dividing by R , we get

$$\frac{dR}{R} = \frac{d\rho}{\rho} + \frac{dL}{L} - \frac{dA}{A} \quad (10.6)$$

We define axial strain by $\epsilon_a = dL/L$ and transverse strain by $\epsilon_T = dr/r = -\nu\epsilon_a = -\nu(dL/L)$ (Charles Wheatstone, 1843), where ν is the Poisson ratio (the ratio between axial and transverse strain) for the wire material.

The change of radius of the wire under strain is

$$dr = r \left(1 - \nu \frac{dL}{L} \right) \quad (10.7)$$

And so the rate of change of the cross-sectional area is given by

$$\frac{dA}{A} = 1 - (1 + \epsilon_T)^2 = 2\epsilon_T + \epsilon_T^2 \approx 2\epsilon_T \quad (10.8)$$

And when this is substituted back into Equation 10.1, and dividing by axial strain, we get

$$S = \frac{dR/R}{\epsilon_A} = \frac{d\rho/\rho}{\epsilon_A} + (1 + 2\nu) \quad (10.9)$$

S is the sensitivity of the resistor material to strain—the change of resistance versus strain. This is directly analogous to the sensitivity of the strain gauge to strain and when applied; thus, it is called the Gauge factor; a figure of merit for strain gauges. The material that is used to make the strain gauge dictates the gauge factor, the most common being Constantan (copper–nickel alloy), Nichrome (nickel–chromium alloy), and Platinum (normally alloyed with tungsten) (Charles Wheatstone, 1843). For wire and foil strain gauges made from Constantan or Nichrome, the gauge factor is approximately 2, whereas for Pt-W resistors it is approximately 4. Constantan is a common material for strain gauges as it exhibits a linear response over a large range of strain, and it is relatively stable with changing temperature.

Because the change in resistance is very small, a suitably sensitive circuit is required that can measure it, and the most common circuit configuration used in this type of application is illustrated in Figure 10.7, commonly known as a Wheatstone Bridge (Langdon, 1985).

In order to be balanced, $R_1R_3 = R_2R_4$. The simplest form of strain gauge bridge is made by placing a single strain gauge into the circuit in place of R_1 with R_2 , R_3 , and R_4 chosen to balance the bridge—often equal. It can be shown (Charles Wheatstone, 1843) that the system sensitivity in its simplest form ($R_1 = R_g$) is

$$S_s = \frac{r}{1+r} S_g \sqrt{p_g R_g} \quad (10.10)$$

where p_g is the power dissipation of the gauge, which limits the maximum supply voltage, and r is the ratio R_1/R_2 . Of course, where R_2 , R_3 , and R_4 are chosen to be equal to R_g then $r = 1$ although a value of r in the range 3–5 gives circuit efficiencies of between 75 and 83% while allowing a reasonable supply voltage.

FIGURE 10.7 Classic representation of a Wheatstone Bridge circuit.

Sensitivity varies with different configurations, with the most sensitive being the use of four gauges in the bridge—normally with the gauges in positions R_1 and R_3 oriented to measure strain in one dimension (tension or compression) and R_2 and R_4 in the other—which roughly doubles the sensitivity over the simplest form. It must be remembered that although sensitivity can be increased by attaching more gauges, the cost will increase accordingly due to the extra work involved in bonding the gauges.

So, the Wheatstone bridge, when properly balanced, is well suited to sensing very small changes in the balance of the bridge, and the output of a strain gauge circuit is measured in mV/V , where V is the excitation voltage. Most commonly, strain gauge circuits are designed to give an output of 2, 3, or 4 mV/V . The disadvantage here is the need for amplification of the output, which also increases any noise in the system.

10.4.1 Strain Gauge Circuit Compensation

To an extent, the Wheatstone bridge design lends itself to self-compensation for environmental factors such as temperature by virtue of the balanced nature of the resistors—if all resistors are the same then they will be affected by temperature to the same extent and the net effect is theoretically zero. For more demanding transducer applications, compensation is required for temperature and sometimes zero-balance, where, however well balanced the gauges are, their characteristics cannot be identical and so the balance of the bridge is not exact when under zero load. These things can be compensated for by careful tuning of compensation resistors placed at the vertices of the bridge where the output is read, as shown in Figure 10.8. Placing a well-tuned resistor with high thermal conductivity (commonly copper) at the vertex of R_4 and R_3 can compensate for zero drift due to

FIGURE 10.8 Strain gauge bridge with compensation for zero balance (R_{bal}), zero temperature compensation (R_{tc}), span adjust (R_{span}), and span temperature compensation (R_{tc}).

temperature, whereas a temperature stable resistor, commonly Constantan, at the vertex of R_1 and R_2 can compensate against bridge imbalance. Span effects can be compensated for by placing resistors either side of the voltage supply.

10.5 RESONANT ELEMENT TRANSDUCERS

Sometimes also known as tuning fork sensors, these devices are used in a wide variety of applications from measuring pressure, to liquid density and from accelerometers to torque sensors (Langdon, 1985). The principle of operation is similar to a guitar string, which, when plucked, resonates with a tone which is relative to the tension on it. In other words, the resonant frequency of the string is a function of the measurand—tension, the string material property, and its thickness and length. The frequency then increases with increasing axial force.

Similarly in a resonant element force transducer, the structure of the device is a vibrating element, which when excited, vibrates with a natural resonant frequency. When a stress or strain is applied to the device the frequency changes proportionally.

The fundamental frequency of a vibrating beam under tension, T is governed by the equation:

$$T \times \frac{d^2 Y}{dX^2} - E \times I \times \frac{d^4 Y}{dX^4} = \rho \times A \times \frac{d^2 Y}{dt^2} \quad (10.11)$$

where I is the second moment of area: $(b \times h^3)/12$, E is the Young's modulus of the material, r is the material density, A is the cross-sectional area of the beam ($b \times h$), b and h are breadth and height of the beam, respectively, and t is the time.

Then, assuming simple harmonic motion and applying the boundary conditions, the natural frequency f_{01} , when axial force $T=0$, is given by

$$f_{T1} = \frac{a^2}{2\pi \times l^2} \times \sqrt{\frac{E \times I}{\rho \times A}} \quad (10.12)$$

where a is the value determined by mode number of vibration $n_v \approx 0.5 \times \pi \times (1 + 2n)$, and l is the beam length.

When the applied tension changes, the natural frequency of the beam under axial force f_{T1} becomes

$$f_{T1} = f_{01} \times \sqrt{1 + \frac{1}{a^3} \times th \times \frac{a}{2} \times \left(a \times th \times \frac{a}{2} - 2 \right) \times \frac{l^2 \times T}{2E \times I}} \quad (10.13)$$

These equations can be used to determine the design of a tuning fork sensor with respect to the motion of the device under strain, the nominal frequency of the device and frequency change at full scale.

An electronic closed loop circuit such as the one illustrated in Figure 10.9 (Cheshmehdoost and Jones, 1993) tracks the output of the device and, by also phase shifting the output by 90° , brings the input and output into phase. This keeps the sensor in continuous oscillation, and as the transducer is loaded the resonant frequency is maintained.

FIGURE 10.9 Illustrating the closed loop circuit that maintains relative oscillation.

Examples of three common forms of resonant element transducer: single, double beam, and triple beam are illustrated in Figure 10.10 (Eernisse et al., 1996):

They are manufactured by conventional means, usually by laser cutting the resonant element from steel and then photo-etching down to the required thickness (Yan et al., 2003). The associated excitation and readout piezoelectric components can then be screen printed on to the element. These are all well-understood manufacturing methods and so volume production can be low, which is attractive commercially.

Figure 10.11 shows a photograph of a triple beam tuning fork design, as represented in Figure 10.10c (Yan et al., 2003).

Because the device has a frequency output, it requires no analogue to digital electronics to read it out. Advantages that are claimed for this type of sensor are

- long-term stability ($\pm 3.5 \times 10^{-5}$ over 12 months),
- easy interface to digital electronics,
- relatively easy manufacturing and cost-effective in quantity.

Their disadvantages include a relatively small operating range and design considerations to retrofit into existing applications.

Tuning fork transducers have mostly been used in torque measurement applications as shown in Figure 10.12 and described in (Intiang, 2007) and in precision scales, but they are becoming more widely used, with a 50 N load cell based on tuning fork technology having been recently evaluated using the 500 N force standard machine at the National Metrology Institute of Japan (Toshiyuki et al., 2006). Although they show some good characteristics such as low hysteresis and good long-term stability, they are large when compared with strain gauge load cells and have only comparable repeatability.

FIGURE 10.10 Three different types of tuning fork sensor: (a) single, (b) double, and (c) triple beam.

FIGURE 10.12 Resonant sensors mounted in a torque measurement arrangement (Forcesenssys Ltd., 2007).

10.6 SURFACE ACOUSTIC WAVE TRANSDUCERS

The existence of surface waves, or Rayleigh waves, was first proposed theoretically in 1885 by, as their name suggests, the then Lord Rayleigh (John William Strutt) (Rayleigh, 1885) who predicted their presence during earthquakes. However, it would be some 35 years before the development of seismological measurements, which confirmed his theories.

When an earthquake occurs, its energy is propagated in waves of three main types: The primary wave, or P-wave; the secondary wave, or S-wave; and surface waves in the form of Love and Rayleigh waves. The P-wave is analogous to an acoustic, or compression wave. It travels faster than the other two wave types and so is normally detected first. The S-wave is a sinusoid with associated amplitude and frequency. A surface wave is a hybrid of P- and S-waves, which propagates at the interface between two materials, and whose amplitude decreases exponentially with depth beneath—in the context of an earthquake—the surface of the Earth. Rayleigh waves are those surface waves that propagate with particle motion perpendicular in the vertical direction to the direction of propagation. Love waves have particle motion in the transverse direction and perpendicular to the direction of propagation. Diagrams illustrating these wave types can be seen in Figure 10.13 (Ikelle and Amundsen, 2005).

In 1965, the practical implementation of a surface acoustic wave (SAW) on an elastic substrate (quartz) was realized by Voltmer and White (1965) and this paved the way to the subsequent extensive use of SAW devices in telecommunications as band-pass filters and delay components (Campbell, 1989).

SAW devices such as the one in Figure 10.14 consist of an excitation construction made up of “fingers,” spaced at half the resonant wavelength of the desired wave, on a piezoelectric substrate. There are then receivers placed on the substrate, which detects the arrival of SAW’s and the output frequency is then transmitted as a quasi-digital signal to the processing electronics. The frequency of the SAW is given by (Hauptmann, 1991)

$$f = \frac{(2n\pi - \varphi_{el}) \times v_{SAW}}{L} \quad (10.14)$$

where φ_{el} = electrical phase shift of the amplifier circuit, n = constant determined by electrode design, v_{SAW} = velocity of the SAW, and L = distance between transmitter and receiver structures.

This means that frequency is directly dependent on wave velocity and L , which enables development of SAW devices to measure a range of parameters including

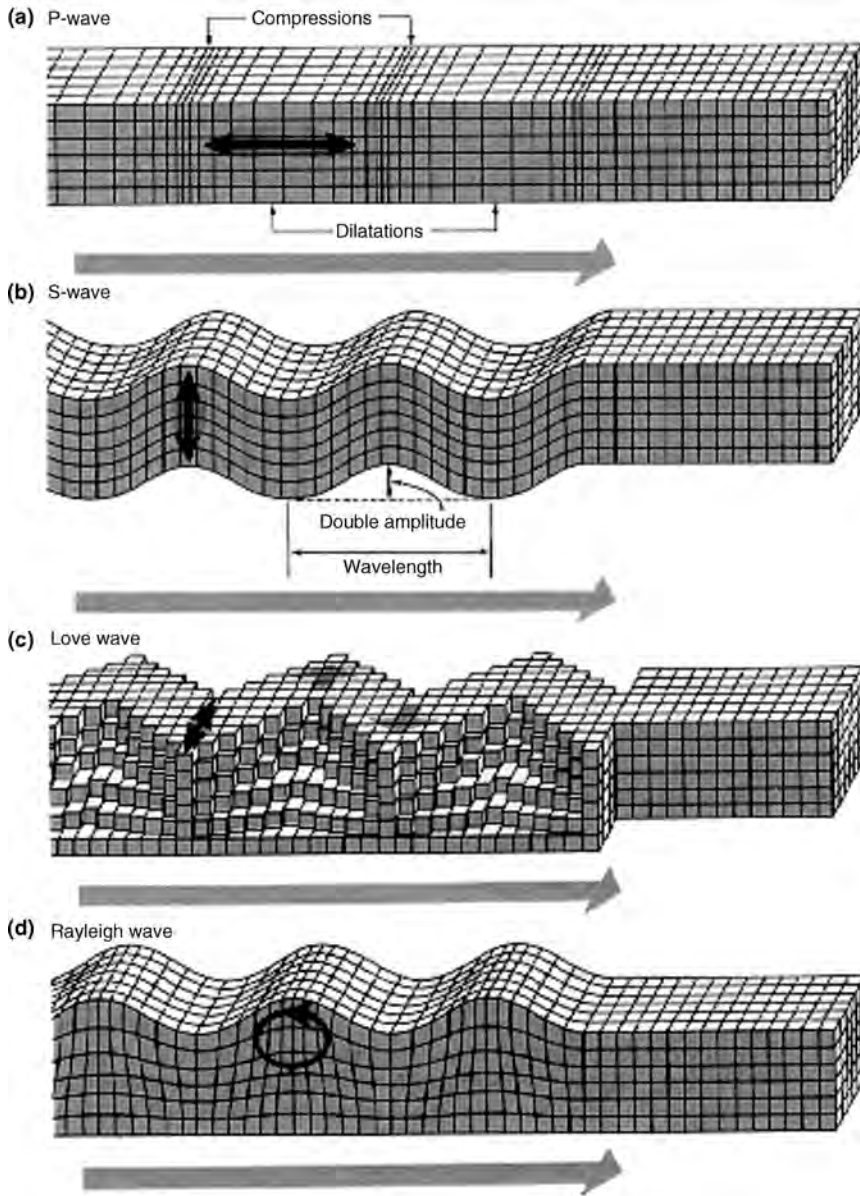

FIGURE 10.13 Illustrating the different wave types observed during earthquakes.

acoustic, temperature, and dimensional changes (and hence force and torque) to name but a few.

Since then the use of SAW transducers has broadened into other applications, which include temperature (Wold et al., 1991) and pressure measurement (Cullen and Reeder, 1975; Cullen and Montress, 1980), and of course, force measurement—in particular torque measurement.

FIGURE 10.14 The layout of a typical SAW transducer.

In 1990, the first noncontact torque transducer based on a SAW device was patented (Lonsdale and Lonsdale, 1990) and since then the noncontact torque measurement industry has been served mostly by this technology. Applications include Formula 1 vehicle drive train monitoring as well as uses in torque monitoring for regenerative braking systems (Kalinin et al., 2010).

If the SAW device is rigidly mounted to a flat spot on a shaft, and the shaft experiences a torque, this torque will stress the sensor and turn it into a wireless passive lightweight torque sensor. As the shaft is rotated one way, the SAW torque sensor is placed in tension. As the shaft is rotated the other way, it is placed in compression. For practical applications, two SAW torque sensors are utilized such that their center lines are at right angles (Figure 10.15) (Lonsdale and Lonsdale, 1990). With this system, when one sensor is in compression, the other sensor is in tension. Since both sensors are exposed to the same temperature, the combination of the two signals will act to minimize temperature drift effects.

When compared with other torque sensors, including resistive strain gauges, optical transducers, and torsion bars, SAW torque sensors offer lower cost, higher reliability, and wireless operation.

FIGURE 10.15 Configuration of SAW devices on a shaft to measure torque.

FIGURE 10.16 Schematic of a proving ring with manually adjusted micrometer screw.

10.7 DYNAMOMETERS

Strictly speaking, a dynamometer is any force transducer that uses the elastic nature of a material to determine the force causing deformation. This includes load cells, pressure transducers, and so on. A particular type of dynamometer that is encountered in the field of force measurement is a ring dynamometer, or “proving ring.”

The common form, shown in Figure 10.16, utilizes a manually adjusted micrometer readout to measure the diameter of the ring under tension and compression. In this configuration, a vibrating reed is set in motion by tapping it with a pencil. The micrometer is then adjusted to move the contact button until it is just in contact with the reed, which will make an audible buzzing noise. The graduated scale is then read off, which will indicate the force applied to the ring. This method was developed in 1946 (Bruce et al., 1946), and remains to this day as a proven and reliable method of measuring force with relatively low uncertainty. If a digital readout is required, then the micrometer can be replaced by strain gauges or a LVDT—a displacement transducer.

Proving rings are used commonly to measure soil compaction but also as calibrating instruments.

10.8 OPTICAL FORCE TRANSDUCERS

There are two main types of optical strain gauge, but both are spectroscopic in nature. One utilizes a change in the arms of an interferometer arrangement of fiber optics. In another, a diffraction grating is incorporated into the fiber with the spacing of the grating being altered by strain upon the fiber through the substrate material. This is otherwise known as a fiber Bragg grating sensor or FBG sensor, a diagram of which can be seen in Figure 10.17.

FIGURE 10.17 Representation of a FBG sensor.

The Bragg condition for constructive interference is a product of the theory of X-ray diffraction by crystals. It is named after father and son physicists, Sir William and Lawrence Bragg who jointly won the Nobel Prize for physics in 1915, and is utilized in fiber optic sensors that measure, among other things, strain. The condition states (Born and Wolf, 1999)

$$2d \times \sin\psi = n\lambda \quad (10.15)$$

where λ is the wavelength of light, n is an integer, ψ is the angle of incidence with respect to the crystal surface, and $2d$ is the path length difference between two incident light rays.

When this is applied to fiber optic, the isolated wavelength, that is, the one of interest is the one reflected by the grating elements and the equation slightly changes (Yun-Jiang, 1997)

$$\lambda_B = 2\eta \times G_s \quad (10.16)$$

where λ_B is the “Bragg” wavelength, η is the refractive index of the optical fiber, and G_s is the spacing of the grating elements in the fiber.

In reality, there are thousands of elements in a FBG sensor, which is manufactured by “writing” the elements into a length of Germanium doped optical fiber. The “writing” is done by exposing the fiber to a spatial pattern of ultraviolet light in the region of 244–248 nm. This fabrication process is based on the photorefractive effect, which was observed in Ge-doped optical fibers in 1978 by Hill et al. (1978).

When a FBG sensor is subjected to a strain, the spacing between the grating elements is increased, and the Bragg wavelength is altered according to the equation (Manfred Kreuzer)

$$\Delta\lambda = \lambda_B(k \times \varepsilon + \alpha_\delta \times \Delta T) \quad (10.17)$$

where $\Delta\lambda$ is the change in Bragg wavelength, $k = 1 - p$, (p is the photo-elastic coefficient of the fiber), α_δ is the refractive index temperature coefficient, and ΔT is the change in temperature.

And so, provided temperature is compensated for (fiber-optic sensors are highly temperature dependent and so are used as temperature sensors also) the change in wavelength can be used as a measurement of the strain on the fiber.

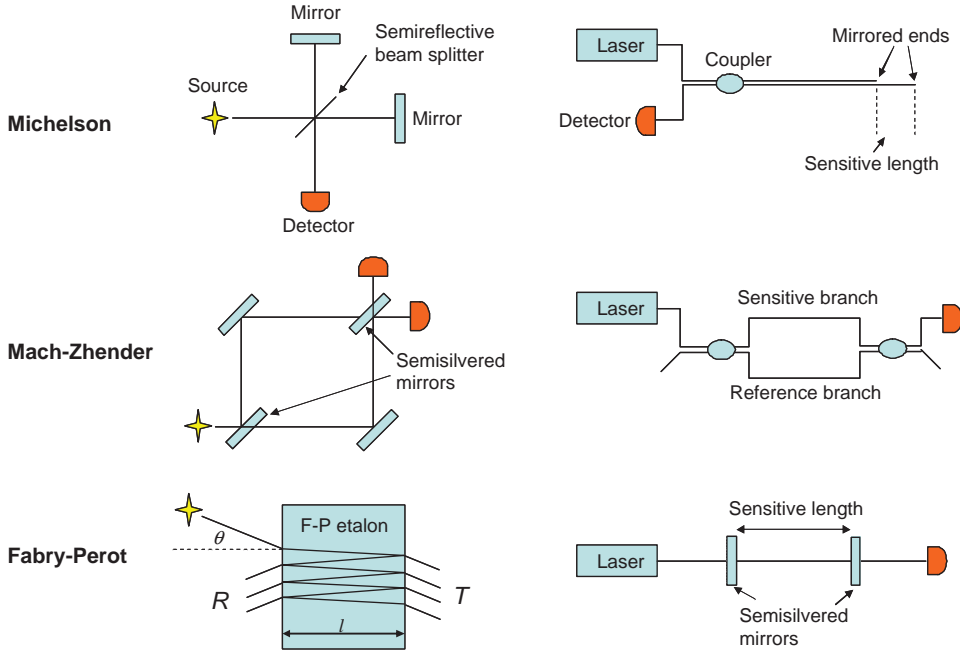

FIGURE 10.18 The different interferometer types and their fiber-optic counterparts.

Fiber-optic interferometers such as those illustrated in Figure 10.18 constitute the most sensitive of the fiber-optic force sensors and may be based on the many available designs including Michelson, Mach-Zehnder, and Fabry-Perot (Tatti et al., 1997).

In an interferometer, interference between two beams of light is described by the following equation:

$$\Delta\Phi = \frac{2\pi}{\lambda} n \times \Delta l \quad (10.18)$$

where $\Delta\Phi$ is the phase change of the resultant signal, n is the refractive index, λ is the wavelength, and Δl is the relative path change of the two beams.

In the case of a fiber-optic strain sensor, the path length is introduced when the paths of the interferometer are subjected to a differential strain. When this happens, two changes occur: its length changes and also the refractive index.

$$\Delta l = \varepsilon_1 \times l_0 \quad (10.19)$$

$$n = n_0 \left\{ 1 - \frac{1}{4} n_0^2 [2 \times P_{12} \varepsilon_1 + (P_{11} + P_{12})(\varepsilon_2 + \varepsilon_3)] \right\} \quad (10.20)$$

where l_0 and n_0 are the initial (unstrained) length and refractive index, respectively, P_{xy} are coefficients that depend upon the glass material, and ε_1 , ε_2 , and ε_3 are strain components acting on the fiber.

FIGURE 10.19 Representation of a fiber-optic intensity monitoring force sensor.

These, when substituted into Equation (10.18), and if it is assumed that $\varepsilon_2 = \varepsilon_3 = -\nu_f \varepsilon_1$, gives the phase change due to a strain ε_1 on the fiber.

$$\Delta\Phi(\varepsilon_1) = \frac{2\pi}{\lambda} l_0 \varepsilon_1 n_0 \left\{ 1 - \frac{1}{2} n_0^2 [P_{12} \varepsilon_1 - \nu_f \varepsilon_1 (P_{11} + P_{12})] \right\} \quad (10.21)$$

where ν_f is Poissons ratio for the fiber.

The Intensity at the detector of the resultant signal is given by

$$I = \alpha [1 + V \cos \Delta\Phi(\varepsilon_1)] \quad (10.22)$$

where $\alpha = E^2$ (E is the optical electric field) and V is the fringe visibility.

Hence, intensity at the detector can be related to strain directly.

Other fiber-optic sensors include intensity monitoring sensors (Gholamzadeh and Nabovati, 2008) (Figure 10.19) where a cavity length is altered by the applied load.

An increase in cavity length induces an intensity drop and a vice versa. A detector monitors the output intensity and this is then converted to a strain. Although simple in their design, they suffer from inefficiencies due to the coupling, alignment and bending.

Fiber-optic force sensors can be very sensitive and are also immune to electromagnetic interference, and because of this find their applications in challenging environments, such as the measurement of strain in overhead power cables.

10.9 MAGNETO-ELASTIC TRANSDUCERS

In 1842, Joule (1847) discovered that the properties (by which he meant its dimensions) of ferromagnetic material are coupled to its magnetic field flux. It is known as the Joule effect, but more commonly called Magnetostriction. He observed that if the material magnetic flux was increased, its length changed and as its length changed, so did its transverse dimension, thus keeping the material volume (approximately) constant. There is a reciprocal effect, known as the Villary effect, whereby subjecting a magnetic material to stress or strain will alter its magnetic flux. There are other magnetoelastic phenomena, such as the Matteucci effect, in which a material exhibits a change in an induced helical magnetic flux when subjected to a torque. Both of these principles are used in force transducers.

Nearly, all ferromagnetic materials will exhibit some magnetostrictive behavior, although much current research involves amorphous alloys (Hauptmann, 1991)—the so-called giant magnetoelastic materials, such as Terfenol-D—an alloy of terbium, iron, and dysprosium because they give such high values of magnetostriction. An illustration of the effect is shown in Figure 10.20 (Ekreem et al., 2007).

FIGURE 10.20 The Joule effect (a) The changes in shape in response to the magnetic field H . (b) The relationship between $\Delta L/L$ and H .

In Figure 10.20, a rod of a magnetic material with length, L , is surrounded by a coil of wire carrying an electrical current so that a magnetic field, H , is produced along the rod. When current is flowing, the length of the rod will increase by a small amount ΔL . The strain $\Delta L/L$ is called the magnetostriction, denoted by λ , and normally measured in ppm. The graph in Figure 10.20b shows that as the magnetic field, H , increases, λ also increases but not indefinitely. There is a saturation point, normally denoted λ_{sat} whereby no matter how intense the magnetic field, the magnetostriction does not change. Also to be noted is that the rod exhibits an increase of length regardless of the sign of the magnetic field increase.

Magneto-elastic force sensors are used in many industrial applications, including as torque sensors in the automotive industry (Dan Mihai, 2011), as sensors and transducers in railway engines (Bienkowski et al., 2010) and in civil engineering applications (Ausanio et al., 2005) to name but a few.

10.10 FORCE BALANCE TRANSDUCERS

The force balance utilizes one of the oldest forms of weight measurement, the beam balance. If we have ever been weighed by our family doctor, we have seen the beam balance in action. In the balance, an unknown mass is balanced against a known mass, with the distance from the fulcrum giving the value of the weight given by the known mass.

In a modern force balance, the deflection caused by the applied, unknown, mass is used to regulate a current input to an actuator that acts to balance the applied force. This feedback system works to retain the balance in equilibrium, and the current applied to the actuator is directly related to the force applied by the unknown input.

Force balances are widely used as accelerometers in seismographs, aircraft and drilling platform stabilization systems, and so on (Dan Mihai, 2011).

10.11 FORCE TRANSDUCER CHARACTERISTICS

Any force transducer will be supplied with a quoted specification, which places quantitative values on various aspects of the characteristics of a force measurement system. Table 10.2 lists the typical values in a 1000 N (220 lbf) strain gauge load cell.

So what does all this mean? Taking these items in turn.

TABLE 10.2 Typical Load Cell Characteristics

Capacity	1000 N
Output	2 mV/V
Creep	$\pm 0.01\%$ FS
Non linearity	$\pm 0.05\%$ FS
Hysteresis	$\pm 0.05\%$ FS
Repeatability	$\pm 0.05\%$ FS
Temperature coefficient	$\pm 0.025\%$ FS
Temperature range	40°C to +60°C
Accuracy	$\pm 0.1\%$
Combined uncertainty	$\pm 0.02\%$

10.11.1 Capacity

This is the maximum force that can be measured reliably using this particular load cell. However, commercially available load cells may have up to 200% overload capacity whereby the load cell can withstand an overload without damage, although it is advisable that load cells that have been overloaded be recalibrated. As with most transducers, it is inadvisable to use load cells within the first or last 10% of their design range. Table 10.1 shows that there is considerable crossover between device types and their operable ranges, but some will be much better suited to some applications than others, and so care should be taken to specify the device to the application accordingly.

10.11.2 Output

The output of a strain gauge load cell is expressed as mV/V, with the specified output being that at the rated capacity. So, with a specified output of 2 mV/V, the actual output voltage from a strain gauge load cell with a 10 V DC excitation (supply) voltage will be 20 mV.

Figure 10.21 illustrates the various concepts of nonlinearity and hysteresis as well as rated output and capacity. Load cells by their spring-like nature are linear in their

FIGURE 10.21 Illustration of a typical load cell response curve.

response but with manufacturing inconsistencies and engineering tolerances, there may be some deviation from true linear behavior. When adjusting a load cell prior to calibration, a straight-line fit is made to the device output, and the maximum deviation from this line is calculated and reported as the device nonlinearity. Hysteresis is the maximum difference in output with increasing and decreasing input. Often, load cell manufacturers or suppliers will specify a *combined error*, which is a combination of nonlinearity and hysteresis.

10.11.3 Repeatability

Repeatability is the standard deviation of output at any given repeated input, while keeping the measurement conditions the same. In a normal calibration, the repeatability is calculated for all points in the calibration and the specified repeatability is normally the maximum standard deviation. Repeatability should not be confused with reproducibility, which is the measurement of the output variation when the measurement conditions are different each time. This should not be confused with *reproducibility*, which is sometimes also quoted, but is the standard deviation of output at a given input but under differing conditions.

10.11.4 Creep

This is the extent of output change over time after a step change input is given, normally measured over a 30 s.

10.11.5 Temperature Coefficient

This is a measurement of the load cell susceptibility to temperature change, normally stated as %FSD per degree Celsius.

10.11.6 Accuracy

This is the statement of closeness of the output to the input quantity, taking into account uncertainty of measurement. This value is determined during calibration. Accuracy should not be confused with *precision* or *resolution*, these being closeness of repeated output values and the minimum observable output change, respectively.

10.12 CALIBRATION

The importance of having traceable calibration records for your force transducer is not to be underestimated. All calibrated load cells can be traced back to primary mass standards, which are in turn directly traceable to the International Prototype kilogram (IPK), Figure 10.22.

The IPK and its six sister copies are stored at the International Bureau of Weights and Measures in an environmentally monitored vault in Sèvres on the outskirts of Paris. Official copies of the IPK, which are measured against the IPK every 50 years, are held by other nations and constitute the national standard kg. Masses used in calibration laboratories to calibrate other masses are calibrated against the national standard. Those masses are called primary standards and are used to calibrate the so-called secondary standards,

FIGURE 10.22 A photograph of the IPK in Paris.

which may be either masses or very accurate force transducers. The key to any acceptable calibration is traceability to the primary standard. That is to say that a documentation trail can be followed back to the national primary standard.

Of course, it is not enough to know that your mass is the equivalent of a kilogram when measuring force: Equation 10.2 states $F = mg$, where g is the acceleration due to gravity. So, to measure static forces on Earth, we need to know what the acceleration due to gravity is at our location. Because g decreases radially from the center of the Earth according to the inverse square law, the acceleration due to gravity at the Earth's surface very much depends on the altitude and latitude of your measurement position according to the equation (Boynnton, 2001)

$$g = 9.80613 (1 - 0.0026325 \cos 2L) (1 - 3.92 \cdot 10^{-7} H) \quad (10.23)$$

where L is the latitude of the measurement position in degrees and H is the altitude, or height.

The force applied by an adjusted 1 kg mass measured with a force transducer in a laboratory in Mexico local g is 9.77954 ms^{-2} , would be approximately 0.4% different from an identical measurement made in Oslo local g is 9.825 ms^{-2} .

Load cells are calibrated using a force application system, which can be as simple as a calibrated mass hung by a hook, normally for smaller force ranges for health and safety reasons, or a so-called weight stack, which may be manually or computer controlled,

FIGURE 10.23 (a) A small 2500 N weight stack and (b) a basic frame for hanging calibrated masses onto a force gauge (Courtesy of Mecmesin Ltd).

where a set of calibrated masses can be applied sequentially to measure a load cell's output at regular intervals across its range. Weight stacks can range from small (<1 kN) through to the very large (>1 MN). The largest weight stack in Europe has a capacity of 1.2 MN and is at the National Physical Laboratory in London, England (Figure 10.23). The largest weight stack in the world resides in the United States and is rated at 4.45 MN (1000,000 lbf)!

10.12.1 Uncertainty

There are many texts (International Organization for Standardization, 1995; M3003, M2007; European co-operation for Accreditation, 1999) that cover uncertainty of measurement in much more detail than is given here, but we will give a brief overview.

In all measurements, there is never absolute certainty of the result. However, we can estimate the level of uncertainty in a measurement in order to communicate the likelihood of a result being accurate. We can also design our measurement systems in such a way as to minimize uncertainty. This is especially important in calibration, because whoever is providing the calibration service is making a statement about a device's accuracy that a customer will use in their analysis of the measurements they make. Given that some applications are safety critical it is vitally important that the customer is provided with accurate estimations of calibration measurement uncertainty. Using masses calibrated against primary standards ensures that the uncertainties related to the masses are minimized, but there are many other contributing factors.

Temperature: Because load cells (and the systems that hold them) are made of metal (aluminum or steel mostly), temperature will have an effect on performance. Temperature stability during calibration is therefore vital.

Humidity: Humidity affects the buoyancy of the air, thereby affecting the applied force, and so should be kept as constant as possible during calibration.

Gravity: The local value for gravitational acceleration (g) should be taken into account when calibrating and using masses. If a calibrated mass is taken elsewhere to be used to verify a measurement, then a simple correction factor should be calculated for the new location depending on its value for g . An example follows that illustrates this.

For example, say we want to calibrate a device at our laboratory using a mass that applies a force of 1000 N. Previously, g at our location has been calculated to be 9.81 ms^{-2} . A mass is then manufactured and adjusted to our specification and it is delivered with its certificate confirming traceability to the primary standard, so that if an instrument is then calibrated in our lab using the mass, we will know that exactly 1000 N (with a small uncertainty) is being applied to our device. The instrument is then sold to a customer in a different location with a local g value of 9.8120000 and 12 months later the customer requires a recalibration at their premises. The following options are presented: We could purchase a mass that is adjusted to the g value at the customer premises, which could be costly and of limited use, or we could use our own adjusted masses and apply a correction factor taking into account the g value where the customer is. The correction factor would be evaluated as follows.

A mass is calibrated and adjusted to apply a specific force according to Equation 10.2, so if that mass is transported elsewhere and applied to an instrument previously calibrated in the laboratory, the resultant measurement will read

$$F' = m(g + \Delta g) \quad (10.24)$$

Taking m out of the equation

$$F' = F \left(1 + \frac{\Delta g}{g} \right) \quad (10.25)$$

And so

$$F' \left(1 + \frac{\Delta g}{g} \right)^{-1} = F \quad (10.26)$$

Substituting the g values from the example, a correction factor of 0.9997962 should be used to correct the displayed force. Without using g correction, at 1000 N the error would be approximately 0.2 N.

For the 1.2 MN calibration stack in Figure 10.24, in order to reduce uncertainties associated with the force application it is constructed on top of 40 m piles for stability and each mass in the stack is trimmed to its own value of g depending upon its altitude in the stack!

In minimizing uncertainties, providing the correct mechanical linkage is also vital, that is, the means to connect your load cell to the applied force. Because strain gauges are positioned very carefully on an elastic element of a specific shape, which is designed to measure force in a specific direction, and which as a whole is calibrated to measure axially, any off axis loading (i.e., side-loading) will result in an erroneous

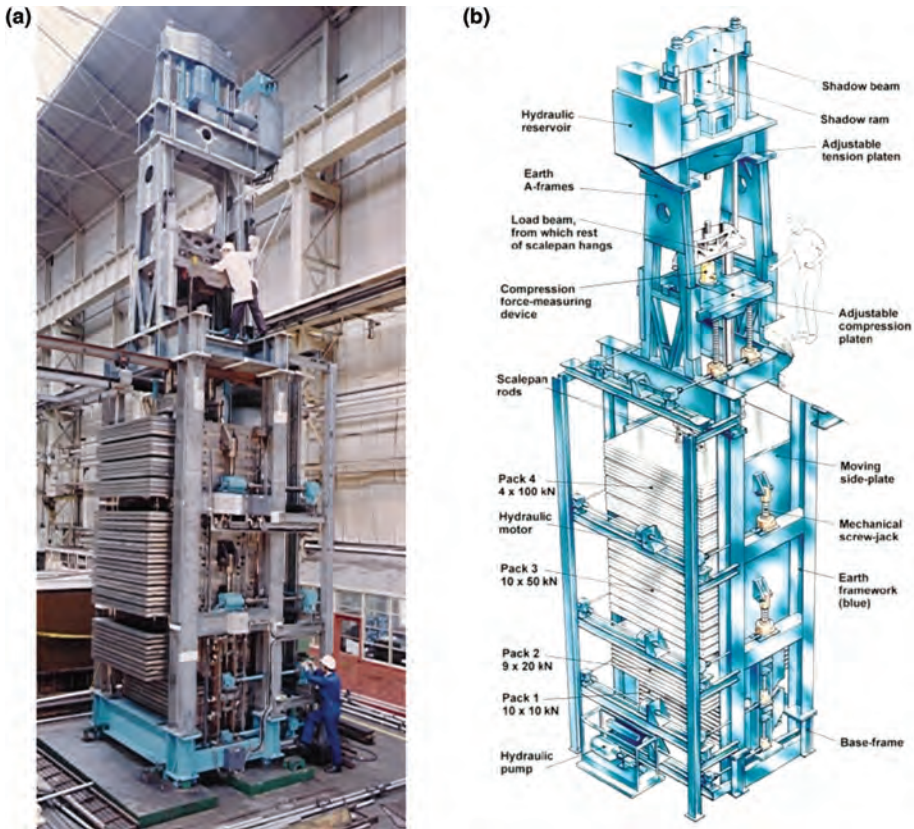

FIGURE 10.24 (a) Photograph of the construction of the 1.2 MN weight stack at NPL in London. (b) a schematic of the design. (Both courtesy of NPL, Teddington, London, UK.)

measurement. For this reason, it is vital that when using the load cell that it is mounted correctly, as incorrect fixturing can cause off-axis loading that will introduce errors, sometimes significant. Axial alignment of force vectors is easier in tension than in compression, because in tension, provided that no part of the system is rigidly fixed, the system will have a tendency to self align. In compression though, it is easy to end up in a situation where you are trying to “push a rope” so to speak, and in doing so can introduce significant alignment errors, and so a reliable method of linking the system components needs to be devised.

10.12.1.1 Other Equipment If other equipment is used in the calibration, for example voltmeters, thermometers, and so on, then the uncertainties of these instruments should be considered in the uncertainty budget.

10.12.1.2 Operator Inconsistency Finally, in a laboratory with more than one operator, results of calibrations can vary depending on the operator. Laboratory procedures may be in place that minimize the uncertainties introduced when different operators perform the same function, but there may be random errors introduced that should be considered.

FIGURE 10.25 (a) Rectangular, (b) triangular, and (c) normal probability distribution.

The list could go on, but the contributions made become smaller until they are no longer significant—it is also important to retain a sense of proportion! While it may be commendable to calculate the uncertainty contribution of a given item to the eighth decimal place, this is hardly significant to a device with a required accuracy of 0.5%.

When preparing your uncertainty budget, it is important to note that, because uncertainties are not precisely known they normally quoted as $\pm x\%$ along with a confidence limit. We must, therefore, understand the probability distribution associated with it. Taking the contributing factor of resolution as an example: If, say, a force gauge is reading a nominal value of 1.55 N but the last significant digit of the display is fluctuating between 1.54 and 1.56 N then, because we only know the upper and lower bounds of the error, the true value could be anywhere between these limits with an equal probability of any one true value in that range. If we plotted the probability distribution it would look like the diagram in Figure 10.25a).

The uncertainty of this type of contributing factor has what we call a rectangular distribution. A combination of two rectangle distributions gives, by the process of convolution, a triangle distribution as shown in Figure 10.25b. Triangular distributions are rare but could apply to the process of interpolation between two known values for example, and this is unlikely in the case of an uncertainty budget of a measurement process. If many probability distributions are combined or where random factors are involved, then the result will be a normal distribution—Figure 10.25c. Normal distributions are assigned to uncertainties given in calibration certificates, for example, the “calibration of adjusted masses” entry in Table 10.3. In force measurement, the majority of uncertainty budget contributors have rectangle or normal distributions.

Once all contributions have been accounted for and their values calculated, a divisor is applied, which is dependent upon the probability distribution function. Uncertainties are combined by quadrature addition, that is

$$\text{Combined}_U = \sqrt{\sum u^2} \quad (10.27)$$

In order to quote a confidence level of 95%, the combined uncertainty is multiplied by a factor of 2. If a value, $k = 3$ were to be used, the confidence level would rise to 99.7% but this is rarely used in force measurement. A typical uncertainty analysis table for a dead-weight frame such as the ones in Figure 10.19 is shown in Table 10.3.

Looking at the table, we can see the contributors that have been considered in the overall uncertainty budget along with their probability distribution functions. There was one contributor in this particular analysis that was not included, which was the effect of temperature on the deadweight frame. Because of thermal fluctuations, the metal frame will

TABLE 10.3 A Typical Uncertainty Budget for a Deadweight Calibration System

Source of Uncertainty	Value $\pm\%$	Distribution	Divisor	c_i	u_{iT}
Static frame alignment	0.001	Rectangle	1.73	1	0.00058
Frame flex under load	0.0001	Rectangle	1.73	1	0.000058
Calibration of adjusted masses	0.01	Normal	2	1	0.005
Drift of adjusted masses	0.01	Rectangle	1.73	1	0.0058
Random	0.001	Normal	2	1	0.0005
Combined uncertainty normal		Normal			0.011
Expanded uncertainty		Normal ($k = 2$)			0.022

(Courtesy of Mecmesin Ltd)

undergo a dimensional change due to expansion and contraction. After analysis it was seen that the overall effect on the application of mass was approximately 0.0000001% and so was not included.

10.13 CONCLUSION

There are many ways to measure force and torque, and this chapter has given a review of but a few of the more common methods, along with an overview of calibration and traceability considerations. Which method is used will depend on many factors including range, application, environment, life requirement of the sensor, instrumentation availability, and, of course, cost.

GLOSSARY OF TERMS

Accuracy

This is an expression of how close a measurement is to the actual value. Not to be confused with precision.

Analogue Output	An analogue output is a continuous signal, from a transducer, given usually as a voltage or a current. The output from a load cell is an analogue one but it is put through an analogue to digital converter so that it can be manipulated and stored in a useful form for computers.
Axial Strain	Axial, meaning “on axis.” This is the extent of sample deformation in the direction in which the force is applied.
Band Pass	In filtering, a filter that allows a given range of frequencies to pass unhindered, while frequencies above and below the filter band limits are blocked.
(Load Cell) Bridge Resistance	The nominal electrical resistance of the load cell circuit measured at the excitation connections of the load cell with zero load applied to the load cell and the output connections open circuit. Expressed in ohms (Ω).
Calibration	The comparison of transducer output against input quantities that are traceable to international standards. Calibration would normally be carried out by a recognized authority and should result in the issue of a calibration certificate. If there is any change in transducer performance or damage to the transducer or if there is any unusual behavior exhibited by the transducer, it should be recalibrated.
Capacity (of Load Cell)	The maximum axial load a load cell is designed to measure within its specifications.
Compression	The application of a force, the end result of which is to reduce the sample height. Applying pressure to a sample in order to deform or flatten it.
Creep	When a change in load is applied to a specimen, the new stress and/or strain reading can drift by a small amount over time. This is termed creep.
Deflection	The degree to which a structural element is displaced under a load. In Mecmesin systems, this is measured from the crosshead position as standard, but where more accurate measurement of deflection is required an extensometer should be used.
Deformation	A change in the dimensions of a material under stress or strain.
Displacement	The total driven movement of a test stand. Linear displacement is usually measured in millimeters or inches, whereas rotary displacement is usually measured in revolutions (revs) or degrees. Note that displacement may differ from specimen deformation.
Drift	The change in transducer output when zero input is given. Not to be confused with creep, which is the change in transducer output under a load.
Ductility	The amount of plastic deformation exhibited by a material before it ruptures.

Eccentricity	The difference between the direction of load application to the true axial direction.
Elastic/Elasticity	A material is said to be elastic if it deforms under stress (e.g., external forces), but then returns to its original shape when the stress is removed. The amount of deformation is called the strain. Elasticity is the ability of a material to return to its original dimensions subsequent to the application of stress or strain. The linear portion of the stress/strain curve of a Hookean material is called the elastic region because if applied force is removed within this region, the material will return to its original shape and size.
Elastic Limit	This is the stress value during a tensile or compression test after which the sample suffers permanent deformation. For Hookean materials, it is roughly equal to the limit of proportionality (LOP).
Energy	The work done on a sample during a tensile or compression test. It is calculated as the area under the stress/strain curve and is measured in Joules, the SI derived unit for energy.
Equilibrium	Achieved when the sum of all forces acting upon a body is zero.
Extension	The amount by which an object is increased in length.
Extensometer	An instrument used to measure extension.
Extrinsic	Extrinsic properties are characteristics of a test specimen as a whole, rather than the material from which it is made. Examples of extrinsic properties are mass and volume. Opposite of intrinsic, examples of which include temperature, density, and melting point.
Force	The classic definition of force is any action that alters or tends to alter a body's state of rest or of uniform motion in a straight line. Force has both magnitude and direction, making it a vector quantity. Newton's second law states that an object with a constant mass will accelerate in proportion to the net force acting upon and in inverse proportion to its mass. Equivalently, the net force on an object equals the rate at which its momentum changes. Force is measured in newton, which is an SI derived unit. One Newton is the force required to accelerate 1 kg to 1 m/s^2 . Forces acting on three-dimensional objects may also cause them to rotate or deform, or result in a change in pressure and/or volume in some cases. The tendency of a force to cause changes in rotational speed about an axis is called torque.
Frequency	The number of times an event occurs per unit time. Rate. Measured in hertz (Hz), kilohertz (kHz), or megahertz (MHz).

Frequency Response	This is the ability of a system output to replicate the input. Most electrical systems have limited frequency response (bandwidth), which allows the elimination of noise from the measurement. It is important for a system to have a bandwidth sufficient to capture significant events of the test, for example, details at sample break. Mecmesin Emperor driven systems have a sampling frequency of 2000 Hz, which means that a reading is taken every 0.5 ms.
Friction	Static friction is the force required to start one surface sliding against another. Dynamic friction is the force required to keep one surface sliding over another.
Full Scale (FSD)	This is the capacity of a sensor, in this context, the load measurement system or load cell. FSD stands for full-scale deflection and is derived from old analogue displays, which used a needle against a background scale.
Gauge Factor	A figure of merit for strain gauges. A sensitivity ratio that describes the relative ability of a strain gauge to measure strain.
Gauge Length	Used to calculate elongation. This is often stated in industry standards as the distance between the grips on a universal testing machine.
Grating	An optical device that allows spectroscopic analysis of incident light.
Gravity	The relatively weak force that is measured between two masses.
Grips/Fixtures	A mechanical device that grasps and holds the test specimen. Mecmesin grips include mechanical, pneumatic, vice grips, textile attachments, and specialist fixtures.
Hooke's Law	Assuming perfectly elastic behavior, stress is linearly related to strain: Robert Hooke, in the seventeenth century, stated "As the extension, so the force." $F = -kx$, where x is the displacement, F is the restoring force required and k is the force, or spring constant. Materials that exhibit near ideal elastic behavior are sometimes called "Hookean" materials.
Hysteresis	When a material is cycled from zero stress to a peak stress and then back to zero again, the stress/strain curve follows a closed loop. This is because the material does not have perfect elasticity and is slightly stretched on the "up" stroke. The maximum difference between stress on the upward and downward strokes of the cycle is quoted as the hysteresis, normally in terms of % FSD.

Intrinsic	The fundamental properties of a material. Melting point, density, heat capacity, and so on.
Joule	The SI derived unit of work, energy, and heat. It is the work done when a force of 1 N moves through a distance of 1 m. The area under a stress/strain curve gives the measurement of work done on a sample during a test.
Kilogram Force (Kgf)	The “kilogram force” is 9.80665 N. The practice of expressing force in kgf arose from the historical confusion that existed between “mass” and that particular force with which we are all familiar and which we refer to as “weight.” Although not adopted as a unit by the International System of Units (SI), kgf may be defined as “the force that produces an acceleration of 9.80665 m/s^2 (this is the internationally adopted value of the acceleration due to gravity) on a mass of one kilogram.” A kgf may sometimes be written as “kp” and referred to as a “kilopond.”
Kilopascal (kPa)	The SI derived unit of pressure and stress is the Pascal (force per unit area: $1 \text{ Pa} = 1 \text{ N/m}^2$). The “kilopascal” is 1000 N/m^2 or 1 mN/mm^2 .
lbf	The true imperial unit of force is the poundal (the force that produces an acceleration of one foot per second per second on a mass of one pound), but this is no longer used. Instead the term “pound force” is in widespread use and is a curious mixture of imperial and metric measurements. One lbf is about 4.44822 N, the force required to accelerate 1 lb by 9.80665 m/s^2 .
Load	An alternative term to mean force. The two are used interchangeably.
Load Cell	The transducer used in Mecmesin Universal testing machines. Load cells are based on strain gauge technology. This is a tried and tested method of measuring force using a change in electrical resistance brought about by

	dimensional changes in a metal block caused by increasing and decreasing force.
Load at Yield	The load reported at the point at which a specified deviation from proportionality of stress and strain occurs.
LOP (Limit of Proportionality)	This is the point on the stress/strain curve beyond which the stress does not increase proportionally with strain.
LVDT	Linear variable differential transformer. A type of electrical transformer used to measure linear displacement. Three coils are used, with the central coil being the primary. When an alternating current is present in the primary coil, a voltage is induced in the secondary coils, which is proportional to the inductance between them and the primary. As the coils are moved along a tube, their mutual inductances change and a voltage change is seen in the secondary coils. The difference between the two secondary coil voltages is proportional to the linear displacement along the tube.
Mass	Mass is related to force by the equation, $F = mg$, where mass is effectively constant, subject to the special theory of relativity where the mass of a body is measured in terms of its total energy content.
Magnetostriction	The effect seen when a change in the strain on a magnetic object produces a change in the measured magnetic flux in the object.
Measuring Range	The difference between maximum and minimum loads in a specific test or application. It must not exceed load cell capacity.
Median Force	This is the central value in a group of values, when placed in order. If there is an even number of values, then the median is halfway between the two central values.
Minimum Load	The lowest load in a specific test or application. This is not necessarily zero load, but includes the weight of any fixtures which are attached plus any intentional preload which is applied.
Modulus of Elasticity	Rate of change of strain as a function of stress. The slope line portion of a stress/strain diagram.
MPa	The SI derived unit of stress is the Pascal (1 N/m^2). The “megapascal” is 1 N/mm^2 .
Newton	The SI derived unit of force is the newton (the force that produces an acceleration of 1 m/s^2 on a mass of 1 kg).
Nonlinearity	Nonlinearity can be evaluated for either an individual data point or for a measurement run. For an individual point it is the difference between measured output at a specific load and the corresponding point on the straight-line fit to the output data. Normally expressed in units of %FSD. The nonlinearity for a measurement is usually defined as the maximum deviation between the measured output

and straight-line fit to the output data. This can be expressed in terms of the measurement units or %FSD.

Nonrepeatability
Overload

Sometimes used to mean the same as repeatability. Applying a force that exceeds the capacity of the load cell. Repeated overload, or significant overload can damage the load cell and require a recalibration or replacement. It is important to ensure that there is headroom built in to your system, that is, use a load cell that has a capacity of approximately 120% of the expected maximum load.

Photo Etch

A manufacturing process utilizing light upon a photo chemically sensitive layer to create a template pattern on very thin material.

Piezoelectric effect

Whereby a material exhibits a voltage created when its dimensions are changed. Conversely, a piezoelectric material will exhibit a dimensional change if an electric field is applied.

Precision

The expression of how close multiple measurements of the same quantity are to each other. Not to be confused with accuracy.

psi	“Pounds per square inch,” the imperial unit of stress.
Quasi-digital	An output signal that is time-based, for example, a frequency, that can be then coupled directly to a digital circuit with time measurement capability.
Refractive Index	The ratio of speed of light in a material to the speed of light in a vacuum
Repeatability	<p>The closeness of agreement between independent results obtained with the same method on identical test material, under the same conditions (same operator, same apparatus, same laboratory and after short intervals of time). Traditionally, repeatability is expressed as the standard deviation of results from repeated measurements of loadings under identical loading and environmental conditions using the same operator. When using this method, quoting 2 times the standard deviation gives approximately 95% confidence. Sometimes the maximum difference between output readings is used. Normally expressed in units of % RO or %FSD.</p> <p>In some contexts repeatability may be defined as the value below which the absolute difference between two single test results obtained under the above conditions, may be expected to lie with a specified probability.</p>
Reproducibility	Reproducibility, although similar, should not be confused with repeatability. It is the closeness of agreement between independent results obtained with the same method on identical test material, under the same conditions but with different operators.
Guide to the Expression of Uncertainty in Measurement	The resolution corresponds to the smallest two digits/values which can be read from a measurement device. Resolution should in no way be confused with Accuracy.
Resonance	Resonance occurs when the frequency of an input signal coincides with the natural resonant frequency of a material or object.
Sensitivity	The response of a device to a unit change input.
SI unit	<p>In 1960, the <i>Système International d’Unités</i> was introduced to replace systems of units based upon the meter/kilogram/second (mks), the centimeter/gram/second (cgs) and the foot/pound/second (fps). It is based on seven basic units:</p> <p>Length, meter (m) Mass, kilogram (kg) Time, second (s) Electrical current, ampere (A)</p>

	Temperature, Kelvin (K)
	Amount of a substance, mole (mol)
	Luminosity, candela (cd)
	All other measurement units can be derived by a combination of these basic units.
Signal	The absolute level of the measurable quantity into which a force input has been converted. Normally expressed as a displacement (as in a dial-type force gauge), or a voltage or current in electrical gauges and load cells.
Standard Deviation	This is the root mean square deviation from the mean of a random distribution.
Standard Uncertainty	A component of uncertainty in a measurement, expressed as a standard deviation S . All components of an uncertainty will be combined to form the uncertainty of measurement as quoted on a calibration certificate.
Static Force	In door closing applications: This is the average force from the end of the dynamic time until data acquisition stops, that is, at 6 s.
Strain	Usually used to denote the engineering strain. Quantitatively, it is the change in length of a specimen (as a result of an applied load) divided by the original length of the specimen; it is usually expressed as a percentage.
Strain Gauge	A device with electrical resistance that is a function of the applied strain. Normally in a Wheatstone bridge configuration
Stress	Usually used to denote the engineering stress. It is the load applied to a specimen, divided by the cross-sectional area of the specimen. Pressure. Can be measured in N/mm^2 , N/m^2 , psi, MPa, or kPa.
Tare	To automatically subtract either the weight of a container, fixture, or specimen, or the residual force being exerted by the specimen. Subsequent readings correspond either to the weight of the contents of a container, or to the force being exerted (through the fixturing) by a specimen under tensile or compressive load.
Temperature Range, Compensated	The range of temperature over which the load cell is compensated to maintain output and zero balance within specified limits.
Temperature Range, Operating	The extremes of ambient temperature within which the load cell will operate without permanent adverse change to any of its performance characteristics.
Tension	A force tending to stretch or elongate a specimen or material.

Tensile Strength

The ultimate strength of a material subjected to tensile loading. It is the maximum stress developed in a material during a tensile test.

**Tensile Test**

A tensile test is a way of determining how something will react when it is being pulled apart, or more correctly, when a force is applied to it in tension. Also known as a Pull test.

Torque

A twisting effect, or moment, exerted by a force acting at a distance on a body, equal to the force multiplied by the perpendicular distance between the line of action of the force and the center of rotation at which it is exerted.

Torque is often expressed in units: N m, Kgf m, kgf cm, lbf ft, and lbf in

Torsion Test

Method for determining behavior of materials subjected to twisting loads. Shear properties are often determined in a torsion test (ASTM E-143).

Torsional Modulus

AKA torsional modulus of elasticity, it is usually equal to the shear modulus. It is the modulus of elasticity of a material subjected to a twisting force.

Traceability

Traceability is the property of a measured result or value of a standard, whereby it can be related to stated references, usually national or international primary or secondary standards, through an unbroken chain of comparisons and all having stated uncertainties.

Transducer

Device that converts a physical input into an output of a different form.

True Strain

This differs from engineering strain in that it is determined from the rate of change in gauge length with respect to the instantaneous gauge length. It is expressed as a natural logarithm of engineering strain.

True Stress

True stress is the load divided by the instantaneous area of the specimen.

Ultimate Strength

The highest engineering stress developed in material during a test and prior to rupture, or break. Normally, changes in area due to changing load and Necking are disregarded in determining ultimate strength.

Wave

Consisting of amplitude and frequency, a wave is a disturbance through a material or vacuum that is normally accompanied by a transfer of energy.

**Yield Point/
Yield Strength**

The point during a tensile test when a specimen ends elastic deformation and begins plastic deformation. There is an increase in strain with no corresponding increase in stress.

Yield strength is an indication of maximum stress that can be developed in a material without causing plastic deformation. It is the stress at which a material exhibits a specified permanent deformation and is a practical approximation of elastic limit.

**Young's
Modulus**

Hooke's law states

$$F = -kx$$

where F is the restorative force, x is the displacement, and k is a force (or spring) constant. Put another way

$$E = \text{stress/strain}$$

where stress is the force applied to the specimen and strain is the relative elongation of the specimen from its original length. E is known as Young's Modulus, represented as the gradient of the stress/strain curve within the initial linear region.

11.1 PRELIMINARY DISCUSSION

11.1.1 Scope

The measurement of strain is a fundamental necessity in many engineering disciplines and related industries. Consequently many strain measurement techniques have been developed. Methods of measurement can be roughly grouped into two major categories: those based on the behavior of light and those based on electronic devices. Examples of the former include reflection photoelasticity, geometric moiré, moiré interferometry, holographic interferometry, and digital image correlation (DIC). Examples of the latter include techniques that infer strain based on some change in an electrical characteristic of a strain measurement device, such as changes in resistance, inductance, or capacitance.

A significant discussion of all of these techniques would require a major treatise and is beyond the scope of this chapter. Rather, discussion is focused herein on one subcategory: strain measurements obtained by monitoring resistance changes. This focus is appropriate because at present strain measurement via resistance strain gages is by far the most widely used technique, although other methods (particularly DIC) are gaining in popularity. The reader interested in strain measurement methods beyond those described here is referenced to one of several excellent books devoted to these topics, including references (Sharpe, 2008; Shukla and Dally, 2010; Dally and Riley, 2005; Cloud, 1995; Sutton et al., 2009).

11.1.2 Definition of Strain

In this chapter, strain is discussed within the framework of continuum mechanics. In continuum mechanics, matter is studied at a physical scale large enough such that existence of individual atoms or molecules is not perceptible. That is, continuum mechanics analyses treat matter as a continuous substance, rather than as an assembly of discrete particles. This forms the basis of two major fields of study, *solid* mechanics and *fluid* mechanics. A solid substance is one that can resist deformation due to shear stress, whereas a fluid substance cannot. This chapter is devoted to strains encountered in solid mechanics.

Strain is essentially a description of the deformations that have occurred at a point in a solid body. Many different factors may have caused the deformation, including application of surface forces, gravity effects, electromagnetic forces, temperature changes, and so on or some combination thereof. The mechanism(s) that caused the deformations are immaterial to this discussion. It is sufficient to say that the deformation has occurred, and hence a nonzero *state of strain* may exist at any point in the solid body. The definition used to describe strain depends on the magnitudes of the deformation. *Finite strain theory* is used when the deformation is arbitrarily large, whereas *infinitesimal strain theory* is used when the magnitude of the deformation is small. Throughout this chapter it will be assumed that deformations are small, such that infinitesimal strain theory can be applied. This is usually the case for structures encountered in civil, mechanical, and aerospace structural engineering.

Displacements of a solid body in the x -, y -, and z -directions are typically denoted $u(x, y, z)$, $v(x, y, z)$, and $w(x, y, z)$, respectively. Infinitesimal strains are related to displacements as follows:

$$\begin{aligned} \epsilon_{xx} &= \frac{\partial u}{\partial x} & \gamma_{xy} &= \gamma_{yx} = \left(\frac{\partial v}{\partial x} + \frac{\partial u}{\partial y} \right) \\ \epsilon_{yy} &= \frac{\partial v}{\partial y} & \gamma_{yz} &= \gamma_{zy} = \left(\frac{\partial w}{\partial y} + \frac{\partial v}{\partial z} \right) \\ \epsilon_{zz} &= \frac{\partial w}{\partial z} & \gamma_{zx} &= \gamma_{xz} = \left(\frac{\partial u}{\partial z} + \frac{\partial w}{\partial x} \right) \end{aligned} \quad (11.1)$$

Strain components ϵ_{xx} , ϵ_{yy} , and ϵ_{zz} are called *normal strains*, whereas $\gamma_{xy} = \gamma_{yx}$, $\gamma_{yz} = \gamma_{zy}$, and $\gamma_{zx} = \gamma_{xz}$ are called *engineering shear strains*. To fully describe the state of strain at a point, the numerical values of all six independent strain components must be specified.

Although strains occur in three-dimensions, most strain measurements are limited to strains that occur on the surface of a solid. Let the surface of interest lie in the x - y plane. Therefore, the three strain components to be measured are ϵ_{xx} , ϵ_{yy} , and γ_{xy} .

A physical interpretation of normal and engineering shear strains that occur in the x - y plane can be developed based on the two-dimension sketch shown in Figure 11.1. Imagine that a rectangle with dimensions dx and dy has been drawn on a flat surface. Three corners of the rectangle are labeled as A , B , and C . Initially, the angle $\angle ABC$ is precisely $\pi/2$ radians (i.e., initially $\angle ABC = 90^\circ$). Now assume some mechanism(s) causes a displacement of the surface, and consequently the rectangle displaces as shown. The sides of the rectangle have increased in length and rotated, such that $\angle A'B'C' < \pi/2$.

Normal strains in the x - and y -directions, ϵ_{xx} and ϵ_{yy} , respectively, are defined as change in length divided by the original length of the rectangle sides in the x - and y -directions. From Figure 11.1, and assuming small displacements and displacement gradients, we have

$$\epsilon_{xx} = \frac{\left(\partial x + \frac{\partial u}{\partial x}\right) - (\partial x)}{\partial x} = \frac{\partial u}{\partial x}$$

and

$$\epsilon_{yy} = \frac{\left(\partial y + \frac{\partial v}{\partial y}\right) - (\partial y)}{\partial y} = \frac{\partial v}{\partial y}$$

These results are among those listed in Equation (11.1). A normal strain corresponding to an increase in length is called a *tensile strain* and is algebraically positive. Conversely, a normal strain corresponding to a decrease in length is called a *compressive strain* and is

FIGURE 11.1 Sketch used to visualize infinitesimal strain.

algebraically negative. Note that normal strain is a unitless quantity, since it is a ratio of two lengths.

Referring again to Figure 11.1, engineering shear strain γ_{xy} is defined as the *change* in $\angle ABC$, expressed in radians. That is, engineering shear strain equals the *sum* of angles θ_1 and θ_2

$$\gamma_{xy} = \gamma_{yx} = \theta_1 + \theta_2$$

The tangent of angle θ_1 is given by

$$\tan \theta_1 = \frac{\frac{\partial v}{\partial x}}{\frac{\partial u}{\partial x} + \frac{\partial v}{\partial x}} = \frac{\frac{\partial v}{\partial x}}{1 + \frac{\partial u}{\partial x}}$$

Assuming small displacement gradients, the denominator in this expression is very close to unity, and hence

$$\tan \theta_1 \approx \frac{\partial v}{\partial x}$$

An identical process leads to

$$\tan \theta_2 \approx \frac{\partial u}{\partial y}$$

Again assuming small displacements and displacement gradients, which in the present context implies that both θ_1 and θ_2 are small angles expressed in radians, we have

$$\tan \theta_1 \approx \theta_1 \quad \text{and} \quad \tan \theta_2 \approx \theta_2$$

Combining the above, we find

$$\gamma_{xy} = \gamma_{yx} = \theta_1 + \theta_2 = \frac{\partial v}{\partial x} + \frac{\partial u}{\partial y}$$

This result is among those listed in Equation (11.1). A shear strain is positive if $\angle ABC$ has *decreased* (thus, Figure 11.1 illustrates a *positive* engineering shear strain). Since shear strain is an angle measured in radians, and since radians are defined as the ratio of two lengths and are, therefore, unitless, shear strain is a unitless quantity.

In passing, the reader should contrast the definition of engineering shear strain described earlier to the definition of *tensoral shear strain*, usually denoted $\varepsilon_{xy} = \varepsilon_{yx}$. Tensoral shear strains are defined as the *average* of angles θ_1 and θ_2 , rather than the sum:

$$\varepsilon_{xy} = \varepsilon_{yx} = \frac{\theta_1 + \theta_2}{2}$$

Hence, engineering shear strain differs from tensoral shear strain by a factor of 2:

$$\gamma_{xy} = \gamma_{yx} = 2\varepsilon_{xy} = 2\varepsilon_{yx}$$

Although the use of tensoral shear strain is mathematically elegant, engineering shear strains are far more commonly used in practice. The use of engineering shear strain will be assumed throughout the remainder of this chapter. In the following discussion, the phrase “engineering shear strain” will be abbreviated as “shear strain.”

Consider the tensile member shown in Figure 11.2a. A square grid pattern referenced to the x - y coordinate system is printed on the surface of the member. An axial tensile load is applied, causing both an increase in length and decrease in width (Figure 11.2b). It is apparent that the initially square grids will deform into rectangles. Qualitatively, the following strains are induced

$$\begin{aligned}\varepsilon_{xx} &< 0 \text{ (compressive)} \\ \varepsilon_{yy} &> 0 \text{ (tensile)} \\ \gamma_{yy} &= 0 \text{ (no change in angle)}\end{aligned}$$

Now consider the identical tensile member shown in Figure 11.3a. In this case, the square grid pattern is referenced to a x' - y' coordinate system oriented θ -degree counter-clockwise from the longitudinal axis. An identical axial load is applied, causing an identical increase in length and decrease in width. However, the initially square grids now deform into a rhombus. The insert implies that the following strains have been induced

$$\begin{aligned}\varepsilon_{x'x'} &< 0 \text{ (compressive)} \\ \varepsilon_{y'y'} &> 0 \text{ (tensile)} \\ \gamma_{y'y'} &> 0 \text{ (decrease in corner angle)}\end{aligned}$$

FIGURE 11.2 Beam with a square grid pattern parallel to beam axis. (a) Undeformed. (b) Deformed.

FIGURE 11.3 Beam with a square grid pattern inclined θ -degree from the beam axis. (a) Undeformed. (b) Deformed.

Figures 11.2 and 11.3 illustrate two important points. First, although strain is a description of deformation, the numerical values of the individual strain components that (collectively) describe the deformation depend on the coordinate system use. For example, the numerical values of the strain components illustrated in Figure 11.2 differ from the numerical values of the strain components illustrate in Figure 11.3, even though the tensile member deformation is identical in both cases. The description of the deformation, that is, the strains, can be rotated from one coordinate system to another using the *strain transformation equations*. Recall that the present discussion has been limited to strains within a plane. For this case, if strain components relative to the x - y coordinate system are known (ϵ_{xx} , ϵ_{yy} , γ_{xy}), then strain components referenced to a new x' - y' coordinate system-oriented θ -degree from the x - y coordinate system are given by

$$\begin{aligned}\epsilon_{x'x'} &= \epsilon_{xx}\cos^2\theta + \epsilon_{yy}\sin^2\theta + \gamma_{xy}\sin\theta\cos\theta \\ \epsilon_{y'y'} &= \epsilon_{xx}\sin^2\theta + \epsilon_{yy}\cos^2\theta - \gamma_{xy}\sin\theta\cos\theta \\ \gamma_{x'y'} &= 2\sin\theta\cos\theta(\epsilon_{yy} - \epsilon_{xx}) + \gamma_{xy}(\cos^2\theta - \sin^2\theta)\end{aligned}\quad (11.2)$$

The algebraic sign of angle θ is defined in accordance with the right-hand rule. For example, in Figure 11.3 angle θ is a positive angle since axis x' is rotated *from* the x -axis *toward* the y -axis.

The second important point illustrated by Figures 11.2 and 11.3 is that there is always a particular coordinate system, called the *principal strain coordinate system*, in which shear strains are zero. Obviously, the coordinate system used in Figure 11.2 is a principal strain coordinate system, whereas the coordinate system used in Figure 11.3 is not. The normal strains that exist in the principal coordinate system are called the *principal strains* and are denoted ϵ_1 , ϵ_2 , and ϵ_3 . Since in this discussion it has been assumed that out-of-plane shear strains $\gamma_{yz} = \gamma_{xz} = 0$, one of the principal strains is the out-of-plane normal strain ϵ_{zz} . The other two principal strains lie within the x - y plane. Ordinarily, the three principal strains are ordered such that $\epsilon_1 > \epsilon_2 > \epsilon_3$. However, since in the present case ϵ_{zz} is always a principal strain, the

convention adopted here is that $\varepsilon_3 = \varepsilon_{zz}$, and the two in-plane strains will be labeled ε_1 and ε_2 . If strain components ($\varepsilon_{xx}, \varepsilon_{yy}, \gamma_{xy}$) are known, then the in-plane principal strains are given by

$$\varepsilon_{1,2} = \frac{\varepsilon_{xx} + \varepsilon_{yy}}{2} \pm \sqrt{\left(\frac{\varepsilon_{xx} - \varepsilon_{yy}}{2}\right)^2 + \left(\frac{\gamma_{xy}}{2}\right)^2} \quad (11.3)$$

The angle θ_p from the x -axis to the 1-axis is given by

$$\theta_p = \tan^{-1} \left[\frac{2(\varepsilon_1 - \varepsilon_x)}{\gamma_{xy}} \right] = \tan^{-1} \left[\frac{\gamma_{xy}}{2(\varepsilon_1 - \varepsilon_y)} \right] \quad (11.4)$$

11.1.3 Practical Implications

As is evident from the preceding discussion, strain measurement involves two types of measurements. Normal strains require measurement of a change in length, and shear strains require measurement of a change in angle. Conceptually, these could be made with a simple ruled scale and protractor. For two reasons, these simple measurement devices are usually inadequate. First, the changes in lengths and angles involved are exceedingly small and difficult to measure precisely with simple measurement devices. A numerical example will serve to illustrate this difficulty. Many steel alloys will yield at a strain level of about 0.0012 m/m, or about $1200 \times 10^{-6} \text{ m/m} = 1200 \mu\varepsilon$ (read: “1200 microstrain”). This implies a steel element with an initial length of 10 mm will increase to a length of 10.012 mm at yielding. Recognizing that structural engineers are required to measure strains well below yielding, it is obvious that ruled scales do not provide the resolutions required. Similarly, many steel alloys subjected to a pure shear strain will yield at a shear strain level of about 0.0016 rad, or about $1600 \times 10^{-6} \text{ rad} = 1600 \mu\varepsilon$ (about 0.09°). Once again, simple protractors cannot be used to measure such small angular changes.

Second, since strains generally vary throughout a structure, the goal is usually to measure strains “at a point.” Thus, not only must very small changes in length and angle be measured, but also these changes must be measured over as small an initial area as possible.

Finally, for a simple isotropic structure such as that shown in Figure 11.2 the orientation of the principal axis is known by inspection. In contrast, for the complex structural shapes and loadings typically encountered in practice, the orientation of the principal coordinate system is rarely known a priori.

11.2 RESISTANCE METAL STRAIN GAGES

11.2.1 General Description

Nowadays, the most widely used strain measurement device is certainly the resistance metal strain gage and is originally known as “bonded wire strain gages,” they are based on a phenomenon first noticed by William Thomson (later named Lord Kelvin) in 1856: the resistance of an electrically conductive metal wire is increased if the wire is stretched

FIGURE 11.4 Basic elements of a metal foil strain gage.

and decreased if the wire is compressed. This phenomenon has since come to be known as the piezoresistive effect.¹

Based on this observation and working independently, Edward Simmons (in about 1937) and Arthur Ruge (in 1938) bonded small metal wires to structures they were studying and monitored the resistance change as the structures were loaded. The change in resistance provided an indirect measure of the change in wire length and hence strain. Simmons and Ruge are considered to be the coinventors of resistance strain gages. The first resistance strain gages became commercially available in 1941 and were marketed under the trade name “SR-4 gage,” in honor of Simmons, Ruge, and two colleagues who helped perfect and market the gage.

The next major development occurred in 1952, when engineers at Saunders-Roe Ltd. used the photoetch process to produce strain-sensing elements from thin metal foil rather than wire. The etching process makes it possible to produce large numbers of very small and complex sensing elements from a single parent sheet of metal foil. Although wire gages are still used in some circumstances, today most resistance metal strain gages are produced using the photoetch process.

The basic construction of a metal foil strain gage is summarized in Figure 11.4. The sensing element is etched from a parent metal foil in the desired pattern and bonded to a thin and flexible polymeric backing film. Backing films of polyimide or glass-reinforced epoxy are most commonly used, and serve to stabilize the delicate foil pattern during handling and also to electrically isolate the metal foil from the underlying substrate. The metal foil/backing film is subsequently adhesively bonded to the surface of interest. A good bond between the surface and the gage assembly is critically important, since the strain being measured must be transferred through the adhesive bondline and backing film to the metal foil. Detailed strain gage bonding instructions are provided by strain gage manufactures, and the user is well advised to follow these instructions precisely.

¹ The piezoresistive effect should not be confused with the piezoelectric effect. In the former, a mechanical strain results in a resistance change. In the latter, a mechanical strain causes an electrical potential to occur.

The gage pattern is designed such that strain is sensed primarily in the axial direction of the grid. Alignment marks are included as an alignment aid during the bonding process. Traditionally, leadwires are soldered to the solder tabs of the gage after it has been bonded to the surface, although it is possible to attach the leadwires prior to bonding, and in fact most strain gage manufacturers now offer gages with preattached leadwires.

11.2.2 Strain Sensitivity

Strain sensitivity is a measure of how much resistance changes per unit strain and is defined as

$$S = \frac{\left(\frac{\partial R}{R}\right)}{\varepsilon} \quad (11.5)$$

Strain sensitivity for pure metals ranges from about $-12 < S < 6$. Alloys commonly used in strain gages have strain sensitivities ranging from about 2 to 4. Note that a positive strain sensitivity implies that a tensile strain ($\varepsilon > 0$) causes an increase in resistance ($\partial R > 0$).

Strain sensitivity is often equated to the “gage factor” of the strain gage. In reality, there is a subtle difference between strain sensitivity, as defined by Equation (11.5), and the gage factor measured for a strain gage. The difference arises because of differences in the strain field present during measurement of strain sensitivity versus the strain field present during measurement of the gage factor. That is, strain sensitivity of an alloy is measured by applying uniaxial stress to an unconstrained metal specimen (typically a wire with circular cross-section) with initial resistance R . The resulting normal strain in the direction of loading ε and change in resistance ∂R are measured and used to calculate the strain sensitivity. Since the specimen is unconstrained, due to the Poisson effect a transverse strain equal to $-\nu\varepsilon$ also occurs, where ν is the Poisson ratio of the wire. The definition of strain sensitivity implies that this transverse strain is allowed to occur.

If the transverse strain actually differs from $-\nu\varepsilon$, which is a common occurrence for a strain gage bonded to a structure, then the resistance change of the bonded strain gage may not correspond to the strain sensitivity. This situation is described in greater detail in a following subsection entitled “Gage Factor and Transverse Sensitivity Coefficient.”

11.2.3 Strain Gage Alloys and Calibration Parameters

Strain gages have been produced using many different metal alloys since their introduction in 1941. The most common gage alloys are summarized in Table 11.1. These alloys have become preferred for various reasons, including the ability to roll the alloy into thin metal foils, ease of soldering leadwires to the alloy, linear change in resistance with strain, high strain to failure, good fatigue life, and thermal stability. Calibration parameters provided by the manufacturer include the gage resistance, the gage factor and transverse sensitivity coefficient, and the self-temperature compensation (STC) number.

Gage Resistance: In principle, a strain gage with any initial resistance can be used. In practice, 120, 350, or 1000 Ω gages are most common, since most commercial

TABLE 11.1 Common Resistance Strain Gage Alloys

Alloy	Nominal Composition	Gage Factor (S_g)	Comments
Constantan (or advance)	45% Ni, 55% Cu	2.1	Most widely used general purpose gage alloy Max strain $\sim 3\text{--}5\%$ (30,000–50,000 $\mu\epsilon$)
Karma	74% Ni, 20% Cr, 3% Al, 3% Fe	2.0	Excellent long-term stability More difficult to solder than Constantan Max strain $\sim 1.5\%$ (15,000 $\mu\epsilon$)
Isoelastic	36% Ni, 8% Cr, 0.5% Mo, 55.5% Fe	3.6	High thermal output Max strain $\sim 1.5\%$, but nonlinear at strains above 0.5% (5,000 $\mu\epsilon$) Excellent fatigue life
Nichrome V	80% Ni, 20% Cr	2.1	Used for high-temperature strain gages
Armour D	70% Fe, 20% Cr, 10% Al	2.0	Difficult to solder using standard methods
Alloy 479	92% Pt, 8% W	4.0	

strain gage amplifiers and data acquisition systems are designed to accept one of these resistances. The primary reason for selecting one gage resistance over another is the self-heating effect. That is, during the measurement process a voltage is applied to the gage, and the associated electrical current passing through the gage will cause an increase in gage temperature. Unstable temperature fluctuations may occur if a relatively high voltage is applied and the gage is bonded to a substrate that is a poor thermal conductor. The manufacturer provides recommendations on the maximum voltage (i.e., power) that can be safely applied based on the thermal properties of the substrate.

Gage Factor and Transverse Sensitivity Coefficient: A strain gage subjected to a biaxial strain field is shown in Figure 11.5. The resistance of the gage will be changed due to *both* the axial and the transverse strain components, ϵ_a and ϵ_t , respectively. This is an undesirable characteristic, since it would be ideal if the gage would respond *only* to the axial strain component. The gage factor and transverse sensitivity coefficient are calibration parameters that allow the user to remove the undesirable response to transverse strains from the strain signal.

Suppose a gage is subjected to an axial strain *only* (i.e., assume $\epsilon_t = 0$). The axial strain sensitivity of the gage, S_a , is defined under this condition

$$S_a = \frac{\left(\frac{\Delta R_a}{R_g}\right)}{\epsilon_a} \quad (11.6)$$

where R_g = original gage resistance; ΔR_a = change in gage resistance due to axial strain.

FIGURE 11.5 A strain gage subjected to a biaxial strain field.

Note that the definition of the axial strain sensitivity is similar to the expression used to calculate the strain sensitivity of an alloy (Eq. 11.5). However, a requirement associated with Equation (11.6) is that the transverse strain is zero, whereas this restriction is not imposed during measurement of the strain sensitivity of an alloy.

Now consider a case in which the gage is subjected to a transverse strain *only* (i.e., $\varepsilon_a = 0$). For this condition the transverse strain sensitivity of the gage can be defined as

$$S_t = \frac{\left(\frac{\Delta R_t}{R_g} \right)}{\varepsilon_t} \quad (11.7)$$

where ΔR_t = change in gage resistance due to transverse strain ε_t .

Gage manufacturers measure both the axial and the transverse strain sensitivities by subjecting a gage to pure axial or pure transverse strain, using a fixture specially designed for this purpose and described in an ASTM standard (ASTM Standard E 251, 2009). The *transverse sensitivity coefficient*, K_t , is defined as the ratio of the transverse and axial strain sensitivities:

$$K_t = \left(\frac{S_t}{S_a} \right) \quad (11.8)$$

The measured K_t is included in the calibration materials provided with each gage and is customarily defined as a percentage. For example, if a transverse sensitivity of 0.010 is measured for a particular gage, the manufacturer will report a value $K_t = 1.0\%$.

Now consider the case in which the gage is subjected to *both* the axial and transverse strains simultaneously. The total change in gage resistance ΔR in this case equals the sum of Equations (11.6) and (11.7):

$$\frac{\Delta R_g}{R_g} = \left(\frac{\Delta R_a}{R_g} \right) + \left(\frac{\Delta R_t}{R_g} \right) = S_a \varepsilon_a + S_t \varepsilon_t \quad (11.9)$$

Substituting the definition of K_t , this equation can be written as

$$\frac{\Delta R_g}{R_g} = S_a (\varepsilon_a + K_t \varepsilon_t) \quad (11.10)$$

During calibration, the strain gage is subjected to a *biaxial* strain field with a known ratio of $\varepsilon_t/\varepsilon_a$ (ASTM Standard E 251, 2009). This is achieved by mounting a gage in the axial direction on a tensile specimen with known Poisson ratio ν_o and applying an axial load (usually, $\nu_o = 0.285$). The resulting uniaxial state of stress causes a biaxial strain field, where the transverse strain is caused by the Poisson effect:

$$\varepsilon_t = -\nu_o \varepsilon_a \quad (11.11)$$

Substituting Equation (11.11) into Equation (11.10), the change in resistance for these conditions is

$$\frac{\Delta R_g}{R_g} = S_a (1 - \nu_o K_t) \varepsilon_a \quad (11.12)$$

The *gage factor* S_g is defined as

$$S_g = S_a (1 - \nu_o K_t) \quad (11.13)$$

Substituting this definition into Equation (11.12), we have

$$\frac{\Delta R_g}{R_g} = S_g \varepsilon_a \quad (11.14)$$

Through careful design of the gage grid strain gage manufacturers have successfully reduced transverse strain sensitivities to near-zero levels for many gage alloys and styles. If transverse strain sensitivity is reduced to a negligibly small value, then $K_t \approx 0$, $S_g \approx S_a$, and Equation (11.14) reduces to Equation (11.5). If transverse strain sensitivity is not negligibly small, then a strain gage measurement must be corrected for transverse sensitivity effects. Methods to correct for transverse sensitivity effects will be described in Section 11.2.4.

The strain sensitivity of an alloy, and consequently the gage factor of a strain gage, exhibits a modest temperature dependency. The magnitude and linearity of gage factor variation with temperature depends on the alloy used. As a rough rule of thumb, the gage factor for most commercial strain gages changes by 1–2% for a 100°C temperature change.

Self-Temperature Compensation Number: Consider a structure that is subjected to both external loading and to a temperature change ΔT . Some fraction of the strains induced in the structure is due to the external loading, while a fraction is due to thermal expansion or contraction caused by the temperature change. For modest temperature changes strains associated with thermal expansion/contraction (ε^T) can be calculated using the linear thermal expansion coefficient, α :

$$\varepsilon^T = \alpha(\Delta T) \quad (11.15)$$

The linear thermal expansion coefficient has been measured for most structural materials and is available in reference handbooks. For example, the thermal expansion coefficient for steel alloys is about $11 \mu\text{ε}/^\circ\text{C}$ ($6 \mu\text{ε}/^\circ\text{F}$).²

A strain measurement is said to be “temperature compensated” if that portion of the strain associated with free thermal expansion or contractions is subtracted from the total strain measurement. If this can be achieved, then only strains associated with stress will be measured.

A straightforward method of strain gage temperature compensation is to mount a gage on a small coupon of the material of interest, and to subject the unconstrained coupon to uniform temperature changes under carefully controlled laboratory conditions. The obtained measurements are plotted against temperature, generating a so-called “thermal apparent strain” curve. An identical strain gage is now bonded to a structure made from the same material, and the structure is subjected to the loads and temperature changes that occur in service. Apparent strains at a given temperature are subtracted from the strains measured in service, thereby compensating the strains measurements for temperature.

Initially, one might suppose that apparent strains would simply reflect the difference in thermal expansion of substrate and gage, $(\alpha_s - \alpha_g)\Delta T$. However, a change in the resistance of an *unbonded* strain gage also occurs with a change in temperature. Consequently even if the thermal expansion coefficients of the substrate and gage are identical, such that no mismatch exists, the resistance of a strain gage will change with temperature and an apparent strain will be measured. The change in resistance caused by a uniform temperature change ΔT can be written as

$$\left. \frac{\partial R}{R} \right|_{T_o} = \left[\beta_g + S_g \left(\frac{1 + K_t}{1 - \nu_o K_t} \right) (\alpha_s - \alpha_g) \right] \Delta T \quad (11.16)$$

where β_g is called the temperature coefficient of resistance of the gage alloy and is a measure of the change in gage resistance with temperature. In general, β_g is a highly nonlinear function of temperature, and can be algebraically negative or positive depending on temperature. For most alloys β_g can be manipulated over a wide range, through the use of cold-working and heat treatment processes. This gives rise to the concept of a

²This discussion assumes that the material is isotropic. Anisotropic materials, such as composites, usually exhibit three different thermal expansion coefficients, which are measured along the principal material coordinate system. This added complexity will not be addressed here. Suffice it to say that temperature-compensated strain gages can be used to measure strains in anisotropic materials, although extra care is needed to account for different thermal expansion coefficients in different material directions.

“self-temperature compensated” strain gage. The gage manufacturer manipulates β_g such the change in gage resistance due to a temperature change is equal and opposite to resistance changes due to the mismatch in thermal expansion coefficients. Because β_g is highly nonlinear compensation, it is not exact and can only be approximated over a limited temperature range. The *self-temperature compensation* number of a strain gage corresponds roughly to the thermal expansion coefficient of the test material the strain gage is intended to be bonded to. The system of temperature measurement used by the gage manufacturer is reflected in the STC number. That is, some manufacturers define the STC number in °F, whereas others define the STC number in °C. For example, a gage produced by manufacturer “A” and intended for use on steel could have an STC number of 06 (corresponding to $6\text{ }\mu\epsilon/\text{°F}$), whereas a similar gage offered by manufacturer “B” may have an STC number of 11 (corresponding to $11\text{ }\mu\epsilon/\text{°C}$).

A typical apparent strain is shown in Figure 11.6. In this case, a self-temperature compensated gage has been mounted to a sample of 17-4PH (a precipitation hardened stainless steel alloy), and the self-temperature compensated gage exhibits an apparent strain of less than $\pm 100\text{ }\mu\epsilon$ over the range $-75\text{°C} \leq T \leq 200\text{°C}$. The gage manufacturer typically fits the entire apparent structure curve to a fourth-order polynomial, and provides this curve-fit to the user. Curve fits based on temperatures measured in °C and °F are provided below the apparent strain curve shown in Figure 11.6.

11.2.4 Strain Gage Rosettes

The strain gage shown in Figures 11.4 and 11.5 is called a “uniaxial” strain gage, since it is intended to measure strain in only one direction. As discussed in the background

FIGURE 11.6 An apparent strain curve obtained for a strain gage with STC number 06, mounted in a coupon of 17-4 precipitation hardened stainless steel.

FIGURE 11.7 Common strain gage rosettes. (a) Biaxial rosette. (b) Rectangular rosette. (c) Delta rosette.

section 11.1.2, in practice three components of strain must be measured to determine the state of strain within a plane: ϵ_{xx} , ϵ_{yy} , and γ_{xy} . Once these strain components are known, the principal strains ϵ_1 and ϵ_2 and the orientation angle θ of the principal strain coordinate system can be calculated using Equations (11.3) and (11.4), respectively.

Since there are in general three unknowns (ϵ_{xx} , ϵ_{yy} , and γ_{xy} , or equivalently, ϵ_1 , ϵ_2 , and θ), three independent strain measurements are normally required to determine the state of strain within a plane. An exception occurs when the orientation angle θ is known a priori due to specimen geometry and loading (as in Figure 11.2, for example), in which case there are only two unknowns (ϵ_1 and ϵ_2), and only two independent strain measurements are required.

Conceptually, three uniaxial strain gages (or two uniaxial gages, if there are only two unknowns) could be used to measure strains in three (or two) different directions. However, as a practical matter it is easier to precisely align the gages in the intended orientation if three (or two) strain gages are bonded to the same backing by the gage manufacture. Strain gages produced in this manner are called *strain gage rosettes*.

Strain gage rosettes are commonly available in three forms, as shown in Figure 11.7. A biaxial rosette (also known as a T-rosette) consists of two perpendicular and electrically independent gage elements. Two types of three-element rosettes are available: the rectangular rosette, where the three gage elements are orientated in 45° increments, and the delta rosette, where the three gage elements are oriented in 60° increments.³

11.2.4.1 Rosette Equations Three strain gages oriented at distinct angles θ_a , θ_b , and θ_c relative to the x -axis are shown in Figure 11.8. Applying the first of Equation (11.2) to each of these gages in turn, we have

$$\begin{aligned}\epsilon_a &= \epsilon_{xx}\cos^2\theta_a + \epsilon_{yy}\sin^2\theta_a + \gamma_{xy}\sin\theta_a\cos\theta_a \\ \epsilon_b &= \epsilon_{xx}\cos^2\theta_b + \epsilon_{yy}\sin^2\theta_b + \gamma_{xy}\sin\theta_b\cos\theta_b \\ \epsilon_c &= \epsilon_{xx}\cos^2\theta_c + \epsilon_{yy}\sin^2\theta_c + \gamma_{xy}\sin\theta_c\cos\theta_c\end{aligned}\quad (11.17)$$

³ As is evident in Figure 11.7c, delta rosettes are so named because the pattern of the three strain gages often resembles the upper case Greek letter “Δ.”

FIGURE 11.8 A rectangular rosette relative to an x - y coordinate system.

Equation (11.17) is called the *general rosette equations*. Since ε_a , ε_b , ε_c , θ_a , θ_b , and θ_c are all measured, we have three equations involving three unknowns, ε_{xx} , ε_{yy} , and γ_{xy} .

A rectangular rosette is shown relative to an x - y coordinate system in Figure 11.8. In this case,

$$\theta_a = 0^\circ \quad \theta_b = 45^\circ \quad \theta_c = 90^\circ$$

Substituting these angles into Equation (11.17) and solving for the unknown strains, we have

$$\begin{aligned} \varepsilon_{xx} &= \varepsilon_a \\ \varepsilon_{yy} &= \varepsilon_c \\ \gamma_{xy} &= 2\varepsilon_b - (\varepsilon_a + \varepsilon_c) \end{aligned} \quad (11.18)$$

Equation (11.18) is the rosette equations for use with rectangular rosettes.

A delta rosette is shown relative to an x - y coordinate system in Figure 11.9. In this case,

$$\theta_a = 0^\circ \quad \theta_b = 60^\circ \quad \theta_c = 120^\circ$$

FIGURE 11.9 A delta rosette relative to an x - y coordinate system.

Substituting these angles into Equation (11.17) and solving for the unknown strains, we have

$$\begin{aligned}\varepsilon_{xx} &= \varepsilon_a \\ \varepsilon_{yy} &= \left(\frac{1}{3}\right)[2(\varepsilon_b + \varepsilon_c) - \varepsilon_a] \\ \gamma_{xy} &= \left(\frac{2}{\sqrt{3}}\right)[\varepsilon_b - \varepsilon_c]\end{aligned}\tag{11.19}$$

Equation (11.19) is the rosette equations for use with delta rosettes.

11.2.4.2 Corrections for Transverse Sensitivity Effects As previously discussed, strain gages generally respond to both axial and transverse strains. Therefore, a measured axial strain is generally in error due to transverse sensitivity effects. The transverse sensitivity coefficient K_t provided by the manufacturer indicates the severity of this problem for a given strain gage. Gage manufacturers have been successful in reducing K_t to low levels; for modern metal foil gages K_t is usually less than $\pm 5\%$ (i.e., $|K_t| < 0.05$). At these low levels transverse sensitivity can often be ignored, depending on the level of accuracy needed in a given application. Nevertheless, for the highest accuracy strain gages measurements should be corrected for transverse effects. At least two orthogonal strain measurements are required to correct for transverse sensitivity, which means that a 2- or 3-element strain gage rosette must be used.

Consider first the correction of strains measured using a biaxial rosette. Referring to Figure 11.7a, denote the uncorrected strains measured by the two gage elements as ε_{m0° and ε_{m90° . Strain measurements corrected for transverse sensitivity effects, ε_{0° and ε_{90° , are then given by

$$\begin{aligned}\varepsilon_{0^\circ} &= \frac{(1 - \nu_o K_t)(\varepsilon_{m0^\circ} - K_t \varepsilon_{m90^\circ})}{(1 - K_t^2)} \\ \varepsilon_{90^\circ} &= \frac{(1 - \nu_o K_t)(\varepsilon_{m90^\circ} - K_t \varepsilon_{m0^\circ})}{(1 - K_t^2)}\end{aligned}\tag{11.20}$$

where ν_o = Poisson's ratio of the calibration material used by the gage manufacturer during measurement of K_t (usually $\nu_o = 0.285$).

In the case of a 3-element rectangular rosette (Figure 11.7b), denote the uncorrected strain measurements as ε_{m0° , ε_{m45° , and ε_{m90° . The corrected strain measurements are given by

$$\begin{aligned}\varepsilon_{0^\circ} &= \frac{(1 - \nu_o K_t)(\varepsilon_{m0^\circ} - K_t \varepsilon_{m90^\circ})}{(1 - K_t^2)} \\ \varepsilon_{45^\circ} &= \frac{1 - \nu_o K_t}{1 - K_t^2} [\varepsilon_{m45^\circ} - K_t (\varepsilon_{m0^\circ} + \varepsilon_{m90^\circ} - \varepsilon_{m45^\circ})] \\ \varepsilon_{90^\circ} &= \frac{(1 - \nu_o K_t)(\varepsilon_{m90^\circ} - K_t \varepsilon_{m0^\circ})}{(1 - K_t^2)}\end{aligned}\tag{11.21}$$

Finally, for the case of a 3-element delta rosette (Figure 11.7c), denote the uncorrected strains as ε_{m0° , ε_{m60° , and ε_{m120° . The corrected strain measurements are given by

$$\begin{aligned}\varepsilon_{0^\circ} &= \frac{1 - \nu_o K_t}{1 - K_t^2} \left[\left(1 + \frac{K_t}{3} \right) \varepsilon_{m0^\circ} - \frac{2}{3} K_t (\varepsilon_{m60^\circ} + \varepsilon_{m120^\circ}) \right] \\ \varepsilon_{60^\circ} &= \frac{1 - \nu_o K_t}{1 - K_t^2} \left[\left(1 + \frac{K_t}{3} \right) \varepsilon_{m60^\circ} - \frac{2}{3} K_t (\varepsilon_{m0^\circ} + \varepsilon_{m120^\circ}) \right] \\ \varepsilon_{120^\circ} &= \frac{1 - \nu_o K_t}{1 - K_t^2} \left[\left(1 + \frac{K_t}{3} \right) \varepsilon_{m120^\circ} - \frac{2}{3} K_t (\varepsilon_{m0^\circ} + \varepsilon_{m60^\circ}) \right]\end{aligned}\quad (11.22)$$

Equations (11.20) and (11.21) are based on the assumption that all gage elements exhibit the same transverse sensitivity coefficient, which is usually the case. Analogous expressions that account for different transverse sensitivities for different gage elements are available (Errors due to Transverse Sensitivity in Strain Gages).

11.2.5 The Wheatstone Bridge

In practice, strain gages are routinely used to measure strains to a resolution of $1 \mu\varepsilon$. The change in gage resistance caused by $1 \mu\varepsilon$ is very small. Using Equation (11.14) and assuming a gage factor $S_g = 2.0$

$$\frac{\Delta R}{R} = S_g \varepsilon_a = (2)(1 \mu\varepsilon) = 2 \times 10^{-6}$$

This shows that the change in resistance caused by $1 \mu\varepsilon$ is only about 2 parts per million. For example, a strain gage with an initial resistance of precisely 120Ω will exhibit a resistance of about 119.9998Ω if subjected to a tensile strain of $1 \mu\varepsilon$. It is very difficult to measure these small resistance changes directly. Consequently strain gages are usually wired into special electrical circuits that convert the small resistance change into a relatively larger voltage change that is easier to accurately measure. The Wheatstone bridge is the most widely applied circuit of this type and will be reviewed here.

A basic Wheatstone bridge circuit is shown in Figure 11.10. Four resistances (R_1 to R_4) are wired into a four-arm pattern. An excitation voltage (V) is applied across junctions a and c , and an output voltage (E) is monitored between junctions b and d .

FIGURE 11.10 The Wheatstone bridge circuit.

Output voltage E is related to the excitation voltage V as follows:

$$E = \left[\frac{R_1 R_3 - R_2 R_4}{(R_1 + R_2)(R_3 + R_4)} \right] V \quad (11.23)$$

The bridge is said to be “balanced,” if the output voltage is $E = 0$. From Equation (11.23) it is seen that this occurs if $R_1 R_3 = R_2 R_4$. That is, the bridge is balanced if

$$\frac{R_2}{R_1} = \frac{R_3}{R_4} \quad (11.24)$$

In strain gage applications, the bridge is initially balanced. Often (but not always) the four resistances are initially identical ($R_1 = R_2 = R_3 = R_4$). As discussed later, one or more of the resistances may be a strain gage. If any of the four resistances change the bridge may become unbalanced ($E \neq 0$). Suppose that all four resistances are strain gages, that the initial resistance of all gages is identical ($R_1 = R_2 = R_3 = R_4 = R$, say), and that all four gages experiences a strain and consequently exhibit a change in resistance. It can be shown (Sharpe, 2008; Shukla and Dally, 2010; Dally and Riley, 2005) that the resulting output voltage is given by

$$E = \left(\frac{V}{4R} \right) [\Delta R_1 - \Delta R_2 + \Delta R_3 - \Delta R_4] (1 - \eta) \quad (11.25)$$

The quantity η represents a nonlinear term. That is, rigorously speaking the output voltage of the Wheatstone bridge is a nonlinear function of the change(s) in resistance. In most cases, the nonlinearity is very small and can be ignored, although if the bridge is initially unbalanced then errors due to nonlinearities can be significant. As a rule of thumb, in practical strain measurements the percent error due to bridge nonlinearities are roughly equal to the measured strain expressed as a percentage. Wheatstone bridge nonlinearities can usually be safely ignored and will not be further considered here.

Ignoring the nonlinear term η , Equation (11.25) becomes

$$E = \left(\frac{V}{4R} \right) [\Delta R_1 - \Delta R_2 + \Delta R_3 - \Delta R_4] \quad (11.26)$$

Equation (11.26) shows that the effects of resistance changes in adjacent arms (ΔR_1 and ΔR_2 , for example) are subtractive, whereas changes in opposite arms (ΔR_1 and ΔR_3 , for example) are additive. In fact, if $\Delta R_1 = \Delta R_2 = \Delta R_3 = \Delta R_4$, the output voltage is $E = 0$, and the bridge remains balanced.

In general-purpose strain analysis each strain gage is monitored using a separate Wheatstone bridge circuit as shown in Figure 11.11, rather than placing four gages in a single bridge. This is called a quarter-bridge circuit, since resistances R_2 – R_4 are now fixed, and only the gage resistance R_g changes as strain is applied. Equation (11.26) becomes

$$E = \left(\frac{\Delta R_g}{R_g} \right) \frac{V}{4} \quad (11.27)$$

FIGURE 11.11 A quarter Wheatstone bridge circuit.

Combining Equations (11.14) and (11.26), we find

$$\varepsilon = \frac{4E}{S_g V} \quad (11.28)$$

Equation (11.28) summarizes how a resistance strain gage is used to measure strain. A strain gage with known gage factor S_g is bonded to a surface of interest. The gage is then wired into a quarter-bridge Wheatstone circuit, a known voltage V is applied, and the circuit is initially balanced. If the strain gage subsequently experiences a strain the resistance will change, the bridge becomes unbalanced, and the resulting output voltage E is measured and interpreted in terms of strain using Equation (11.28).

11.2.5.1 The Three-Leadwire System During practical implementation of the Wheatstone circuit fixed resistors R_2 – R_4 are incorporated into a strain gage amplifier and leadwires of the appropriate length are used to connect the strain gage to the rest of the circuit and complete the bridge. The situation that exists if only two-leadwires are used is shown schematically in Figure 11.12a. Note that the leadwires possess a measurable resistance R_L , so the total resistance in arm a – b is $(R_g + 2R_L)$. The magnitude of R_L depends, in part, on the length of the leadwire and is often a few ohms. Assuming $R_2 = R_3 = R_4 = R_g$, the resistance of the leadwires will cause an initial imbalance of the Wheatstone bridge. For this reason commercial strain gage amplifiers often incorporate variable resistors that

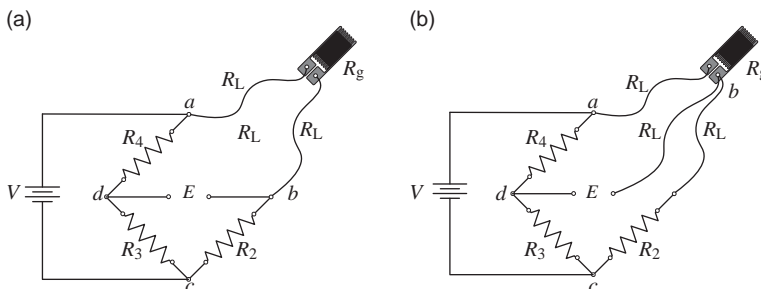

FIGURE 11.12 Illustration of the two-leadwire circuit versus three-leadwire Wheatstone bridge circuit. (a) Two-leadwire circuit, resulting in an increase of $2R_L$ in resistance of arm a – b . (b) Three-leadwire circuit, where equal an equal resistance of R_L is added to arms a – b and b – c .

allow the resistance of adjacent arms to be varied, so that the bridge can be initially balanced in accordance with Equation (11.24). However, if a temperature change occurs during the course of a strain measurement the *leadwire* resistance will change, since the resistance of the leadwires is governed in part by the temperature coefficient of resistivity of the leadwire alloy. A change in resistance due to leadwire effects is interpreted as strain, so changes in leadwire resistance results in an erroneous apparent strain measurement.

Due to the characteristics of the Wheatstone bridge this situation can be remedied through the use of three leadwires. A three-leadwire circuit is shown in Figure 11.12b. Note that use of three leadwires effectively places an additional resistance R_L in adjacent arms $a-b$ and $b-c$, and moves junction b to one of the strain gage solder tabs. The voltmeter used to measure the output voltage E has very high impedance (on the order of $M\Omega$), so adding a small resistance of R_L between junctions $b-d$ has no effect on measurement of the output voltage. The resistance of arm $a-b$ is $(R_g + R_L)$, whereas the resistance of arm $b-c$ is $(R_2 + R_L)$. All three leadwires are kept physically as close as possible so that the temperature along the length of the leadwires is essentially identical (this is easily achieved in practice, since in most cases all three leadwires are encased in the same sheathing). Therefore, identical leadwire resistance changes occur in adjacent arms and are canceled, as per Equation (11.26).

11.3 SEMICONDUCTOR STRAIN GAGES

Like metals, semiconductors exhibit the piezoresistive effect; their resistance changes when subjected to strain. In fact, the piezoresistive effect is much more pronounced in semiconductors than in metals or metal alloys, and consequently semiconductor strain gages have much higher gage factors than metal foil gages. Despite this advantage semiconductor gages are not widely used for general-purpose strain measurement. Two major drawbacks have limited their use. First, although the gage factor of semiconductors is very high, it is also a nonlinear function of strain. The gage factor of semiconductor strain gages varies substantially over the strain range of interest to structural engineers (often by a factor of 2–3), and this nonlinearity must be accounted for when interpreting the measured change in resistance. Second, the resistivity of semiconductors is far more sensitive to temperature changes than that of metals, so temperature compensation of semiconductor strain gages is generally less exact than for metal gages.

Semiconductor gages were first developed in the 1950s (Smith, 1954; Mason and Thurston, 1957) and were commercially available by about 1960. Most semiconductor gages are based on doped silicon. The two most common doping agents are phosphorous and boron. Silicon doped with phosphorous results in an n-type semiconductor, in which electrical conduction occurs due to the flow of electrons (a negative charge carrier). In contrast, silicon doped with boron results in a p-type semiconductor, where electrical conduction occurs due to vacancies in the atomic lattice (also called “holes”; a positive charge carrier).

The available literature and technologies describing semiconductor strain gages is not as detailed as for metal foil gages. The basic elements of uniaxial semiconductor gages are shown schematically in Figure 11.13. Since the piezoelectric effect exhibited by semiconductors is high there is no need for the undulating grid pattern that is characteristic of a metal foil gage (as shown in Figure 11.4, for example). Semiconductor gages are

FIGURE 11.13 Typical semiconductor strain gages with polymer backing. (a) Uniaxial gage with a single sensing element. (b) Uniaxial gage with two sensing elements, providing thermal compensation.

commercially available with or without a polymer backing. Backings are usually made of phenolic resin, and serve to stabilize the gage element and as an aid during handling and bonding. Gages are often provided with preattached leadwires or leadwire ribbons. Both uniaxial and biaxial (T-rosettes) gages are available. Three-element rosettes are apparently not commercially available, at least as an off-the-shelf product. The uniaxial gage with two semiconductor elements shown in Figure 11.13b is a particularly interesting configuration because, as will be discussed later, the combined use of one n-type semiconductor and one p-type semiconductor in a Wheatstone bridge results in self-temperature compensation.

The transverse sensitivity of semiconductor strain gages has apparently not been measured, or at least a transverse sensitivity coefficient is not provided with commercially available semiconductor strain gages. The gage factor for semiconductor gages is simply equated to the strain sensitivity:

$$S_g = S = \frac{\left(\frac{\partial R}{R}\right)}{\epsilon}$$

The *magnitude* of gage factors of n- and p-types silicon semiconductors are similar, and range from about 40 to 200, compared with only 2–3 for metallic foil gages. Interestingly, the gage factor of p- and n-types semiconductor gages differ in algebraic sign. That is, the resistance of p-type silicon increases with a tensile strain (as do metal conductors); therefore, p-type semiconductor strain gages have a positive gage factor. In contrast, the resistances of n-type silicon decrease with tensile strain; therefore, n-type semiconductor gages have a negative gage factor.

The change of resistance of a semiconductor gage bonded to an unconstrained test sample and subjected to a change in temperature is given by Equation (11.16), except that it is now assumed that $K_t = 0$:

$$\left.\frac{\partial R}{R}\right|_{T_0} = [\beta_g + S_g(\alpha_s - \alpha_g)]\Delta T \quad (11.29)$$

It would be ideal if a semiconductor gage could be produced for which $\beta_g = -S_g(\alpha_s - \alpha_g)$, which would eliminate the resistance change due solely to free expansion or contraction due to ΔT and allow development of a self-temperature

compensated semiconductor gage using a single semiconductor element. Unfortunately, the temperature coefficient of resistance β_g for semiconductors is established strictly by the level of doping employed and cannot be modified by cold working or thermal treatments. However, thermal compensation can be achieved using the configuration shown in Figure 11.13b. This configuration placed sensing elements in two arms of a half-bridge Wheatstone circuit, where the p- and n-types gage elements are placed in adjacent arms. Compensation is achieved because the gage factor of p-type semiconductors is positive, whereas the gage factor of n-type semiconductors is negative, and because resistance changes in adjacent arms of a Wheatstone bridge are subtractive. As long as β_g and α_g for both elements are the same, resistance changes associated with the thermal coefficient of resistance and the mismatch in thermal expansion coefficients occur in adjacent arms and cancel. Since gage factors of p- and n-types silicon have opposite algebraic signs, resistance changes due to mechanically induced strains do not cancel, and in fact the overall strain sensitivity is increased. A practical requirement is that both gage elements must experience the same strain and temperature change. This requirement is generally satisfied since the gage elements are small and bonded to the same backing.

11.4 LIQUID METAL STRAIN GAGES

Liquid metal strain gages can be used to measure very large strains (in excess of 150% or more). They are often used to measure strain in biological tissues such as ligaments or tendons, and are also used in engineered structures that experience large deformations during service such as automobile, truck, or aircraft tires.

The first liquid metal strain gage was developed and applied to the study of biological structures by Whitney in the late 1940s (Whitney, 1949, 1953). Various applications have been described in the literature since that time, and design and fabrication guidelines appeared in 1983 (Stone et al., 1983). The demand for these devices has never been large enough to warrant commercialization, so liquid metal gages are usually custom-made and calibrated by the user. A typical configuration is shown in Figure 11.14. The gage consists of a column(s) of liquid metal, usually mercury, encased in an elastomeric casing capable of large extensions, often silicon rubber. Leadwires in contact with the liquid metal and embedded within the elastomeric body and are connected to external instrumentation.

FIGURE 11.14 Typical configuration of a liquid metal strain gage.

The method of attachment to the structure varies according to application; in biological studies, the gage is often sutured to the tissue of interest.

The resistance of the gage is established by the liquid metal used and by length and diameter of the liquid metal column. Initial resistance is often very low, on the order of a few ohms. If a tensile strain is applied the length is increased and diameter is decreased (due to the Poisson effect), resulting in an increase in gage resistance. A gage factor is defined as normal and is determined by measuring the resistance change as a function of strain:

$$S = \frac{\left(\frac{\Delta R}{R}\right)}{\varepsilon}$$

A typical gage factor for liquid metal gages cannot be defined, since these devices are custom made. In general, gage factors are about 2, at least at small strain levels. Although these gages can sustain very high strain levels repeatedly and without failure, a cautionary note is that the gage factor often becomes nonlinear at high strain levels. The strain level at which nonlinear effects become pronounced cannot be specified, again because these gages are custom made, but in general substantial nonlinearities occur at strain levels greater than about 40%.

12.1 INTRODUCTION

Vibration can be defined as an oscillation about an equilibrium point. This chapter will focus on techniques of vibration measurement used to characterize vibrations of structural systems. However, many of the concepts discussed here can be applied to other systems, such as oscillations in electrical circuits or fluidic systems. Vibrations are desirable in a wide range of structural systems, for example, musical instruments,

sieves, compactors, ultrasonic welding machines, and massaging cushions. In other systems, vibrations can be detrimental, possibly generating excessive noise and/or large oscillating displacements or forces that could lead to rapid wear or fatigue failure. In either case, vibration measurements can be used to obtain information about the dynamic response of a system so that the system's performance may be improved or structural failure avoided.

Vibration measurements can be used to obtain natural frequencies and mode shapes of a structure. The natural frequencies and mode shapes define the dynamic characteristics of the structure and can be used to predict the structure's response to other loading conditions. This information is useful when designing or modifying a system to decrease deleterious vibrations and/or to improve the system's performance. Often design specifications set a lower limit on a structure's natural frequencies to avoid a resonance response. Knowledge of a structure's dynamic characteristics is also useful when designing vibration isolation or vibration absorber systems for the structure.

Vibration measurements can also be used to determine a machine's dynamic response to forces that are generated during operation. Measurement of a structure's vibration response to operating forces can be used to identify optimum operating conditions or to monitor the condition of a machine. Any imbalance of a rotating shaft or component will produce a periodic force during operation. These periodic forces will cause vibrations that may affect operating performance. For example, in grinding machines, these vibrations can cause undesirable cutter marks. Identifying operating conditions that minimize vibration amplitudes can be used to improve the performance of a machine. In addition, vibrations can increase with part wear, and therefore the condition of a machine may be diagnosed by monitoring these self-generated vibrations. Machine condition monitoring can be used to identify, for example, bent, eccentric, or unbalanced shafts, faulty bearings or gears, and loose mechanical parts.

Measuring a system's response to impulsive, periodic, or random external excitations is useful in a wide range of applications. Shock or impulse excitation can be used to determine a structure's resistance to failure when dropped or when subjected to an earthquake or other impulsive loading. Time harmonic or more general periodic excitation can be used to determine a system's response to excitations caused by nearby rotating components/machinery or to predict a structure's fatigue life. Random excitation can also be used when it more accurately replicates real world environments, such as a vehicle's travel over a bumpy road.

An overview of the current state of the art in vibration measurement will be presented in this chapter. First, basic notation and concepts needed to interpret vibration measurements will be introduced in Section 12.2, by discussing the response of a one-degree-of-freedom system. These concepts will be generalized to multi-degree-of-freedom systems in Section 12.3 to emphasize the need to analyze vibration measurements in the frequency domain. Discrete Fourier transforms, the frequency response function, and parameters that control the accuracy of a dynamic measurement will also be discussed in Section 12.3. In Section 12.4, a range of vibration measurement equipment and techniques will be described that can be used to excite a structure and to measure and analyze its response. A summary of modal analysis techniques that can be used to obtain the natural frequencies, mode shapes, and modal damping parameters of a structure will be given in Section 12.5. Finally, in Section 12.6, some applications of vibration measurement will be discussed.

FIGURE 12.1 Single-degree-of-freedom system. The mass displacement x is measured from the static equilibrium position.

12.2 ONE-DEGREE-OF-FREEDOM SYSTEM RESPONSE

Fundamental vibration concepts and terminology will first be introduced by describing the vibration response of a system with a single degree of freedom. This one-degree-of-freedom system can adequately represent the measured response of a structure, when the lowest natural frequency of the structure dominates its response.

A one-degree-of-freedom vibration system can be modeled by a spring, with spring constant k , and a damper, with viscous damping constant c , both fixed at one end and attached to a mass m at the other end, as shown schematically in Figure 12.1. The displacement of the mass from its static equilibrium position is denoted by x . If an excitation force $F(t)$ is applied to the mass, the governing equation for the displacement $x(t)$ can be written as

$$m\ddot{x} + c\dot{x} + kx = F(t) \quad (12.1)$$

where a superposed dot denotes a time derivative, that is, $\dot{x} = dx/dt$. The initial displacement $x(0) = x_0$ and the initial velocity $\dot{x}|_{t=0} = v_0$ are needed to completely define the response of this system to a given excitation force.

12.2.1 Free Vibration Response—Time Domain

A single-degree-of-freedom system can be characterized by its free vibration response, that is, by its response when there is no externally applied force. The free vibration response of an undamped system ($c = 0$) is a harmonic oscillation of constant amplitude that can be expressed as

$$x(t) = x_0 \cos(\omega_n t) + \frac{v_0}{\omega_n} \sin(\omega_n t) \quad (12.2)$$

In Equation (12.2)

$$\omega_n = \sqrt{\frac{k}{m}} \quad (12.3)$$

is the *natural frequency* of the system in units of rad/s. The system will vibrate at its natural frequency when given an initial displacement or when excited by an impulse force. In vibration measurements, frequency f is typically specified in units of Hertz (Hz), where 1 Hz is equal to 1 cycle per second. Therefore, the natural frequency in Hz is defined as $f_n = \omega_n/2\pi$.

Any real vibrating system will lose energy to the environment. In Equation (12.1), the energy loss is modeled by a viscous damping term with damping force, $F_d = -c\dot{x}$, proportional to the mass's velocity. This is the easiest form of damping to include analytically. Damping in many systems is small so that this approximation is adequate for representing the dissipation in the system's response. The *nondimensional damping ratio*

$$\zeta = \frac{c}{2\sqrt{km}} \quad (12.4)$$

is often used to characterize the damping of a system. For underdamped systems ($\zeta < 1$), the free vibration will be oscillatory, but the amplitude of the oscillation will decay exponentially with time. The free vibration response of an underdamped system, satisfying Equation (12.1) (with force $F(t) = 0$) can be written as

$$x(t) = e^{-\zeta\omega_n t} \left(x_0 \cos(\omega_d t) + \frac{v_0 + \zeta\omega_n x_0}{\omega_d} \sin(\omega_d t) \right) \quad (12.5)$$

where

$$\omega_d = \omega_n \sqrt{1 - \zeta^2} \quad (12.6)$$

is the frequency of damped vibration. In typical systems, damping is small ($\zeta \ll 1$) so the frequency of damped vibration is approximately equal to the natural frequency, that is, $\omega_d \sim \omega_n$ or $f_d \sim f_n$.

The periodic nature and exponential decay of the free vibration response of a single-degree-of-freedom system is illustrated in Figure 12.2. The *period* T_d of the oscillation is the time between successive peaks. The frequency of damped vibrations can be obtained from the period as

$$f_d = \frac{1}{T_d} \text{ or } \omega_d = \frac{2\pi}{T_d} \quad (12.7)$$

FIGURE 12.2 Transient response of a single-degree-of-freedom system with viscous damping for $\zeta = 0.02$. The dashed lines show the exponential decay envelope. The i th peak displacement $x(t_i)$ occurs at time t_i . The period of oscillation is denoted by T_d .

The exponential decay can be characterized by the *logarithmic decrement* δ defined as

$$\delta = \ln \left(\frac{x(t_i)}{x(t_{i+1})} \right) \quad (12.8)$$

where $x(t_i)$ is the amplitude of the i th oscillation peak. More accuracy can sometimes be obtained using peaks separated by n cycles with the equation

$$\delta = \frac{1}{n} \ln \left(\frac{x(t_i)}{x(t_{i+n})} \right) \quad (12.9)$$

where n is an integer. The nondimensional damping coefficient can be obtained from the logarithmic decrement as

$$\zeta = \frac{\delta}{\sqrt{(2\pi)^2 + \delta^2}} \sim \frac{\delta}{2\pi} \quad (12.10)$$

where the last term is a good approximation when $\zeta \ll 1$.

In summary, the natural frequency f_n and nondimensional damping ratio ζ are the parameters of a single-degree-of-freedom system that characterize its dynamic response. Both of these parameters can be obtained from a time domain measurement of the system's free vibration response.

When a structure's response is dominated by a single frequency, similar time domain measurements can be used to characterize the structure's dynamic response. However, if additional frequencies contribute significantly to the response of the structure, then it is often not practical to separate these frequency contributions from a time domain measurement. Therefore, most vibration measurements are analyzed in the frequency domain. The easiest way to understand frequency domain measurements is to consider the steady-state response of a system to time harmonic excitation as discussed in Section 12.2.2.

12.2.2 Time Harmonic Excitation—Frequency Domain

The natural frequency f_n and nondimensional damping ratio ζ of a single-degree-of-freedom system can also be obtained from its response represented in the frequency domain. Consider excitation of a single-degree-of-freedom system by a harmonic force $F(t) = F_0 \cos(2\pi f t)$. After transients decay to negligible levels, the steady-state response of the system is given by

$$x(t) = X \cos(2\pi f t - \phi) \quad (12.11)$$

This is a vibration at the forcing frequency f with magnitude

$$X = \frac{F_0/k}{\left[\left(1 - \left(\frac{f}{f_n} \right)^2 \right)^2 + \left(2\zeta \frac{f}{f_n} \right)^2 \right]^{1/2}} \quad (12.12)$$

and phase lag between the excitation and the response given by

$$\phi = \tan^{-1} \left[\frac{2\zeta \frac{f}{f_n}}{1 - \left(\frac{f}{f_n}\right)^2} \right] \quad (12.13)$$

The dependence of the response amplitude and phase lag on the forcing frequency is shown in Figure 12.3.

There is a peak in the amplitude plot (Figure 12.3a) that occurs at

$$f_{\text{peak}} = f_n \sqrt{1 - 2\zeta^2} \quad (12.14)$$

When $\zeta \ll 1$, $f_{\text{peak}} \sim f_n$. Therefore, peak frequency is a good approximation for the natural frequency when damping is sufficiently small. The large amplitude response that occurs when a system is excited near its natural frequency is called *resonance*. One reason for determining a structure's natural frequencies is so that operational parameters can be chosen to avoid resonance excitations.

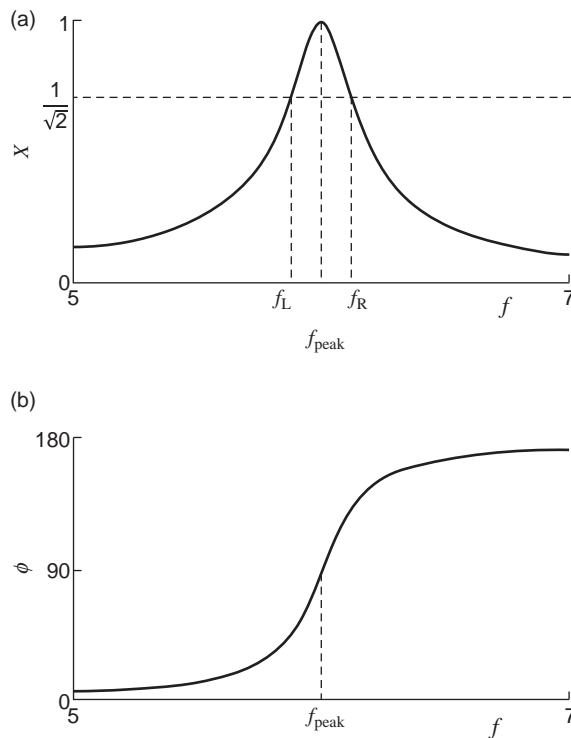

FIGURE 12.3 The (a) amplitude and (b) phase lag of the steady-state response plotted versus forcing frequency f for a single-degree-of-freedom system. The same system parameters were used to obtain the results for Figures 12.2 and 12.3.

The nondimensional damping ratio can be approximated from a plot of response amplitude $X(f)$ versus frequency f (as in Figure 12.3a), using the equation

$$\zeta \sim \frac{f_R - f_L}{2f_{\text{peak}}} \quad (12.15)$$

In Equation (12.15), f_L and f_R are the half power points, defined by

$$X(f_L) = X(f_R) = \frac{1}{\sqrt{2}}X(f_{\text{peak}}) \quad (12.16)$$

The *quality factor* or *Q factor* is a dimensionless quantity often used to characterize the amount of damping in the system. The quality factor

$$Q = \frac{1}{2\zeta} \sim \frac{f_{\text{peak}}}{f_R - f_L} \quad (12.17)$$

is inversely proportional to the damping coefficient. A system with low damping will have a large Q factor. A peak in the frequency response plot for a system with low damping will appear to be proportionally narrower than a peak for a system with high damping.

Figure 12.3b shows that the phase lag is equal to 90° when the response amplitude is near its maximum. The response is nearly in phase ($\phi \sim 0^\circ$) with the force for excitations below the natural frequency and out of phase ($\phi \sim 180^\circ$) for excitations above the natural frequency.

In Section 12.2, a single-degree-of-freedom system was used to illustrate how the natural frequency and damping ratio can be obtained from a plot of response versus time or from a plot of the response amplitude versus excitation frequency. In Section 12.3, this analysis is generalized to systems with more than one degree of freedom to illustrate why typical vibration measurements are analyzed in the frequency domain.

12.3 MULTI-DEGREE-OF-FREEDOM SYSTEMS AND THE FREQUENCY RESPONSE FUNCTION

A two-degree-of-freedom system will be used in this section to describe important phenomena that occur when more than one frequency contributes to a vibration measurement. While most structural components, such as beams, plates, and shells, have distributed mass and elasticity, their dynamic responses can be approximated by discrete multi-degree-of-freedom models. For example, a finite element model of a continuous structure is a discrete multi-degree-of-freedom system that can be used to obtain the important vibration characteristics of the structure (see, e.g., Petyt, 2010 or Friswell and Mottershead, 2010). Because the vibrational behavior of multi-degree-of-freedom systems and continuous structures are similar, concepts discussed here for multi-degree-of-freedom systems can be generalized for continuous systems. Only the most important concepts for vibration testing are introduced in this chapter, so the reader is referred to texts on mechanical vibration, such as de Silva (2000), Kelly (2000), and Rao (2011), for more in depth treatments of the subject.

FIGURE 12.4 Schematic of a two-degree-of-freedom system. The two degrees of freedom, denoted by x_1 and x_2 , are the displacements of masses m_1 and m_2 , respectively, measured from their equilibrium positions.

A system with two degrees of freedom, denoted by x_1 and x_2 , shown schematically in Figure 12.4, will be used as a simple illustration of a system with more than one degree of freedom. The coupled equations for a discrete multi-degree-of-freedom system with viscous damping can be written in a matrix form similar to Equation (12.1) as

$$M\ddot{\mathbf{x}} + C\dot{\mathbf{x}} + K\mathbf{x} = \mathbf{F}(t) \quad (12.18)$$

where, for the two-degree-of-freedom example, the unknown displacement vector is

$$\mathbf{x} = \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} \quad (12.19)$$

The initial displacements $\mathbf{x}(0) = \mathbf{x}_0$ and the initial velocities $\dot{\mathbf{x}}|_{t=0} = \mathbf{v}_0$ for each degree of freedom are needed to completely define the response of this system to a given excitation force $\mathbf{F}(t)$.

12.3.1 Free Vibration Response—Time Domain

A two-degree-of-freedom system such as the one shown in Figure 12.4 has two natural frequencies, ω_1 and ω_2 , and two corresponding mode shapes, $\boldsymbol{\varphi}^{(1)}$ and $\boldsymbol{\varphi}^{(2)}$. Similar to the one-degree-of-freedom system discussed in Section 12.2, these frequencies and mode shapes are important in characterizing the system's dynamic behavior. For example, the free vibration response of a system with negligible damping can be written as the sum of oscillations at each of these frequencies

$$\mathbf{x}(t) = A_1\boldsymbol{\varphi}^{(1)}\sin(\omega_1 t + \theta_1) + A_2\boldsymbol{\varphi}^{(2)}\sin(\omega_2 t + \theta_2) \quad (12.20)$$

where θ_1 and θ_2 are the phase shifts of the two contributions.

The coefficients A_1 and A_2 and phase shifts θ_1 and θ_2 are determined by the initial displacements and velocities. Note that the first term $A_1\boldsymbol{\varphi}^{(1)}\sin(\omega_1 t + \theta_1)$ represents a vibration at first frequency ω_1 with the relative displacement amplitudes of the two masses determined by the first mode shape $\boldsymbol{\varphi}^{(1)}$. Similarly, the second term, $A_2\boldsymbol{\varphi}^{(2)}\sin(\omega_2 t + \theta_2)$, represents a vibration at second frequency ω_2 with the relative displacement amplitudes determined by the second mode shape $\boldsymbol{\varphi}^{(2)}$. The *mode shape* $\boldsymbol{\varphi}^{(i)}$ is a vector that contains the normalized displacement amplitude of each mass when an undamped system is vibrating freely at the natural frequency ω_i . For the system shown in

Figure 12.4, the masses will be oscillating in phase for the first mode shape and out of phase for the second mode shape.

A damped system will have a similar behavior, but the amplitudes of oscillation will decay with time. The exact nature of the damping in a system is difficult to determine and quantify. Various loss mechanism exist that gradually convert vibrational energy into heat and/or sound, including coulomb friction between contacting parts, fluid–structure interactions, and internal heating due to time varying strains. Fortunately, damping is small in most of the systems so that the exact causes of damping are typically not important, and an approximation can be used to specify losses when characterizing the dynamic response of a structure.

During vibration testing, a nondimensional *modal damping constant* ζ_i corresponding to each important frequency ω_i is typically measured and used to approximate the damping in the system. The damped free vibration response can be written in terms of the modes shapes using modal damping as

$$\mathbf{x}(t) = A_1 e^{-\zeta_1 \omega_1 t} \boldsymbol{\phi}^{(1)} \sin(\omega_{d1} t + \theta_1) + A_2 e^{-\zeta_2 \omega_2 t} \boldsymbol{\phi}^{(2)} \sin(\omega_{d2} t + \theta_2) \quad (12.21)$$

where $\omega_{d1} = \omega_1 \sqrt{1 - \zeta_1^2}$ and $\omega_{d2} = \omega_2 \sqrt{1 - \zeta_2^2}$ are the damped natural frequencies. The general forced response of the system can also be written in terms of the mode shapes, $\boldsymbol{\phi}^{(1)}$ and $\boldsymbol{\phi}^{(2)}$, with the time dependence of each term determined by the excitation. This illustrates that the frequencies, damping coefficients, and mode shapes are important for determining the dynamic response of a system.

These concepts can be extended to a system with N degrees of freedom, where N is a positive integer. The dynamic response of an N -degree-of-freedom system is governed by Equation (12.18) with the displacement vector written as

$$\mathbf{x} = \begin{bmatrix} x_1 \\ x_2 \\ \vdots \\ x_N \end{bmatrix} \quad (12.22)$$

An N -degree-of-freedom system has N natural frequencies, ω_i , $i = 1, 2, \dots, N$. The frequencies are numbered in ascending order, because the lowest frequencies typically have the largest contribution to the dynamic response of a system. The lowest natural frequency is also called the *fundamental frequency*. Design requirements often stipulate that the fundamental frequency be greater than a specified value to avoid resonance behavior during operation. There is a mode shape $\boldsymbol{\phi}^{(i)}$, $i = 1, 2, \dots, N$, corresponding to each natural frequency. Equation (12.21) can be generalized to express the free vibration response of an N -degree-of-freedom system in terms of the natural frequencies and mode shapes as

$$\mathbf{x}(t) = \sum_{i=1}^N A_i e^{-\zeta_i \omega_i t} \boldsymbol{\phi}^{(i)} \sin(\omega_{di} t + \theta_i) \quad (12.23)$$

The free vibration responses of the masses in the two-degree-of-freedom system shown in Figure 12.4 to a specific set of initial conditions (e.g., resulting from an instrumented hammer impact during vibration measurement) are plotted in Figure 12.5. Even for this

FIGURE 12.5 Transient responses, displacements x_1 (solid) and x_2 (dashed) versus time, for the two-degree-of-freedom system in Figure 12.4 to an initial impact. There are two frequencies contributing to the responses. The higher frequency decays more rapidly so, as time increases, the response will be dominated by the lower frequency.

simple two-degree-of-freedom system, it is not easy to identify both natural frequencies from the time domain responses. As more degrees of freedom are added to the system, the time domain responses become more difficult to interpret, because additional frequencies contribute to the responses. Therefore, typical vibration measurements are plotted in the frequency domain, as discussed in the next section.

12.3.2 Frequency Domain Response

The natural frequencies, ω_i or f_i , modal damping ratios, ζ_i , and mode shapes, $\phi^{(i)}$, of a structure can be obtained from responses represented in the frequency domain. Characteristics of the time domain response can be inferred from these structural parameters using Equation (12.23). Frequency domain plots, therefore, contain the same information as time domain plots, but often in a more useful form.

In vibration testing, frequency domain plots are typically obtained by taking the discrete Fourier transform (DFT) of time domain responses. Alternatively, frequency domain plots can be obtained from measurements of the steady-state response to harmonic excitations across a range of frequencies. The latter method is typically not used because it is more time consuming, but the concepts are useful in interpreting frequency response plots. In this section, discrete Fourier transform methods are used to obtain the frequency domain plots.

Denote the discrete Fourier transform of a response, $x_i(t)$, by $X_i(f)$. The discrete Fourier transform, $X_i(f)$, consists of a set of complex numbers, each of which can either be represented in terms of its magnitude and phase or in terms of its real and imaginary parts. Figures 12.6–12.9 illustrate different representations of the discrete Fourier transform of the free vibration responses for the two masses shown in Figure 12.4. The magnitude and phase of the discrete Fourier transform data are plotted in Figure 12.6a and b, respectively. The real and imaginary parts of the discrete Fourier transform data are plotted in Figure 12.7a and b, respectively. A Nyquist plot of the real and imaginary parts in polar coordinates is shown in Figure 12.8. Finally, the magnitude of the discrete Fourier transform data is replotted using log and dB scales in Figures 12.9a and b, respectively. All of these plot formats can be useful in analyzing vibration measurements.

FIGURE 12.6 (a) Amplitude and (b) phase versus frequency of the discrete Fourier transform of the responses x_1 (solid) and x_2 (dashed) of the two-degree-of-freedom system in Figure 12.4 to an initial impact. The two natural frequencies contributing to the responses are easy to identify. The amplitude and phase of the steady-state response plotted versus forcing frequency f for excitation of the two-degree-of-freedom system at the same location would produce a similar plot. The approximately vertical line (at $f \sim 1800$ Hz) is an artifact of phase wrapping, that is, confining the phase between $+180^\circ$ and -180° . The line connects points at $+180^\circ$ and -180° , two representations of the same phase.

Plots similar to those in Figure 12.6 are obtained by graphing the magnitude and phase of the steady-state harmonic responses to a harmonic excitation, as described for a single-degree-of-freedom system in Section 12.2. Therefore, $|X_i|(f)$ and $\phi_i(f)$ can be also be thought of as the magnitude and phase of a steady-state response of mass i to a harmonic force with frequency, f .

There are two peaks in the magnitude versus frequency plot for this two-degree-of-freedom system (Figure 12.6a) at frequencies (denoted by f_{peak1} and f_{peak2}) near the two natural frequencies. If the system is excited at one of these two frequencies, resonance will occur, possibly resulting in a large amplitude response. Therefore, a typical goal of vibration measurement is to identify natural frequencies of the system so that operating conditions can be chosen or the structure can be modified to avoid resonance excitation.

The two natural frequencies of the two-degree-of-freedom system can simply be approximated from the location of the two peaks in the magnitude versus frequency plot (Figure 12.6a), $f_i \sim f_{\text{peak}i}$, analogous to a single-degree-of-freedom system. Also, the relative width of a peak is indicative of the damping for oscillations near that frequency.

FIGURE 12.7 (a) Real part and (b) imaginary part versus frequency of the discrete Fourier transform of the responses x_1 (solid) and x_2 (dashed) of the two-degree-of-freedom system in Figure 12.4 to an initial impact. The real parts are equal to zero at the natural frequencies, f_1 and f_2 . The peak values of the imaginary parts approximate the amplitude and phase of the mode shapes.

If the two peaks are sufficiently separated, as in Figure 12.6, then the natural frequencies and their nondimensional damping coefficients can be approximated using generalizations of Equations (12.14) and (12.15), respectively. In addition, the peak amplitudes at a resonance can be used to approximate the mode shape for that frequency. Small amplitude peaks can be identified and analyzed more easily if the magnitude is plotted on a log or

FIGURE 12.8 The Nyquist plot of the discrete Fourier transform of the responses x_1 (solid) and x_2 (dashed) of the two-degree-of-freedom system in Figure 12.4 to an initial impact. The imaginary part is plotted versus the real part, tracing out an approximate circle as the frequency increases through each resonance. The larger and smaller circles correspond to f_1 and f_2 , respectively.

FIGURE 12.9 The amplitude of the discrete Fourier transform of the responses x_1 (solid) and x_2 (dashed) of the two-degree-of-freedom system in Figure 12.4 to an initial impact, on (a) log and (b) dB scales. The dB values are $20 \log_{10}(|X|/X_R)$, with $X_R = 1$ mm. An anti-resonance occurs between the two resonance peaks for the dashed curve, but not for the solid curve. The existence of an anti-resonance depends on whether successive peaks are nearly in phase or out of phase.

dB scale, as shown in Figure 12.9. (See Section 12.5.1.3 for more detail. Techniques for obtaining natural frequencies, modal damping coefficients, and modes shapes from responses with and without significant peak overlap are discussed in Section “Single-Mode Analysis Methods” and “Multi-Mode Analysis Methods,” respectively.)

The phase plot in Figure 12.6b shows that the two masses move in phase with each other for frequencies below the lower resonance frequency. The masses move out of phase with each other for frequencies above the upper resonance frequency. The relative phase changes at a frequency (~ 2400 Hz for this system) between the two resonance frequencies.

Both phase curves in Figure 12.6b cross 90° at the first natural frequency, f_1 , similar to the single-degree-of-freedom system response. Near the second natural frequency, f_2 , the phase curves either cross 90° or -90° . The real part of the response (plotted in Figure 12.7a) is equal to zero when the phase is equal to $\pm 90^\circ$. Therefore, zero crossings of plots of the real part of the response versus frequency can be used to identify natural frequencies of the system. When the amplitude of the real part of the response is zero, the amplitude of the imaginary part is equal to the total amplitude. Therefore, peaks in plots of the imaginary part of the response can be used to estimate the amplitude and phase of the mode shapes, as illustrated in Section “Single-Mode Analysis Methods.”

Frequency is a parameter in the Nyquist plot, and a circle is approximately traced as the frequency increases through each natural frequency, as illustrated in Figure 12.8.

Semicircular curve fits to Nyquist plot data can be used to estimate the natural frequencies and damping coefficients, as discussed in Section 12.5.1.3.

In summary, plots of vibration measurements in the frequency domain can be used to identify resonance frequencies, damping coefficients, and mode shapes that characterize the dynamic response of a structure. Vibration testing can also be used to monitor the condition of a machine by identifying and monitoring frequencies that indicate specific machine failure modes. (See Section 12.6.2 for more detail on condition monitoring.) Therefore, vibration measurement data are typically displayed and analyzed in the frequency domain.

A variety of numerical errors can be introduced by the discrete Fourier transform used to obtain a frequency domain plot from a time domain response. For example, to obtain the accuracy and resolution for the plots in Figures 12.6–12.9 and avoid *leakage* (defined in Section 12.3.3.2), the discrete Fourier transform was taken of a longer time span than plotted in Figure 12.5. A summary of discrete Fourier transforms and techniques used to minimize numerical errors in vibration measurements will be discussed in the next section.

12.3.3 The Frequency Response Function and Discrete Fourier Transforms

The *frequency response function (FRF)* is a quantity often used in vibration measurements and modal analysis. The frequency response function, $H(f)$, is obtained by dividing the Fourier transform of the response, $H(f)$, by the Fourier transform of the excitation, $F(f)$

$$H(f) \stackrel{\text{def}}{=} \frac{X(f)}{F(f)} \quad (12.24)$$

The response data $X_i(f)$ used to generate Figures 12.6–12.9 are essentially scaled frequency response functions, since the Fourier transform of an ideal impulsive excitation is independent of frequency, that is, $F(f)$ was constant for the data in these plots.

If the Fourier transform of the displacement, $X(f)$, is used, then the frequency response function, $X(f)/F(f)$, is called the *receptance* or *dynamic compliance*. The *dynamic stiffness* is equal to the reciprocal of the receptance. This definition for dynamic stiffness is an extension of the definition of static stiffness, $k = \text{force/displacement}$, to time harmonic excitation.

If the Fourier transform of the velocity, $V(f)$, is used, then the frequency response function, $V(f)/F(f)$, is called the *mobility*. The reciprocal of the mobility is the *mechanical impedance*. If the Fourier transform of the acceleration, $A(f)$, is used, then the frequency response function, $A(f)/F(f)$, is called the *accelerance*. The reciprocal of the accelerance is the *apparent mass*.

In theory, frequency response functions depend only on the characteristics of the system and are independent of the time dependence of forcing function used to excite the system. For example, for a single-degree-of-freedom system, the expressions for the amplitude X/F_0 and phase ϕ of the frequency response function, given by Equations (12.12) and (12.13), respectively, are functions of the natural frequency, damping and static stiffness of the system.

A measured frequency response function (defined as the discrete Fourier transform of the response measurement divided by the discrete Fourier transform of the excitation measurement) only approximates the ideal frequency response function because of errors

introduced by finite measurement times, discrete sampling, and measurement noise. An overview of discrete Fourier transforms will next be given and techniques to minimize errors introduced by sampling limitations and discretization error will be discussed. The reader is referred to Brigham (1988), Chapters 14 and 19 of Piersol and Paez (2010), and signal processing references for more detailed treatments of the subject.

Digital signal analyzers obtain and analyze discrete samplings of an analog signal, so it is important to be aware of how this discretization can affect measurement results. Given a constant *sampling rate*, Δt , (time between samples) and the *number of samples*, N , an analog signal $x(t)$ can be represented by the discrete set of samples $\{x(0), x(\Delta t), x(2\Delta t), \dots, x((N-1)\Delta t)\}$. The duration of the sampling interval is $t_{\max} = N\Delta t$. Often, N is restricted to be a power of 2, for example, 1024, because more efficient DFT algorithms, called fast Fourier transforms (FFTs), are then available.

The maximum frequency that can be represented with a sampling rate Δt is determined by the *Nyquist criterion*, $f_{\max} = 1/2\Delta t$. The *frequency resolution*, Δf , that is, the distance between points in the frequency domain, is $\Delta f = (f_{\max}/[N/2]) = (1/t_{\max})$. The discrete Fourier transform consists of only $N/2$ points, even though the time domain signal had N data points; however, each data point in the frequency domain is complex. Complex numbers can be represented in terms of an amplitude and phase or a real and imaginary part, so discrete Fourier transform still has N pieces of information.

Digital signal analyzers have a variety of options that can be selected to improve the accuracy of discrete Fourier transforms and frequency response functions. The most important options will be discussed here.

12.3.3.1 Filtering—to Minimize Aliasing The Nyquist criterion states that at least two samples per cycle are required to identify a frequency. A frequency greater than $f_{\max} = 1/(2\Delta t)$ that contributes to an analog signal will be undersampled when a sampling time step equal to Δt is used. As a result, this contribution will appear to be at a lower frequency, as illustrated in Figure 12.10. If you use a modern digital signal analyzer, then a combination of analog filtering, oversampling, and digital filtering will be used automatically to minimize aliasing. However, you may need to implement filtering techniques

FIGURE 12.10 Illustration of aliasing. The 10 Hz signal (solid line) is sampled at 9.5 Hz (dashed line). The solid dots represent the sample points. The frequency measured from the sampled signal appears to be at approximately 2 Hz. A discrete Fourier transform of the sampled signal would have a peak at approximately 2 Hz, rather than at the actual frequency of 10 Hz!

yourself when using a digital oscilloscope or computer application to obtain the discrete Fourier transforms of a signal. To avoid aliasing, analog signals must be low pass filtered to remove contributions from frequencies above $f_{\max} = 1/2\Delta t$, before the discrete Fourier transform is applied. No filter is ideal. However, a higher order filter will be better at minimizing the effects of aliasing.

12.3.3.2 Windowing—to Minimize Leakage or the Effect of Noise The discrete Fourier transform assumes periodic signals. If the sampling interval is denoted by $t_{\max} = N\Delta t$, then $x(t + t_{\max}) = x(t)$ is assumed, as illustrated in Figures 12.11–12.13. That is, a discrete Fourier transform of a signal in the time range $0 \leq t \leq t_{\max}$ assumes that the signal repeats in the time range $t_{\max} \leq t \leq 2t_{\max}$ and again in the time range $2t_{\max} \leq t \leq 3t_{\max}$, and so on. The periodic extension can introduce discontinuities in the signal amplitude or slope.

The periodic extension of the sampled data in Figure 12.11a is shown in Figure 12.11b. The periodic extension did not introduce any discontinuity at the beginning or end of the data, because an integer number of periods occurred in the sampling interval. Therefore,

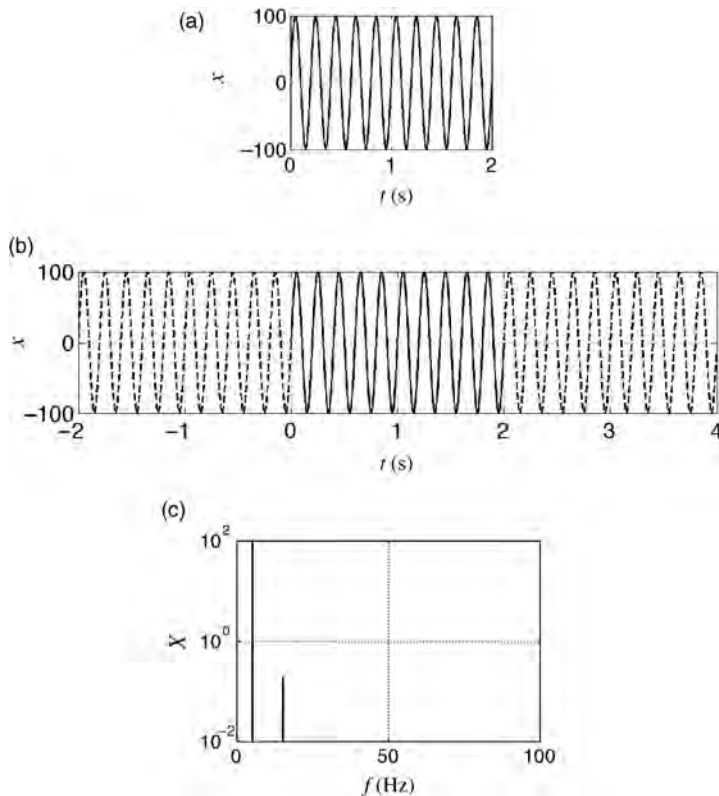

FIGURE 12.11 Illustration of a discrete Fourier transform of an essentially harmonic signal that does not exhibit leakage, including (a) the sampled data, (b) the periodic extension of the sampled data, and (c) the discrete Fourier transform of the sampled data. The discrete Fourier transform has two sharp peaks at the fundamental frequency of 5 Hz and the 2nd harmonic at 15 Hz.

the discrete Fourier transform of Figure 12.11c shows no evidence of leakage, that is, the two peaks are clearly visible and the amplitude everywhere else is many orders of magnitude smaller than the peaks. The largest peak is at 5 Hz, the fundamental frequency. The smaller peak at 15 Hz is due to a contribution at the 2nd harmonic that slightly distorts the signal. The sampled data in Figure 12.12a have a fundamental frequency of 4.75 Hz, so that the sampling interval does not contain an integer number of periods. In this case, the periodic extension introduces a slope discontinuity, as shown in Figure 12.12b. A large range of frequency components are needed to represent this discontinuity, raising the baseline of the frequency domain plot, as shown in Figure 12.12c. The distortion of the discrete Fourier transform due to discontinuities introduced by the periodic extension is called *leakage*. In Figure 12.12c, the 2nd peak is obscured due to leakage.

In vibration measurements, leakage may be a problem when the excitation is continuous, such as when using a shaker driven by random noise or using the rotation of a component of the structural system as the excitation. In these cases, leakage can be minimized by multiply the time domain signal by a weighting function before taking the discrete

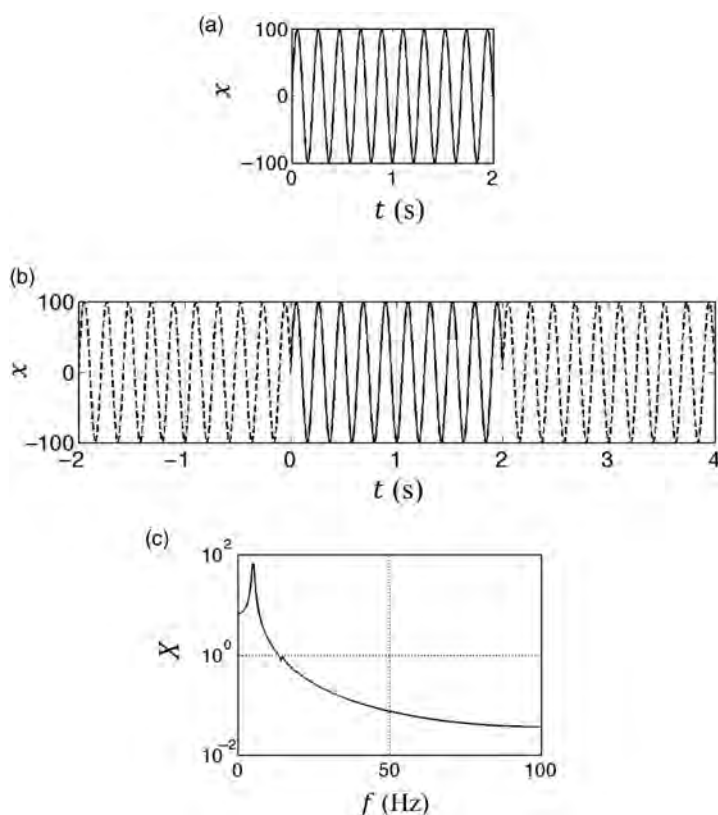

FIGURE 12.12 Illustration of a discrete Fourier transform of an essentially harmonic signal that does exhibit leakage, including (a) the sampled data, (b) the periodic extension of the sampled data, and (c) the discrete Fourier transform of the sampled data. The discrete Fourier transform has a peak at the fundamental frequency of 4.5 Hz but the peak at the 2nd harmonic, 13.5 Hz, is below the raised baseline.

Fourier transform. This process is called *windowing* and the weighting function is called the *window function*.

There are a large variety of windowing functions, but two of the most popular are the *Hanning window* and the *flat-top window*. Both of these functions weight the signal at the beginning and end of the time interval less than the central portion of the signal so that the leakage due to the discontinuity introduced by the period extension is reduced. The flat-top window allows better accuracy in determining the peak amplitude, whereas the Hanning window has better frequency resolution. One caution when using windowing: a window introduces an artificial source of damping that will increase the width and decrease the amplitude of the peaks in the response spectrum, so estimates of damping obtained from the frequency domain plot will be less accurate.

Figure 12.13a shows the sampled data of Figure 12.12a after the Hanning window shown in Figure 12.14 was applied. Figure 12.13b shows that the periodic extension does not introduce a discontinuity for the windowed data. The discrete Fourier transform of the windowed function plotted in Figure 12.13c shows that leakage has been reduced by the windowing process so that the 2nd peak is now visible. However, both peak amplitudes have been reduced and the peaks are wider than those in Figure 12.11c, obtained for a comparable set of sampled data.

Windowing should be used with care, because windowing can cause serious distortion of discrete Fourier transforms. Windowing typically should not be used for sine swept signals produced by a shaker. Sine swept excitations are designed to be periodic, with a period equal to the sampling interval. The amplitude of the sine sweep is typically not zero at the beginning and end of the sampling interval. Therefore, use of a nonuniform window will alter the amplitudes of the frequencies at the beginning and end of the sampling interval resulting in distortion and error in the discrete Fourier transform of the sine swept signal.

Impulse responses obtained by exciting a system with an instrumented hammer often begin at rest and decay to near zero amplitude within the sampling interval. In this case, a Hanning or flat-top window may also cause distortion and error in the frequency response plot if the window alters the initial response. Instead, most digital signal analyzers have force and exponential response windows that can be used to reduce leakage or to minimize the effect of noise that may be present after the excitation or response signals have decayed.

If windowing is used for impact testing, a force window should be applied to the excitation signal and an exponential decay window should be applied to the response signal. The force window should essentially be equal to 1 during the time of impact to preserve the entire force signal, but should be equal to 0 outside of this time range so that any extraneous noise would be eliminated. The exponential response window similarly can be used to minimize the effects of extraneous vibrations that may occur after the impact response has decayed below the noise level. In addition, an exponential window can be used to eliminate leakage if the vibration response has not decayed to zero within the sampling duration. This exponential window also will introduce artificial damping, so damping calculated from the frequency spectrum of exponentially windowed data will be overestimated.

12.3.3.3 Ranging—to Minimize Discretization Effects Not only is the signal sampled only at discrete times, but the voltage amplitude of each sample is also converted (using an analog-to-digital converter) to a discrete number so that it can be stored digitally for further analysis. This discretization of the signal amplitude can also introduce error into

FIGURE 12.13 Illustration of the use of a Hanning window to minimize leakage, including (a) the windowed sampled data, (b) the periodic extension of the windowed sampled data, and (c) the discrete Fourier transform of the windowed sampled data. The sampled data are the same as in Figure 12.12a, weighted by the Hanning window shown in Figure 12.14. The discrete Fourier transform has two peaks at the fundamental frequency of 4.5 Hz and the 2nd harmonic at 13.5 Hz. The windowing function caused a decrease in the peak amplitude as well as a broadening of the peaks, compared to Figure 12.11c.

the discrete Fourier transform. The *input range*, that is, the voltage range that is converted, is defined before a measurement is taken. It is ideal to set the input range on a digital signal analyzer to approximately half the amplitude of the maximum signal (referred to as *half-ranging*) to obtain the best resolution from the analog-to-digital

FIGURE 12.14 The Hanning window used to obtain the plots in Figure 12.13.

conversion. It is also important to avoid signals with amplitudes that exceed the input range (often referred to as *overloading*). Overloading would cause peaks of the time domain signal to be out of range, and therefore the peaks would be clipped, causing distortion of the discrete Fourier transforms.

Because the range for the display of the signal on many digital signal analyzers can be set independently from the input range, the input range on a digital signal analyzer is not as immediately apparent as it is on most oscilloscopes. Therefore, analyzers typically have indicators that identify when the signal amplitude exceeds half the input range (half-ranging) and when the signal amplitude exceeds the input range (overloading).

Often digital signal analyzers have an *autorange* option that automatically increases or decreases the input range until overloading is just prevented. This option works well if the amplitude of the signal is fairly constant, such as when a swept sine excitation is continuously repeated. However, if an instrumented hammer is used for excitation, then the autorange option is not useful if it decreases the range to a low level in between hammer hits. When using an instrumented hammer, an *autorange up only* option can be used to set the correct input range on each channel (receiving either hammer or response signals). This is done by producing a number of consistent hammer hits, so that the input ranges for both the excitation and the response channels are increased until overloading is just avoided. If a new hammer tip is used or the impact location changes, then this procedure should be repeated to set new input ranges for all channels, starting again from a low level.

12.3.3.4 AC Coupling—to Minimize DC Bias Effects A signal with a small amplitude oscillation could have poor resolution after analog-to-digital conversion, if it is superimposed on a large constant (DC) bias. An input range large enough to include the DC bias may have inadequate resolution to capture small variations in the signal. *AC coupling* with a coupling capacitor can be used to remove the DC bias. The capacitor acts as a high pass filter, filtering out the low frequencies. Therefore, AC coupling not only will remove the DC bias, but may also degrade the low frequency components of the signals. The choice between using AC and DC coupling depends on the frequency range of the vibration of interest. For example, when measuring the transmission of floor vibrations to a structure for frequencies on the order of 1 Hz, DC coupling is appropriate. However, when measuring the dynamic response of a machine for a frequency range above 50 Hz, AC coupling may be more appropriate.

12.3.3.5 Averaging—to Minimize Noise Effects The frequency response function assumes that the measured response of a structure is a direct result of the measured excitation. However, nearby machinery and people may cause additional structural vibrations. The measured response will be the sum of the desired response due to the excitation and the response due to environmental noise. *Averaging* a set of frequency response functions can increase the signal to noise ratio, by reducing the effects from random contributions. The input range should be established for all measurements before averaging begins. Analyzers typically have an option to automatically reject a data set if overloading occurs during the acquisition of the data. This option can save valuable time because without this option, all prior measurements would need to be repeated if an overload occurred.

The *coherence function* is used during averaging as an indicator of frequency response functions repeatability. The coherence function is a measure of how much of the output signal is caused by the measured input signal, assuming the excitation and response points

and directions remain the same. The coherence function is plotted versus frequency and its values range between 0 and 1. The coherence function is equal to 1 if all of the output is entirely caused by the input and equal to 0 if none of the output is caused by the input. For example, if the background vibration (noise) in the test environment is high relative to the excitation source, then the coherence will be low. Low coherence can also occur when using an instrumented hammer, if the instrumented hammer does not strike the same point on the structure in the same direction each time. Practice with the instrumented hammer can improve coherence in this case. The coherence should be approximately equal to 1 in the frequency ranges of interest (e.g., near resonance peaks). Lower coherence that can occur in regions of lower response amplitude may be acceptable if no response peaks of interest occur in these regions.

For illustration, the coherence and amplitude of a frequency response function are shown in Figure 12.15 for one set of averaged data. The data were obtained from accelerometer measurements of the transverse response of a plate excited by an instrumented hammer impact. In Section 12.5, this plate structure is used as an example when discussing experimental modal analysis techniques. The coherence is approximately equal to 1 at each of the peaks in the frequency response function, indicating good repeatability of the peak locations and amplitudes. However, the coherence is lower at frequencies below 10 Hz due to inconsistencies in foam pad used to support the plate and low accelerometer sensitivity at low frequencies. The coherence is also lower at the frequency corresponding to the antinode. Because no peaks of interest occur in these regions, the lower coherence would not significantly impact analysis of the response.

FIGURE 12.15 Measured (a) amplitude and (b) coherence versus frequency for the frequency response function (FRF) obtained for transverse vibrations of plate.

12.4 VIBRATION MEASUREMENT EQUIPMENT AND TECHNIQUES

Practical aspects of vibration measurement are considered in this section, with specific emphasis on the equipment used to obtain and analyze vibration data. Even with the best equipment and analysis techniques, however, it can be difficult to obtain meaningful data, especially for complex systems in noisy environments. Therefore, it is important to first clearly define the purpose of the measurements and to carefully consider the experimental setup. An understanding of fundamental vibration theory is needed to choose and apply the correct equipment and analysis methods for a particular purpose as well as to obtain valuable conclusions from the vibration testing results.

Vibrations measurements are obtained for a wide variety of purposes including, characterizing a structure's dynamic behaviors, monitoring the condition of a machine, and testing the durability or lifespan of a component. Because the desired goals for vibration measurements are so diverse, it is not possible to cover all possible scenarios. However, the types of equipment used for vibration testing are similar for the various applications. Therefore, the objective of this section is to give an overview of the most common equipment used to obtain and analyze vibration measurements.

Experimental vibration testing involves measuring structural motions in response to input loads. The response depends on both the structure and the excitation, as shown schematically in Figure 12.16. Generally, one of three things is under investigation in vibration testing: (1) the structural system itself is being characterized; (2) the input that excites the system is being determined; or (3) the system's response to the excitation is being observed.

Vibration measurements can be used to obtain dynamic characteristics of a product or structural component, necessary for further product development. The equipment needed to measure the dynamic characteristics of a structure include (1) an excitation source, (2) a device to measure the system's response, and (3) an analyzer to process the data to obtain the desired information.

Modal analysis methods for characterizing the dynamic behavior of a structure are discussed in Section 12.5. For modal analysis, a controlled excitation is applied to a structure and both the vibration response and the applied excitation are simultaneously measured. A signal analyzer is used to collect and analyze the measurement data to determine the dynamic characteristics of the structure. The quality of the data will depend on both the excitation type (impact, swept harmonic, random, burst, and so on) and the response measurement type (displacement, velocity, acceleration, strain, and so on). Excitation and response measurement types will be discussed in Sections 12.4.1 and 12.4.1.1, respectively. Signal analyzers will be discussed in Section 12.4.2.

Because a test structure's dynamic characteristics are affected by how the structure is supported, the support fixture is also an important consideration for vibration testing.

FIGURE 12.16 Schematic of the components of a test system for characterizing the dynamic response of a structure.

To obtain natural frequencies that closely match the natural frequencies of a structure under operating conditions, vibration measurements should be made in situ whenever possible. When in situ testing is not possible, supporting structures should either be designed to mimic the in situ constraints or to approximate the constraints used in analytical or numerical models of the structure.

Some systems, such as an airplane or satellite in flight, typically operate without any boundary constraints. To approximate free boundary conditions, the structure can be suspended from elastic cords or placed on a soft cushion. As a rule of thumb, to mimic free boundary conditions, the support system stiffness should be low enough so that the rigid body mode frequencies of the structure on its supports are less than approximately 10% of the lowest deformable mode frequency of the structure.

Other structures, such as a grinding tool in a chuck, are held almost rigidly. Perfectly rigid boundary conditions are difficult to approximate for many structures, because of the compliance of the fasteners used to attach the test component to the supporting fixture and the vibration of the supporting structure itself. The motion of the supporting structure at the attachment points can be measured; however, a low response does not necessarily imply that the support has the same effect as a rigid support.

Finite element models can be used to determine the effects of different boundary constraints on the dynamic characteristics of a component. To correlate measurement data with finite element predictions, support fixtures for the vibration measurements are often designed to mimic the either completely free or fixed boundary conditions typically used in finite element models. Once the finite element model predictions and measured responses for a component agree to sufficient accuracy, the model can be used to investigate how other boundary condition will affect the component's dynamic behavior. In particular, the model of the component can be attached to a model of the overall system to predict the component's in situ behavior. For example, a finite element model of an airplane wing can be verified experimentally with free boundary conditions and then used in a complete finite element model of an airplane to determine the wing's in flight response.

Vibration measurements can be used to characterize the excitation experienced by a structure or component when in operation. Knowledge of the excitation may be needed for a number of purposes. For example, more realistic predictions of product life and durability may be obtained from fatigue testing when the excitation applied during the test more accurately represents the in-service excitation. A variety of multiaxis shaker tables have been developed so that different vibration environments can be closely approximated.

Vibration testing can be used to measure the dynamic motion of a machine during operation or to monitor its performance over a period of time. Measurement of the machine vibration can be used to identify sources of vibration problems or operating conditions that minimize vibrations. As discussed in Section 12.6.2, some machine component failure can be identified in their early stages, from measurements of machine vibrations generated by defects in the component. Therefore, vibration monitoring can be used as a sensitive indicator of machine failure.

For any of these vibration measurement applications, there must be an excitation source, a system response measurement, and analysis of the measurement data to obtain meaningful conclusions. While the purposes of the vibration measurements may differ, the equipment used for many of the measurements are similar. In this section, an overview will be presented of some of the most commonly used vibration measurement equipment and some of their advantages and disadvantages.

12.4.1 Excitation Sources

Many types of excitation equipment are available, including instrumented hammers, shakers, and multiaxis tables. Only a brief overview of this equipment will be given here. Impact hammers and electrodynamic shakers will be described in more detail because these are perhaps the most common excitation sources and they can produce the most commonly used types of excitations.

12.4.1.1 Instrumented Hammers—Impulse Excitation An instrumented hammer is used to strike the test structure to produce an impulse excitation. Instrumented hammers have a force transducer near their impact tip, so the time history of the force imparted to the structure can be measured and recorded. This force measurement can be used to obtain frequency response functions for the test structure, as described in Section 12.3.3.

Instrumented hammers are perhaps the easiest source of excitation to use, because no additional fixturing is required. A test structure is excited simply by striking it with the instrumented hammer at the desired load location and in the desired direction. Responses for an array of excitation locations can quickly be measured by changing the impact location of the instrumented hammer.

The size of the hammer and stiffness of the hammer's impact tip control the duration of the impact and thus the frequency content of the excitation. The amplitude of the applied impulse is controlled by the mass and velocity of the hammer impact. Often hammer mass can be adjusted by changing weights attached to the hammer. Two instrumented hammers are shown in Figure 12.17, along with a variety of hammer tips. Time and frequency plots for soft, medium, and hard tips are shown in Figure 12.18a and b, respectively. The more compliant (softer) the tip, the longer the impact time. Conversely, the

FIGURE 12.17 Two instrumented hammers in the mid-size range with additional impact tips that can be used to vary the impulse duration and thus the frequency range of the excitation. Each instrumented hammer has a force sensor adjacent to the attached tip (outlined in white).

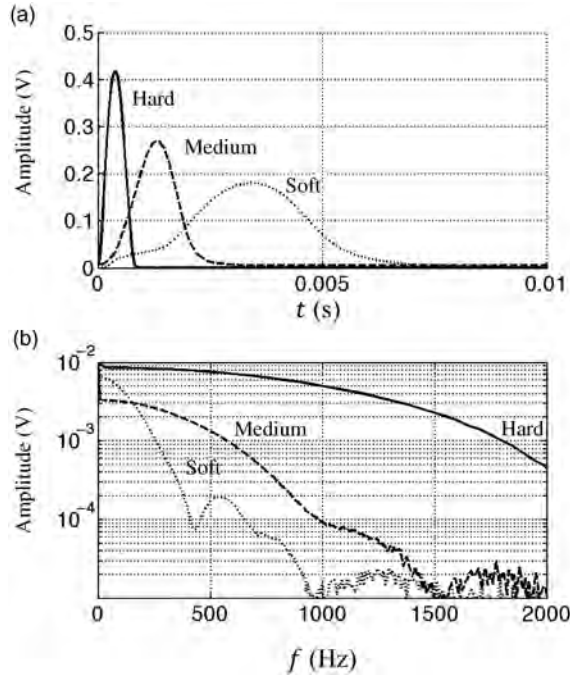

FIGURE 12.18 Signal amplitude versus (a) time and (b) frequency generated by an instrumented hammer striking a rigid surface, with a soft (dotted), medium (dashed), and hard (solid) tip. The usable frequency ranges for this hammer with the soft, medium, and hard tips are from 0 Hz to approximately 400 Hz, 1000 Hz, and 2000 Hz, respectively. The signal amplitudes depend on the impact strength. The noise level is approximately 2×10^{-5} , so signal below this level is not meaningful.

stiffer the tip, the shorter the impact time. Because higher frequencies are needed to represent shorter pulses, the stiffer tip imparts energy over a broader frequency range than the soft tip as shown in Figure 12.18b. The hammer size and tip stiffness are chosen based on the desired impact energy and structural frequency range of interest. Large hammers can impart higher energy to the test structure and therefore are used when testing larger/stiffer structures.

Instrumented hammers have two main limitations. First, the energy imparted to the structure by the hammer impact may be insufficient to excite the modes of interest, resulting in a low signal to noise ratio. Second, it is sometimes difficult to get consistent hammer hits, especially in recessed locations. Double hits, where the hammer actually bounces on the structure instead of hitting it cleanly, typically cause obvious artifacts in the frequency response function and therefore can easily be identified. A double hit can be positively identified if a double peak exists in the time response. Other variations in the location and/or direction of the hammer hit are typically not as obvious when observing the frequency response functions. Therefore, frequency response functions obtained using an instrumented hammer should be averaged, so that the coherence (see Section 12.3.3.5) can be used as a measure of the repeatability of the hammer impacts. A high coherence (~ 1) indicates consistent impact and response data.

FIGURE 12.19 Two shakers, a 4 lbf (a) and a 40 lbf (b) shaker, are shown. A stinger can be attached to the driven section of the shaker at the central threaded hole. The 4 lbf shaker is shown attached to a mount that allows rotation of the shaker to align the direction of motion (along the axis of the shaker) with the desired excitation direction on the test structure.

12.4.1.2 Shakers—Harmonic, Swept Harmonic, Random, or Burst Excitation A shaker produces a unidirectional force when appropriately attached to a test structure. Two shakers of differing size are shown in Figure 12.19. The size of the shaker determines its frequency and forces ranges, with smaller shakers typically having a higher frequency range, but a lower force range. Frequencies can range from a few Hertz to tens of kiloHertz and forces can range from a few Newtons to hundreds of kiloNewtons.

Shakers can produce a wide range of excitation time histories, including harmonic, swept harmonic, burst, or random. The desired excitation signal is specified using a vibration controller, often within the digital signal analyzer, and amplified to drive the shaker. If the test structure's dynamics response is only required at a small number of distinct frequencies, then single frequency harmonic excitation can be used. However, single frequency harmonic excitation is inefficient if the response is required over a broad frequency range. A swept harmonic excitation is often used to obtain the structure's response over a given frequency range. Just as the name implies, swept harmonic excitation applies a harmonic force with a frequency that sweeps through a frequency range, starting at the specified lower frequency and continuously increasing until the upper frequency is reached. A swept sine excitation for the frequency range from 0 to 800 Hz is shown in Figure 12.20. The amplitude versus frequency plot (not shown) indicates that the signal amplitude is approximately constant over this frequency range. Random and burst (burst swept harmonic or burst random) excitation can also be used to obtain the frequency response. Choice of excitation signal depends on what sources are available and how similar the source is to expected forces on the test structure during operation.

Although the ideal frequency response function (defined in Section 12.3.3) for a linear system depends only on the test structure's dynamic characteristics, frequency response functions obtained using different excitation methods will differ somewhat due to errors introduced by limitations in the measurements. To obtain the most accurate results,

FIGURE 12.20 Source signal versus time for a swept sine from 0 to 800 Hz. A discrete Fourier transform of this signal would indicate that the amplitude is nearly constant over the specified frequency range from 0 to 800 Hz. The signal smoothly transitions from the high to low frequency so that the periodic extension of the signal does not introduce a discontinuity.

appropriate parameters need to be specified for data acquisition and for the discrete Fourier transform, as described in Section 12.3.3. In particular, an appropriate windowing function must be used, as described in Section 12.3.3.2. Swept sine and burst excitation require no (sometimes called uniform or rectangular) windowing, while random excitation typically requires a Hanning or similar windowing function.

Electromagnetic (also referred to as electrodynamic) shakers are the most commonly used shakers in vibration testing. Other types of shakers are available and may be better suited for specific applications. For example, electrohydraulic shakers have a lower frequency range and can be used to apply a static load superimposed on the dynamics excitation.

In an electrodynamic shaker, the output from the amplifier passes through a coil located within a magnetic field, producing a force proportional to the current. The force actually applied to the structure (needed to determine the frequency response function of the structure) depends on the response characteristics of the shaker and structure, so *a separate force transducer must be used* to measure this force. This force transducer should be located at the point of excitation on the structure to ensure that the force applied to the structure is accurately measured. In addition, for a small test structure, a small force transducer should be chosen so that the added mass does not significantly affect the structure's dynamic response.

Care must be taken to ensure that only the desired excitation force is applied to the test structure. Often this requires extra fixturing both to support the shaker and to connect the shaker to the structure.

The connection between the shaker and the structure should allow only the desired force, along the direction of the shaker motion, to be transmitted to the structure. A shaker is much stiffer in the direction perpendicular to its motion than in the direction of its motion. Therefore, connecting the shaker directly to the structure will effectively stiffen the structure, detrimentally affecting the frequency response measurements. Typically a shaker is connected to the force transducer attached to the test structure through a *stinger* or push-rod, as illustrated in Figure 12.21. A stinger is a short rod or wire (perhaps ~ 1 cm in free length and 1 mm in diameter), designed to be stiff in the axial direction but flexible in the transverse direction so that essentially only the shaker's axial forces are transmitted to the test structure. The stinger should be stiff enough so that its resonance frequencies

FIGURE 12.21 Experimental setup showing a test structure suspended from above with elastic cords to approximate unconstrained boundary conditions. A shaker, used to excite the structure, is grounded from below and connected to the test structure by a push rod. A force transducer, mounted between the push rod and the structure, is used to measure the excitation force transmitted to the test structure.

are high enough above the frequency range of interest so that they do not interfere with the vibration measurement. In addition, if the path to the desired excitation point is obstructed, then a stiff, but light-weight extension may be required to connect the shaker output to the structure.

The base of the shaker should be supported so that it is isolated from the test structure and does not create an additional excitation force on the structure. Because the frequency response function assumes that the only excitation is that measured by the force transducer, all other excitation of the structure must be minimized for accurate frequency response function measurements. The base of the shaker can be grounded, for example, attached to the floor, while the test structure is isolated from floor vibrations. For example, larger structures can be supported on a vibration isolation system and smaller structures can be placed on a foam pad or hung from the ceiling. Alternatively, the base of the shaker can be suspended so that no force is transmitted to any surrounding structure, except to the test structure through the stinger. However, to create the same excitation force amplitude, a larger shaker mass is required for a suspended shaker than for a grounded shaker.

12.4.1.3 Multiaxis Tables Multiaxis shaker table test systems are designed to excite up to six (three translational and three rotational) degrees of freedom simultaneously, by controlling the output of multiple shakers working in unison. Typically a stiff vibration table is used to apply ground excitation to the test structure, as shown in Figure 12.22. Multiaxis loading not only reduces testing time but also can produce more relevant data.

The shaker table motion can be controlled to replicate actual loading conditions for a structure thereby producing vibration test results that may be more applicable to the actual operation of the structure. For example, operational deflection shapes obtained using realistic multiaxis excitations may indicate points of collision that could be missed if only single axis excitations are applied. In addition, multiaxis excitation can more accurately reproduce operational stresses for accelerated life and durability testing.

However, developing the load data for multiaxis testing is often not a trivial task. Typical in situ loading conditions must be measured and the relevant features identified, often using power spectral density representations of the data. The data also must be filtered and

FIGURE 12.22 A multiaxis shaker table showing ground excitation of an automobile seat. From: http://en.wikipedia.org/wiki/File:Multi_Axis_Shaker_Table.jpg.

conditioned to meet the requirements defined by the physical limitations of the multiaxis table.

12.4.1.4 Operational Loads The dynamic response of a machine to purely operational loads can also be measured and analyzed. Vibration response to operational loads can be used to obtain information about the dynamic characteristics of a machine (see Section 12.5.2) or to monitor the performance of a machine (see Section 12.6.2). The loads experienced by a machine during operation can be generated either externally or internally.

Vibrations are generated internally by moving parts within the machine. Any rotating shaft will have some unbalance that will produce a harmonic force at the shaft rotation frequency. The response of the machine to a range of excitation frequencies can be obtained by varying the shaft rotation rate and taking repeated measurements. Other moving parts such as bearings, reciprocating pistons, and gears will produce more complex loadings.

External loads can be generated by a wide range of sources and transmitted to the machine through the ground supports or through the air. A machine on a factory floor may be excited, for example, by vibration of nearby machines or motions generated by people working in the surrounding area. If the structure of interest is a part of a machine, then the vibration of mounting surface caused by the machine's operation may be considered as the external load of interest. Ground motion caused by earthquakes or nearby explosions may be the relevant excitation, especially for civil structures. Wind loadings may also be important sources of vibration for civil structures and other outdoor structures such as antennas and windmills. Automobiles, trucks, and other land vehicles will

experience a random excitation generated as they are driven over rough terrain. Components in a car crash or dropped object will experience shock loadings. Measurement of a structure's response to loads it experiences in service may provide information to improve its performance or to suggest design modifications.

12.4.2 Response and Force Measurement

In this section, a brief overview of vibration measurement equipment will be given. A device to measure motion is typically required for any vibration test and a wide range of contact and noncontact devices are available. Measurement of additional quantities, such as force, pressure, or sound may also be required for vibration testing.

Transducers are devices that convert a mechanical measurement to an electrical signal that can be used as input to a signal analyzer. The most important characteristics to consider when choosing a transducer for vibration measurement are the (1) sensitivity, (2) resolution, and (3) operating frequency range.

Sensitivity is defined as the ratio of the electrical output to the mechanical input. For example, for a force transducer, the sensitivity may be specified in millivolts per Newton (mV/N). A good transducer has a high sensitivity in the intended measurement direction and a low *transverse sensitivity*, that is, a low sensitivity normal to the intended measurement direction.

The *resolution* of a transducer is the smallest increment of the mechanical input that produces a discernable change in the electrical output. Measurement resolution depends on the equipment used to capture the signal as well as on the transducer and can be limited by noise levels in the measurement system.

Ideally, a transducer's sensitivity would be constant over its entire operating range, although in practice some variation of sensitivity will occur. The *operating frequency range* is specified as the frequency range over which the sensitivity varies less than a specified percent from its rated value. A sensor's natural frequencies essentially determine its operating frequency range. Sensors are typically designed so their natural frequencies are far from the operating frequency range to avoid resonance effects that would cause variations in the sensor's sensitivity.

Environmental factors such as temperature and humidity may affect the operation of a transducer. Often transducers include internal electronic compensation to minimize environmental effects on their output signal and to reduce other undesirable effects such as drift. Specifications for environmental factors should be consulted, especially when choosing a sensor to be used in extreme environments or environments that vary over time.

Sensors should be calibrated periodically, especially when high precision data are required. A sensor can be calibrated by measuring its response to a known calibration excitation or by comparing its response to that of another sensor of known calibration (see, e.g., Chapter 11 of Piersol and Paez, 2010).

12.4.2.1 Relating Acceleration, Velocity, Displacement Acceleration, velocity, and displacement are the most common measures of motion, although indirect measures, such as strain, are also possible. The most appropriate quantity to measure depends on the amplitude and frequency range of the motion as well as on the application. Sections 12.6.2, 12.6.3, and 12.6.4 cover common methods for measuring acceleration, velocity, and displacement, respectively. The relationship between these three quantities will be presented in this section.

Acceleration, velocity, and displacement are related, so theoretically, if one of these quantities is measured, then the other two can be calculated. For example, a time derivative can be applied to the displacement data to obtain velocity, $v(t) = (dx/dt)t$, and a time derivative can be applied to the velocity data to obtain acceleration, $a(t) = (dv/dt)t$. Conversely, acceleration data can be integrated in time to obtain velocity and similarly, velocity data can be integrated to obtain displacement.

Vibration data are typically analyzed in the frequency domain where the relationships between acceleration, velocity, and displacement reduce to simple multiplications. Specifically, in the frequency domain, a time derivative is equivalent to a multiplication by $2\pi jf$, and a time integral is equivalent to a multiplication by $1/(2\pi jf)$, where f is the frequency in Hz and $j = \sqrt{-1}$.

These relationships can be more easily understood by considering a time harmonic response

$$x(t) = A \cos(2\pi f t + \phi) \quad (12.25)$$

at a single frequency f . In Equation 12.25, the phase, $\phi = \phi(f)$, can be a function of frequency. The velocity

$$v(t) = \frac{dx}{dt}(t) = 2\pi f A \sin(2\pi f t + \phi) \quad (12.26)$$

is obtained by taking the time derivative of the displacement. Similarly, the acceleration

$$a(t) = \frac{dv}{dt}(t) = -(2\pi f)^2 A \cos(2\pi f t + \phi) \quad (12.27)$$

is obtained by taking the time derivative of the velocity.

A comparison of Equations (12.25) and (12.27) shows that the amplitude of the acceleration of a time harmonic motion can be obtained by multiplying the displacement amplitude by $(2\pi f)^2$. Therefore, for the same displacement amplitude, higher frequency oscillations will have higher acceleration amplitudes.

Equations (12.25)–(12.27) can be rewritten in complex notation as

$$x(t) = \text{Re}[A e^{j(2\pi f t + \phi)}] \quad (12.28)$$

$$v(t) = \text{Re}[2\pi j f A e^{j(2\pi f t + \phi)}] \quad (12.29)$$

and

$$a(t) = -(2\pi f)^2 \text{Re}[A e^{j(2\pi f t + \phi)}] \quad (12.30)$$

This notation shows that multiplication by j in the frequency domain corresponds to a 90° phase shift (e.g., from $\cos(2\pi f t)$ to $\sin(2\pi f t)$) in the time domain. Therefore, acceleration and displacement are 180° out of phase.

By superposition, the time domain signal for a linear system can be represented as a summation of time harmonic components, each component represented by one point in the frequency spectrum. Therefore, for example, a plot of the amplitude of the velocity

spectrum can be obtained from a plot of the amplitude of the displacement spectrum simply by multiplying each point of the plot by $2\pi f$.

The relationships among displacement, velocity, and acceleration are useful in determining which sensor to use to measure a specific dynamic response. Equations (12.25)–(12.27) imply that, in general, accelerometers will be more sensitive to high frequency motions, while displacement sensors will be more sensitive to low frequency motions. However, because numerical error is introduced in converting from one measure to another, it is often best to measure the quantity most representative of the phenomena under study. Other factors to consider include the sensitivity, resolution, and linear frequency range of the sensor.

12.4.2.2 Acceleration Measurement An accelerometer is a device used to measure acceleration. Currently, accelerometers are the dominant choice for motion measurement, so they will be described in detail.

Accelerometers are seismic transducers that consist of a spring–mass system attached to an outer housing. The displacement of the internal mass relative to the housing is approximately proportional to the housing acceleration, within the operating frequency range of the accelerometer. The upper limit of the operating frequency range is limited to about one-third of the accelerometer’s natural frequency. Therefore, the spring–mass system within an accelerometer is design to have relatively high stiffness and small mass to achieve a high natural frequency. Accelerometers come in a range of sizes, with the smaller accelerometers typically designed for higher frequency measurement.

The relative displacement between the accelerometer mass and housing causes a compression or expansion of the spring element. Therefore, either a measure of the spring compression or relative mass displacement can be used to produce an output signal proportional to the acceleration of the housing. When the housing is firmly attached to a vibrating structure, the output signal will be proportional to the acceleration of the structure at the attachment point.

The three basic types of accelerometers, piezoelectric, piezoresistive, and capacitive, differ by how the relative displacement of the mass (or spring deformation) is measured. The operating frequency range, sensitivity, and measurement resolution typically differ between the types. However, these differences are becoming less significant as transducer design improves.

Piezoelectric accelerometers are the most common and are available in a range of sizes. A variety of piezoelectric accelerometers are shown in Figure 12.23. In piezoelectric accelerometers, a stiff piezoceramic or a piezoelectric crystal serves as the spring and also as the sensing element. Deformation of the piezoelectric crystal produces a charge or electronic potential proportional to the strain. The main advantages of piezoelectric accelerometers are their high operating frequency ranges, smaller size and weight, and their insensitivity to temperature. However, piezoelectric accelerometers are not suited for quasi-static (near zero frequency) measurements because the charge generated in the piezoelectric material will slowly bleed off through internal resistances. In addition, piezoelectric accelerometers are typically not recommended for high shock levels due to strain limits on the sensing element.

There are two types of piezoelectric accelerometers: charge mode piezoelectric (PE) and voltage mode internal electronic piezoelectric (IEPE). Internal electronic piezoelectric accelerometers have a built-in charge amplifier that eliminates the need for an external constant current source and for special low-noise cables. Therefore,

FIGURE 12.23 A variety of piezoelectric accelerometers are shown with different mounting attachments. The uniaxial accelerometer (a) has a threaded stud. The smaller triaxial transducer (b) has an attached magnetic mount. The magnetic and wax mounting surfaces shown can be attached to the larger triaxial accelerometer (c).

internal electronic piezoelectric accelerometers are more popular than charge mode accelerometers.

In a *piezoresistive accelerometer*, the sensor is a strain gage attached to the spring element. The strain gage generates a change in electrical resistance proportional to the compression of the spring element. Historically, piezoresistive accelerometers have had lower operating frequency ranges than piezoelectric accelerometers, but recent design improvements have reduced this distinction. A major advantage of piezoresistive accelerometers is their ability to measure low, near zero, frequency signals. Piezoresistive accelerometers have low sensitivity, so they are better suited to shock applications, such as drop or crash tests, than for vibration testing and monitoring.

Capacitive accelerometers use a capacitance probe to measure the gap between the mass and the housing. Capacitive accelerometers are good for measuring lower frequency vibrations. Microelectrical–mechanical systems (MEMS) type capacitive accelerometers have become popular in video game controllers and cell phones for sensing control inputs and also for sensing tilt.

For vibration measurement, an accelerometer can be mounted on a vibrating structure using a threaded stud, cement, wax, adhesive tape, or magnet. Stud, wax, and magnetic mount attachments are shown in Figure 12.23. The choice of attachment method depends on a number of factors. However, the connection should be as strong as possible, because weak attachments will decrease the operating frequency range of an accelerometer.

For long-term placement, an accelerometer can be mechanically fastened with a threaded stud or bolt or it can be chemically bonded with a cement. These attachment methods are typically the strongest, and therefore they have the least effect on the operating frequency range.

A variety of temporary mounting options exist for accelerometers that need to be frequently repositioned. A magnetic accelerometer base can be used on steel and iron

ferromagnetic surfaces. A stronger magnet will have a smaller effect on the operating frequency range, but the additional mass may affect the motion of the test structure. Wax or double sided tape can be used to temporarily attach an accelerometer to a surface. A thinner bonding layer will have higher stiffness and thus have less effect on the operating frequency range. Flat, smooth, and clean surfaces are needed to ensure good contact between the accelerometer and the test structure for these temporary attachment methods. Holding an accelerometer by hand against the test surface will produce the poorest results, but may be useful for preliminary measurements.

If an accelerometer is not electrically insulated from a test structure, extraneous signals may result. Electrical noise transmission is more likely when a mechanical fastener or magnetic mount is used on a machine with operating motors. A strong 60 Hz signal is a good indication that electrical noise is present and electrical isolation is needed.

Attaching an accelerometer to a structure effectively increases its mass. To avoid significant changes in the dynamic response of the structure, the accelerometer mass should be less one tenth of the dynamic mass of the structure at resonance. Care should also be taken to ensure that the accelerometer cable does not affect the vibration measurement.

As with any linear motion sensor, care should be taken to align the sensor to the desired measurement direction. An angle misalignment θ_{err} from intended direction introduces an error proportional to $(1 - \cos(\theta_{\text{err}}))$. Fortunately, this error is typically negligible for small angles of misalignment.

12.4.2.3 Velocity Measurement Similar to an accelerometer, traditional velocity transducers also consist of a spring-mass system attached to an outer housing. The mass is a permanent magnet that can move along the axis of a cylindrical coil of wire attached to the housing. A voltage signal proportional to housing velocity is produced by the relative motion between the magnet and the coil.

For velocity sensors, the spring is weak and mass is large, so the natural frequency of the spring-mass system is low (a few Hz). The mass is surrounded by a damping fluid, usually oil, to damp out vibration at the natural frequency. The operating frequency range is above the natural frequency, but typically not as high as the operating ranges for typical accelerometers.

These traditional velocity transducers are sturdy and most need no external power supply or charge amplifier, but tend to be larger than comparable accelerometers (see Figure 12.24). Many machinery monitoring standards were written in terms of velocity measurements because these measurements used the technology available at that time. However, due to advances in accelerometer technology, these velocity transducers are not as popular as they once were.

More recently, laser Doppler vibrometer systems have been developed that use the Doppler shift of laser light wavelength to measure the velocity of a vibrating structure (Maurer et al., 2010). Laser Doppler vibrometers and other optical system can be more expensive than other measurement devices, but they offer a number of advantages that have lead to their steady gain in popularity. Because optical systems are noncontact systems, they can be used in harsh environments and on rotating shafts where it would be impossible to mount a motion sensor. In addition, using a noncontact system eliminates mass loading effects. Laser systems usually have higher spatial resolution and the laser beam can be scanned across the test structure so that a large number of data points can be obtained rapidly. Also, laser systems typically have a broader operating frequency range, including near zero Hz.

FIGURE 12.24 A velocity transducer showing its typical large size.

12.4.2.4 Displacement Measurement Displacements may be the most appropriate quantity to measure in applications where clearance between bodies is critical. The most popular displacement transducers are noncontact proximity probes, although contact probes, such as linear variable differential transformers (LVDTs) and string potentiometers, are used in some vibration measurement applications.

Eddy current probes are probably the most common noncontact proximity sensor used in vibration monitoring. Eddy current probes can only measure the vibration displacements of electrically conductive (metallic) surfaces. Eddy current probes are sometimes referred to as inductive proximity sensors, because the electromagnetic field generated at the probe tip induces eddy currents in a nearby metal surface. The interaction between the electromagnetic field and the induced eddy currents depends on the distance between the probe and the metallic surface. The probe senses this interaction and produces an electrical voltage proportional to the gap thickness. The interaction depends on the conductive properties of the metallic surface, so eddy current probes must be calibrated for each material.

Eddy current probes are often used to measure the vibration of rotating shafts. Direct measurement of shaft vibrations is especially useful when the shaft is supported by oil-film bearings. Vibrations transmitted through oil-film bearings are difficult to measure since they are significantly dampened and of much lower amplitude than the vibration of the shaft itself. Because the eddy current probe output is proportional to the gap thickness, probe vibration as well as shaft vibration will affect the output signal. Therefore, proximity probes must be securely mounted to a nonvibrating surface for accurate measurement of shaft displacement. The probe casing is often threaded, as shown in Figure 12.25, to allow for a secure attachment. In addition, shaft run out, imperfections in the shaft material, and shaft surface quality will affect the eddy current probe signal. These latter affects can be measured while the shaft is rotating slowly (so no vibrations are excited) and subtracted from the measurements obtained during vibration testing. A rotary encoder or other angular position measurement is needed to synchronize the angular positions of the two measurements.

Capacitive or optical proximity sensors can be used if the material of the vibrating structure is nonconductive. Capacitive sensors generate an electric field that induces a

FIGURE 12.25 A proximity probe (b) and mounting fixture (a). The proximity probe has a threaded casing used to securely mount the probe into a fixture.

charge in the test surface. The capacitive sensor measures the capacitance of the air in the gap between the probe and test surface to generate a signal that is proportional to the gap thickness. A variety of optical sensors are available, most based on fiber optic technology.

Proximity probes can be used to measure static as well as dynamically changing gaps. Therefore, there is no lower limit to the operating frequency range. However, the upper frequency limit is typically not as high as for accelerometers or velocity sensors.

12.4.2.5 Force Measurement The excitation force imparted by a shaker, hammer, or other source must be measured for many vibration testing applications. Instrumented impact hammers typically have a load cell built into the tip, while external load cells, such as the one shown in Figure 12.26, are needed for other excitation sources. A load cell is a transducer that generates an electrical signal proportional to an applied normal or shear force. The force amplitude is obtained indirectly from a measurement of the strain or deformation of an internal component of the load cell. This is analogous to determining the amplitude of a force, F_s , applied to a spring (with spring constant k) by measuring the extension, x_s , of the spring, using the equation, $F_s = kx_s$. For dynamic measurements, the mass of the load cell may also affect the measurement as well as the response of the structure (McConnell and Varoto, 2008).

Piezoelectric force transducers are the most common load cells used for vibration measurements. Similar to piezoelectric accelerometers, a piezoceramic or piezoelectric crystal acts as the “spring” element and produces an electronic potential proportional to the applied load. Piezoelectric force transducers have advantages and disadvantages similar to piezoelectric accelerometers because the sensing element is the same.

12.4.3 Vibration Analyzers

A signal analyzer is the core element of a vibration measurement system. Digital signal analyzers have been developed to handle both data collection and analysis functions for

FIGURE 12.26 A normal force load cell with mounting stud (foreground) used to measure the force applied to a test structure by a shaker. The stinger with collets attached at both ends (background) is used to connect the shaker to the load cell.

many vibration applications. These functions include signal conditioning, filtering, analog-to-digital (AD) conversion, analysis, storage, and presentation of the vibration data. In addition, many analyzers can output a control signal for shaker or other source excitation. Analyzers are comprised of a hardware unit and software tools. The software runs either on the analyzer itself or on a linked computer. Discrete frequency domain analysis is the main focus of these tools, although capabilities for time domain and other analysis types may also be available. This section covers the basic functions of a digital signal analyzer and the general differences between current analyzers types.

One major function of an analyzer is to acquire measurement data. Most vibration measurement applications require at least two input channels. For example, simultaneous measurements of both excitation and response signals are required to generate frequency response functions (defined in Section 12.3.3) needed for modal analysis (discussed in Section 12.5). Often analyzers have more than two input channels so that multiple responses can be measured simultaneously. Simultaneous measurement not only can save time but also can improve the quality of the analysis results.

Typical force or response measurement devices require a conditioner to convert or amplify the weak analog signal generated by the sensing element of the device to an analog voltage signal in a range that can be used by the analyzer. Modern analyzers may have built-in signal amplification and conditioning functions so that separate conditioning units are unnecessary.

Because vibration analysis is typically done in the frequency domain, digital signal analyzers ultimately generate a frequency spectrum of a time varying voltage. Before the data are acquired, the user must specify the frequency range and number of points for the frequency spectrum. These two quantities determine not only the spectrum's frequency resolution but also the time interval for data acquisition. Higher frequencies require faster

sampling rates and therefore, shorter data acquisition times. Conversely, slower sampling rates and longer data acquisition times are used for lower frequencies.

The frequency spectrum is obtained by applying a discrete Fourier transform to the time domain data. Refer to Section 12.3.3 for a discussion of discrete Fourier transforms. Before the discrete Fourier transform can be applied, the analog voltage input signal must first be low-pass filtered and converted to a digital signal using an analog-to-digital (AD) converter. To prevent aliasing (defined in Section 12.3.3.1), most signal analyzers automatically filter out contributions from frequencies above the user-specified frequency range. Digital signal analyzers use a combination of analog and digital filtering to efficiently reduce contributions from these frequencies to the noise level.

Digital signal analyzers allow the user to select parameters that can affect the accuracy of the resulting spectrum, such as those discussed in Section 12.3.3. Values for these parameters must be properly chosen so that the most accurate time and frequency domain representations of the data are obtained. The input voltage range, coupling type, and triggering parameters must be specified to obtain an accurate discrete representation of the time domain signal needed for analysis and storage. The input voltage range specifies the amplitude range for analog-to-digital conversion. Input signals with voltages outside this range will be cut off and signals that only use a small portion of this range will have poor resolution. Ideally, the range for each input channel should be chosen so that the input signal voltages use most of the input range without exceeding the range limit. The input signal can be either DC or AC coupled to the input channel. AC coupling is essentially a high pass filter that can be used to eliminate a large DC bias to achieve better resolution for small amplitude higher frequency oscillations. Triggering can be used to capture transient signals or to synchronize signals and preserve phase information.

Analyzers typically have a variety of windowing functions that can be selected to prevent leakage (defined in Section 12.3.3.2) or to minimize the effect of noise on the frequency spectrum. Some windowing functions that are useful for vibration measurements are described in Section 12.3.3.2. The effect of windowing on the frequency spectrum can be determined experimentally by comparing the frequency spectrums obtained for different windowing functions.

A frequency spectrum of the response signal is the most basic output of an analyzer and can be useful in a variety of applications. However, frequency response functions are used for most vibration analysis applications and therefore can be calculated by most digital signal analyzers. The frequency response function is defined in Section 12.3.3 as the response spectrum divided by the excitation frequency spectrum. The frequency response function can typically be displayed in a number of formats to allow easier analysis of the results.

Analyzers can also have a variety of software options for further analysis of the vibration data. These analysis options can more rapidly produce meaningful test information for special purpose applications. For example, modal analysis software can be used to determine the natural frequencies, modal damping coefficients, and mode shapes of a structure (see Section 12.5). Software options for other applications, such as machine fault monitoring or fatigue testing, may also be available.

Data are typically stored on digital media. With a link to a computer, analysis results can be transferred and output in various formats including simplified screen shots, spreadsheet data, and video animations files. Modal analysis software often allows for animations of mode shapes or operational deflection shapes so the problem areas of a structure can be quickly identified. Standardized file formats have enabled the transfer of data

across hardware and software platforms, for example, for comparing measured frequency response functions and mode shapes with finite element predictions.

Analyzers come in various sizes and with a variety of capabilities. Factors to consider when selecting an analyzer include the number of channels, the available frequency range, the quality of the signal processing, the analysis software and display capabilities, the analyzer size and portability, and the cost.

Vibration analyzers have experienced a significant reduction in size along with improvements in capability and signal processing quality over the last few decades. Hand-held and very small units with high frequency bandwidths and multiple channels now exist. Medium size, but still portable, multiple channel systems often offer more flexibility and software analysis options for customizable multipurpose applications. As a result, single-chassis portable multichannel analyzers have become commonplace in a variety of industries. Systems with high numbers of channels can be realized by linking individual analyzers with synchronizing connections. Racks of multiple modules can simultaneously record dozens, hundreds, or even more channels. Multiple racks can be synchronized over significant distances between racks, allowing for short rack to sensor connections even when acquiring measurements on very large structures.

12.5 EXPERIMENTAL MODAL ANALYSIS

Experimental modal analysis is the determination of the dynamic characteristics of a structure from vibration measurement data. The basic parameters that define the dynamic response of a structure are the natural frequencies, damping coefficients, and mode shapes. These parameters were introduced in Section 12.3 for multi-degree-of-freedom systems and will be reviewed using a plate model in this section, before experimental modal analysis techniques are presented. Two basic assumptions are typically made: (1) the structure's response is linear and (2) the structure's dynamic characteristics do not change with time.

The natural frequencies, ω_i , are the easiest to measure and often the most important. For example, if a structure is excited at one of its natural frequency, then resonance can occur that might result in large amplitude vibrations. Corresponding to each natural frequency, ω_i , there exist a mode shape, φ_i , that specifies the shape of the vibration at that frequency. Mode shape information is needed to fully characterize the structure's resonance response and to determine the locations of the largest vibration amplitudes. The damping at each natural frequency can be characterized by a modal damping coefficient, ζ_i . Damping will limit the amplitude of vibration when a structure is excited at one of its natural frequencies and will cause the vibration amplitude to decay when the excitation is stopped.

These quantities, natural frequencies, mode shapes, and modal damping, are not only useful in specifying a structure's response to harmonic excitation at one of its natural frequencies, but they also can be used to predict the structure's response to any excitation. These predictions can be made using either a model generated directly from the modal analysis data or a finite element model of the structure. In the latter case, the experimental modal analysis data can be used to verify or update the finite element model. Either model can then be used to investigate design modifications that can minimize the effects of the structure's vibration during operation.

Modal parameters cannot be directly measured, but instead must be inferred from measured vibration responses. There are numerous methods for obtaining the

measurement data and also for extracting modal information from the data. The experimental measurement data can either be analyzed in the frequency domain or the time domain. Frequency domain analysis will be used in this section because it is used in the most common methods. Typically, FRFs (defined in Section 12.3.3) are the basis of the analysis. To obtain frequency response functions, both the excitation and the response must be measured.

Techniques for obtaining modal information when the excitation forces are unknown, for example, from operational excitation, will be briefly discussed in Section 12.5.2. These output-only techniques are useful when vibration measurements can only be obtained on a machine during operation or when a structure is too large to excite with available sources. Also, it may be necessary to measure the natural frequencies of a shaft while at operating speed, because the natural frequencies can change with rotational speed, especially at high rotation rates. See Avitabile (2000) and Batel (2002) for practical discussions of modal analysis and operation modal analysis, respectively, and Bucher and Ewins (2001) for a review of modal analysis for rotating structures.

12.5.1 Modal Analysis Using Frequency Response Functions (FRFs)

In this section, it is assumed that both the excitation and the response are measured when obtaining the experimental data for modal analysis. First, a brief description of modal analysis concepts will be given in Section 12.5.1.1 in the context of a simple thin rectangular plate. These concepts are useful when choosing the excitation and response locations and directions for vibration measurements, and will also add insight when interpreting modal analysis data. In Section 12.5.1.2, experimental measurement data typically used in modal analysis will be discussed. Finally, in Section 12.5.1.3, an overview of methods for estimating the modal parameters from the measurement data will be given.

12.5.1.1 Natural Frequencies, Mode Shapes, and Modal Damping The concepts of natural frequencies, mode shapes, and modal damping discussed for multi-degree-of-freedom systems in Section 12.3.1 can be generalized to structures that have a continuous distribution of mass and stiffness. The rectangular plate, shown schematically in Figure 12.27, will be used for illustration in this section as a simple example of a continuous structure. Result obtained from both experiment measurements and a finite element model of the plate will be used to illustrate basic vibration phenomena. For this illustration, free

FIGURE 12.27 Schematic view of the top surface of a rectangular plate (12 in. by 4 in. by 0.088 in.) with an overlaid rectangular grid of 35 points. For the analysis, the plate is unconstrained. During experimental measurements, the plate was placed on soft foam to approximate the unconstrained boundary conditions.

boundary conditions are used in the finite element model. In other words, no constraints are applied to the boundaries in the finite element model, so the finite element results predict the behavior of a plate floating in space. Experimentally, free boundary conditions can be approximated by supporting the plate on a soft foam pad or suspending the plate with elastic cords.

Theoretically, a continuous structure has an infinite number of natural frequencies. However, the structure's response is dominated by contributions from a finite number of modes and a finite range of frequencies. The relevant range of frequencies is determined by the frequency content of the excitation. Therefore, frequencies are numbered in ascending order, often with the lowest frequencies dominating the structure's response.

Corresponding to each natural frequency, ω_i , is a mode shape, $\boldsymbol{\varphi}^{(i)}(x, y, z)$, that specifies the shape of the structure when vibrating at that frequency. Specifically, $\boldsymbol{\varphi}^{(i)}(x, y, z)$ is a vector that specifies the normalized x , y , and z displacements as a function of location (x, y, z) in the structure.

For illustration, the first five mode shapes of the rectangular plate with free boundary conditions are shown in Figure 12.28. The modes shapes are in order of increasing frequency. Modes 1, 3, and 5 correspond to bending modes of the plate, which are analogous to the bending modes of an unsupported beam. There are similar bending modes across the width of the plate, but these occur at higher frequencies because the width is smaller than the length of the plate, causing a higher stiffness in this direction. Modes 2 and 4 correspond to twisting modes for this plate.

For the modes shapes of the thin plate, the transverse displacements (in the z direction, normal to the plate) are significantly larger than the in-plane displacements (in the x and y directions). Also, the displacements do not vary significantly across the thickness of the plate (in the z direction). Therefore, the i th mode shape for the rectangular plate can be approximated by a scalar, $\varphi^{(i)}(x, y)$, that specifies only the transverse displacement as a function of the (x, y) location on the plate surface. This implies that a good approximation for the plate mode shapes can be obtained experimentally using only normal excitation forces and measuring responses normal to the plate. This demonstrates how an understanding of the expected dynamic behavior of a structure can be used to dramatically reduce the quantity of data required for experimental modal analysis.

Damping is often neglected when determining the frequencies and mode shapes of a structure from analytical or numerical (e.g., finite element) models. In the absence of damping, the predicted phase between the excitation and response at any point is either 0° (in phase) or 180° (out of phase). In a mode shape animation for an undamped structure, all points across the structure will reach their maximum deflection at the same time and will simultaneously pass through zero deflection. Therefore, an animation of an undamped mode shape will appear to be a standing wave.

Any real structure has some damping, although in most structures that damping is small. Therefore, measured mode shapes will be approximately the same as the mode shapes predicted using models without damping. However, the phases from measured data will not be exactly either 0° or 180° . Measured responses of lightly damped structures often will be nearly in phase or out of phase. When the modal responses at different points are nearly in phase or out of phase, the vibration mode is described as having a *low modal complexity*.

Theoretically, if the damping is “proportional damping,” that is, distributed throughout the structure in the same way as the stiffness or mass, then damping will not affect the modal complexity. However, typically joint friction contributes significantly to the

damping of a structure, resulting in “nonproportional damping.” Nonproportional damping can increase modal complexity, especially when successive frequencies are close and their response peaks significantly overlap. A mode is said to have *high modal complexity* if the phase difference between structural points within the mode shape vary significantly from 0° or 180° . In this case, a stationary plot of a complex mode shape would not properly represent the vibration at that frequency. An animation of a mode with high modal complexity will appear more like a traveling wave than a standing wave.

The modal response for repeated roots of symmetric structures can also exhibit modal complexity, even in the absence of nonproportional damping. For example, vibration of a bar with a circular cross-section at its fundamental frequency can be in either of the two

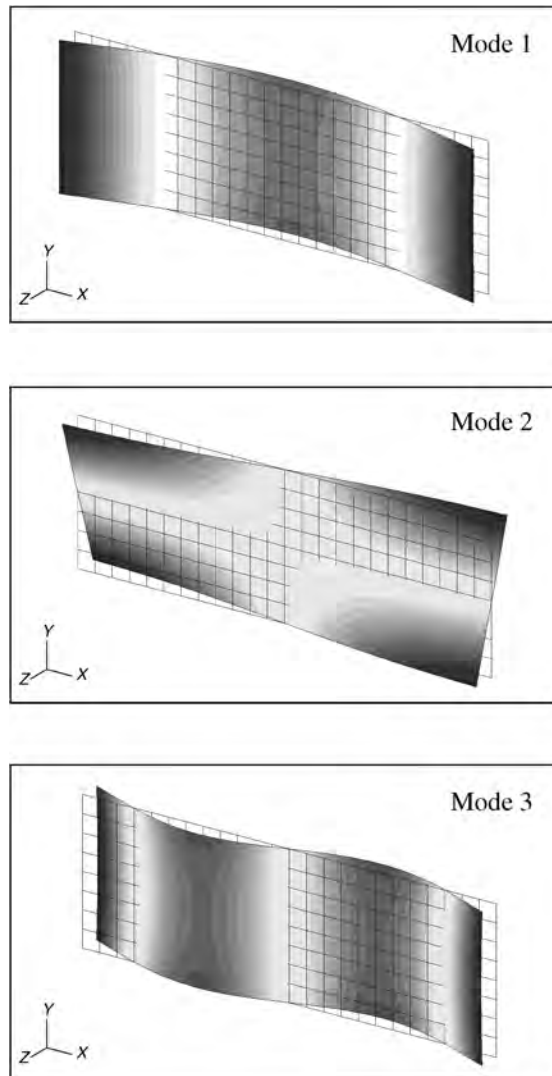

FIGURE 12.28 First five mode shapes of the unconstrained rectangular plate shown in Figure 12.27, predicted by finite element analysis.

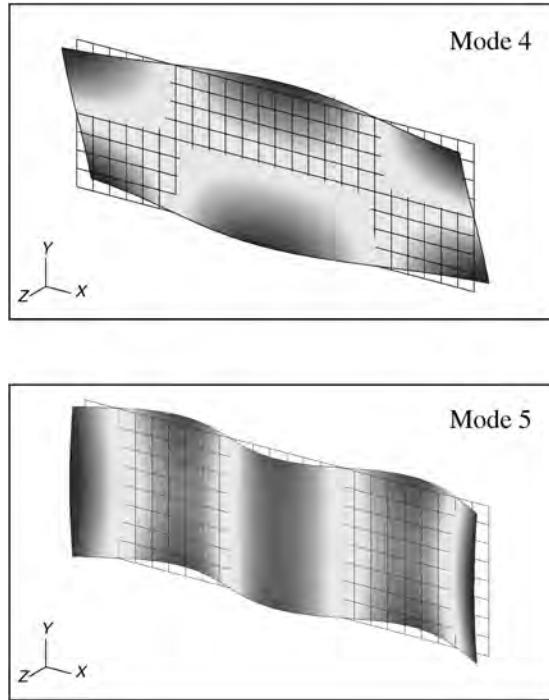

FIGURE 12.28 (Continued)

transverse directions. If these two responses are combined with a 90° phase between them, then the end of the bar will follow a circular or elliptical path in space. Care must be taken in experimental modal analysis as an oversimplified study would not reveal this behavior or enable differentiation between a complex mode, repeated roots, or closely spaced modes.

As described for multi-degree-of-freedom systems in Section 12.3.1, mode shapes are not only useful for understanding the response of a structure when excited at resonance but are also useful for predicting the response of the structure to a more general excitation. For example, when damping is negligible, the transverse displacement response of the plate, $w(x, y)$, can be written in terms of the modes shapes as

$$w(x, y, t) = \sum_{i=1}^{\infty} \varphi^{(i)}(x, y) T_i(t) \quad (12.31)$$

where the time dependence $T_i(t)$ is determined by the excitation.

Damping will limit the amplitude of the response to a continuous excitation and cause the vibration amplitude to decay with time after an excitation has ceased. Although sources of damping are difficult to identify and quantify, an estimate of the magnitude of the damping, ζ_i , can be obtained for each mode from experimental modal analysis data. Analogous to Equation (12.23), the free vibration response of a damped system, with modal damping coefficients ζ_i , can be approximated by

$$w(x, y, t) = \sum_{i=1}^{\infty} A_i \varphi^{(i)}(x, y) e^{-\zeta_i \omega_i t} \sin(\omega_{di} t + \theta_i) \quad (12.32)$$

The coefficients A_i and phase shifts θ_i are determined by the initial displacements and velocities. For the free vibration response, the time dependence for each mode is a decaying oscillation at its damped natural frequency, $\omega_{di} = \omega_i \sqrt{1 - \zeta_i^2}$.

The dynamic response of a structure (given by the infinite sum in Equation 12.32) can be accurately approximated by a sum of contributions from a finite number of modes. Typically only modes with the lowest frequencies or with frequencies in the frequency range of the excitation contribute significantly to the response. This reduced expression for the system response is what makes modal analysis so powerful for interpreting vibration behaviors.

12.5.1.2 Modal Analysis Measurement Data Estimates of a structure's important natural frequencies, damping parameters and modes shapes can be obtained by analyzing a set of vibration response measurements. While some of the resonance frequencies can be estimated from a single measurement, multiple measurements with different excitation and/or response locations are needed ensure that all important resonance frequencies are identified and to obtain mode shape information. For example, to obtain mode shapes for the plate of Figure 12.27, measurements can be taken over a regular grid, such as locations 1 through 35. The responses at these locations can then be analyzed to estimate the modal parameters, including the normalized displacement at each location for the mode(s) of interest. A model using this coarse grid can then be animated to visualize the mode shape(s).

The most basic measurement consists of a single excitation and a single response, often denoted as *single-input/single-output (SISO)*. Both the location and the direction of the excitation and response need to be specified. As stated above, for the plate example, excitation and measurements normal to the plate will provide the best data. Therefore, in this discussion, it is assumed that both the excitation and the response are in the z direction.

The *FRF*, $H_{ij}(f)$, for a single measurement is obtained by dividing the discrete Fourier transform of the response, $X_i(f)$, at location i by the discrete Fourier transform of the excitation, $F_j(f)$, at location j . Because each discrete Fourier transform is a frequency spectrum consisting of a list of complex values (one complex number corresponding to each frequency in a given frequency range), the frequency response function is also a complex frequency spectrum. Therefore, frequency response functions can be represented in terms of either their amplitude and phase or real and imaginary parts, as illustrated in Section 12.3.3.

As an example, the amplitude and phase of a measured frequency response function are shown in Figures 12.29 and 12.30, respectively. The measurements were obtained from the plate of Figure 12.27 for an impact excitation at location 19 and an acceleration measurement at location 18. Note the similarities between the measured frequency response function plot (Figures 12.29 and 12.30) and the plot in Figure 12.6 for the response of a two-degree-of-freedom system. There are two major peaks in the amplitude plots of Figure 12.29 at two of the plate's natural frequencies. The phase plots in Figure 12.30 show a phase change of approximately 180° as the frequency increases through these two natural frequencies. Much of the discussion in Section 12.3 can be extended to the analysis of the dynamic response of continuous systems. For example, as shown in Figure 12.31, the real and imaginary parts of the frequency response functions can be plotted, similar to Figure 12.7a and b or a Nyquist plot similar to Figure 12.8 can be obtained. Analyzer postprocessing software can create these standard plots.

Because the plots shown in Figure 12.29–12.31 are obtained from experimental data, they slightly deviate from predictions of an ideal model. For example, the plate was supported on a soft form pad to approximate a plate with no constraints, that is, with free

FIGURE 12.29 Amplitude of the frequency response function (FRF) for the plate shown schematically in Figure 12.27, measured with an accelerometer at location 18 for a hammer excitation at location 19. The same data are plotted on (a) a linear scale and (b) a logarithmic scale. The low amplitude resonance peaks and anti-resonances (frequencies at which the response amplitude is very low) are more easily identified on the logarithmic scale.

boundary conditions. The resonance frequency of a rigid body plate vibration on this soft support adds a low amplitude peak at 22 Hz in the frequency response function of Figure 12.29. Because this frequency is less than 1/5th of the fundamental (lowest) plate frequency, the support does not significantly affect the response of the plate at its natural frequencies. Effectively, no mass, stiffness, or damping is added to the plate by the foam.

The two major peaks in Figure 12.29 correspond to the 1st and 5th modes shapes of Figure 12.28. Because location 18 is at a nodal point for the 2nd, 3rd, and 4th mode shapes, an ideal model would predict that there would be no response at location 18 at these natural frequencies. In the experimental results of Figure 12.28, there are no discernable peaks in the frequency response function at the 2nd and 4th plate natural frequencies, but there is a low amplitude peak at the 3rd plate natural frequency, likely due to the finite size of the accelerometer. If either the response *or* excitation locations are at a nodal point for a mode shape, then this mode will not have a significant contribution to the response. Therefore, excitation and response locations must be carefully chosen to obtain information for all the frequencies and mode shapes of interest.

Theoretically, the frequency response function is a characteristic of the structure under test and does not depend on the type of excitation (impact, swept sine, or random). Therefore, a general discussion of modal analysis techniques will be given, without reference to the specific excitation source or response measurement. However, the quality of measured

FIGURE 12.30 Phase of the frequency response function (FRF) for the plate shown schematically in Figure 12.27, measured with an accelerometer at location 18 for a hammer excitation at location 19. In (a), the nearly vertical lines going from -180° to 180° and back again are extraneous, but often occur in vibration measurements. These extraneous lines are a result of “wrapping” the phase into the interval from -180° to 180° . The phase is replotted in (b) over a range from -185° to 175° to eliminate these extraneous lines, so that the meaningful characteristics of the plot can be more easily identified.

data will depend on the source (instrumented hammer or a shaker) and response measurement (displacement, velocity, or acceleration) device used, so these should be carefully chosen. The quality of the frequency response functions also will depend on the digital analyzer settings (input range, windowing, averaging, etc.) as discussed in Section 12.3.3. Misleading or meaningless data may be obtained if improper settings are used.

The frequency response functions

$$H_{ij}(f) \stackrel{\text{def}}{=} \frac{X_i(f)}{F_j(f)} \quad (12.33)$$

for a set of measurements at N locations can be assembled into a matrix form as

$$\begin{bmatrix} X_1 \\ X_2 \\ \vdots \\ X_N \end{bmatrix} = \begin{bmatrix} H_{11} & H_{12} & \cdots & H_{1N} \\ H_{21} & H_{22} & \cdots & H_{2N} \\ \vdots & \vdots & \ddots & \vdots \\ H_{N1} & H_{N2} & \cdots & H_{NN} \end{bmatrix} \begin{bmatrix} F_1 \\ F_2 \\ \vdots \\ F_N \end{bmatrix} \quad (12.34)$$

FIGURE 12.31 Plots of the (a) real part and (b) imaginary part of the frequency response function (FRF) of Figures 12.29 and 12.30 versus frequency. The Nyquist plot in (c) is a plot of the imaginary part versus the real part of the frequency response function. The curve in plot (b) is repeated as the third curve (at $x = 2$ in) in the waterfall plot of Figure 12.34.

Any one row or column of the matrix contains sufficient information to estimate the natural frequencies, mode shapes, and modal damping coefficients of the structure in the measured frequency range. Additional measurements can be made to increase the confidence level of the data.

Single-input, single-output techniques can be used to obtain the j th row of the matrix by measuring the response at location j (using an accelerometer or other measurement device) for successive hammer impacts at each grid location i , for $i = 1, 2, \dots, N$. If a shaker is used, it is often easier to move the response measurement location than it is to move the shaker excitation location, so SISO measurements can be used to obtain a column of the matrix, that is, measurements for different response locations for one shaker excitation location.

If a number of accelerometers or other measurement devices are available, then multiple measurements can be taken simultaneously for a single excitation. These measurements are referred to as *single-input/multiple-output (SIMO)*. SIMO techniques not only shorten the data acquisition time but also may reduce measurement inconsistencies caused by variations in the structure or environment over time. *Multiple-input/multiple-output (MIMO)* data may result in additional improvements.

For linear systems, the frequency response function matrix is theoretically symmetric (i.e., $H_{ji} = H_{ij}$) due to Maxwell's reciprocity theorem. The theorem states that the response at location i due to an excitation at location j is equal to the response at location j if the same excitation is instead applied at location i . In other words, the frequency response function obtained from a measurement at location A for an excitation at location B would theoretically be identical to the frequency response function obtained from a measurement at location B for an excitation at location A. For example, the frequency response function obtained for an accelerometer measurement at location 19 for a hammer excitation at location 18 would ideally be identical to the frequency response function plotted in Figures 12.29–12.31. Actual experimental measurements may not show exact symmetry if the mass of the accelerometer or stiffness added by a shaker significantly affects the response of the structure. Verification of the symmetry stated by Maxwell's reciprocity theorem can be used to identify measurement errors and nonlinearities in the response.

Some structures also have geometric symmetries that can be exploited either to reduce the measurement data required or to add redundancy to increase the confidence level of the data. However, care must be taken when exploiting structural symmetries, because vibrational mode shapes can be either symmetric or anti-symmetric about lines or planes of geometric symmetry. For example, the rectangular plate geometry in Figure 12.27 is symmetric about the line $x = 0$. As shown in Figure 12.28, the first mode, is symmetric about this line, but the third mode is anti-symmetric about this line.

12.5.1.3 Modal Parameter Estimation Modal parameter estimation is the process of obtaining estimates for natural frequencies, modal damping coefficients, and mode shapes from a set of measured input/output data. Modal parameter extraction is the key to experimental modal analysis. Many modal parameter estimation algorithms have been developed based on different mathematical models for the response of a test structure. Ideally, all methods should produce similar estimates. However, in practice, the estimates may vary due to limitations in the measurement data and the presence of environmental noise. An overview of all methods is beyond the scope of this chapter, so the reader is referred to Piersol and Paez (2010), Ewins (2000), and other texts on modal analysis and vibration testing for additional information.

In this section, basic concepts that can be used for simple modal parameter estimation will first be summarized. These concepts can also be used as a sanity check on the experimental data and on estimates produced by modal analysis software. Most techniques use FRF data for modal parameter estimation, so only such methods will be discussed in this section. Methods also exist that utilize other forms of the experimental data, such as impulse response functions data, obtained by applying a discrete inverse Fourier transform to the frequency response function data. Time domain methods, such as this, are beyond the scope of this chapter.

Single-Mode Analysis Methods Single-degree-of-freedom modal analysis methods estimate the modal parameters of each mode independently. The basic assumption for

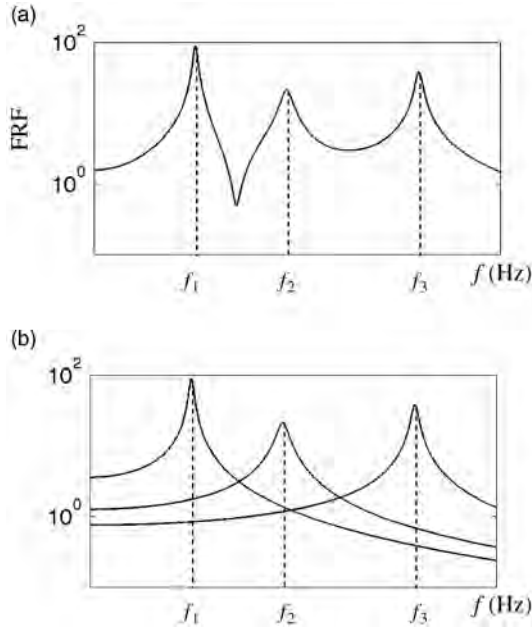

FIGURE 12.32 The frequency response function with three peaks in (a) can be represented in terms of the sum of three single-degree-of-freedom responses, each with a single peak as illustrated in (b). There is an antinode between the first two peaks because the responses corresponding to these peaks are nearly out of phase.

single-degree-of-freedom modal analysis approximations is that in the vicinity of a resonance, the response is due primarily to that single mode. A frequency response function with N peaks can be represented as the summation of N single-degree-of-freedom system peaks as illustrated in Figure 12.32. This also follows from Equation (12.31) or (12.32) which express the structure's response as a sum of contributions from each mode. Therefore, if the peaks of a frequency response function are sufficiently separated, simple single-degree-of-freedom methods described in Section 12.2 can be used to estimate the modal parameters for each mode in the measurement frequency range.

Specifically, if damping is small, then the i th natural frequency, f_i , and nondimensional damping coefficient, ζ_i , can be approximated from the i th peak of the frequency response function by extensions of Equations (12.14) and (12.15). The generalized equations are

$$f_i = \frac{f_{\text{peak}i}}{\sqrt{1 - 2\zeta_i^2}} \sim f_{\text{peak}i} \quad (12.35)$$

and

$$\zeta_i \sim \frac{f_R - f_L}{2f_{\text{peak}i}} \quad (12.36)$$

respectively. In Equations (12.35) and (12.36), $f_{\text{peak}i}$ is the frequency at the i th peak. If damping is small, then the resonance peak ($f_{\text{peak}i}$) occurs at the undamped natural

FIGURE 12.33 Amplitude of the frequency response function (FRF) for the plate shown schematically in Figure 12.27, measured with an accelerometer at location 18 for a hammer excitation at location 19. The measurement was taken using a frequency range from 100 Hz to 200 Hz with 800 lines of resolution.

frequency (f_i). If the amplitude of the peak is denoted by A , then f_L and f_R are the $1/2$ power point frequencies, where the amplitude of the frequency response function is $A/\sqrt{2}$. The i th modal damping coefficient, ζ_i , can be determined from the $1/2$ power point frequencies for the i th peak using Equation (12.36).

The variables used in Equations (12.35) and (12.36) are illustrated on the frequency response function plot shown in Figure 12.33. This frequency response function was obtained for the same excitation and response measurement locations as were used to obtain the plots for Figure 12.29. To increase the resolution of the frequency response function, a reduced measurement frequency range (from 100 Hz to 200 Hz) was used. The amplitude of the frequency response function was plotted for a frequency range 122–128 Hz in Figure 12.33 to show details of the first peak and the definitions of $f_{\text{peak}i}$, f_L , and f_R .

Alternate single-degree-of-freedom techniques exist for approximating the i th natural frequency, f_i , and nondimensional damping coefficient, ζ_i , from plots using the real and/or imaginary parts of the frequency response function. If damping is small, then the natural frequencies and modal damping coefficients predicted by the different techniques will be approximately the same. For example, the natural frequencies, f_i , can be identified by determining the frequencies at which the real part of the frequency response function (Figure 12.31a) is equal to zero. Also for small damping, a peak will occur in the imaginary part of the frequency response function (Figure 12.31b) approximately at the natural frequency, f_i , with an amplitude approximately equal to the magnitude of the i th peak of the frequency response function. If damping is small; however, there may be too few data points to determine the peak amplitudes accurately. For these cases, methods of fitting semicircles to the Nyquist plot (Figure 12.31c) have been developed so that more points around the peak are used in the estimation of f_i and ζ_i . Modal analysis software typically will offer a variety of automatic single- (and multiple-) degree-of-freedom curve fitting methods to estimate the modal analysis parameters. See Piersol and Paez (2010), Ewins (2000), and other texts on modal testing for additional details.

Mode shapes of the structure can be quickly approximated from the imaginary part of frequency response functions measured across the structure. The approximations are most accurate if damping is small and the peaks are well separated. As an illustration, seven frequency response functions were measured along the center ($y = 0$) line of the example

FIGURE 12.34 Waterfall plot of the imaginary part of the frequency response functions (FRFs) for the plate shown schematically in Figure 12.27, measured with an accelerometer at location 18 for seven hammer excitation locations along the $y = 0$ axis. A curve connecting the first major peak (at ~ 125 Hz) of each plot approximates the 1st mode shape, as demonstrated in Figure 12.35a. A curve connecting the second major peak (at ~ 675 Hz) of each plot approximates the 5th mode shape, as demonstrated in Figure 12.35c. Modes 2, 3, and 4 do not significantly contribute to these responses since the accelerometer is at a nodal point for these mode shapes.

plate at locations 15 through 21, with the accelerometer at the center ($x = 0$ and $y = 0$), location 18. These measurements are compared to finite element predictions of the mode shape deflections (given in Figure 12.28), plotted for the line $y = 0$.

The imaginary parts of the seven frequency response functions are displayed in the waterfall plot of Figure 12.34. The imaginary part of the frequency response function at each x location has two major peaks, at the 1st and 5th natural frequencies of the plate. By connecting the 1st major peak in each plot, an approximation to the 1st mode shape can be visualized. This is demonstrated in Figure 12.35a, where the normalized measured peak values are plotted and compared to the centerline deflections of the first mode shape predicted by finite element analysis. The measured mode shape matches the predicted mode shape well except at the center point, where the mass of the accelerometer decreases the response amplitude of the plate.

Similarly, by connecting the 2nd major peak in each plot, the 5th mode shape can be approximated. This is demonstrated in Figure 12.35c, where these measured peak values are compared to the fifth mode shape predicted by finite element analysis. Other mode shapes in the frequency range, for example the 3rd mode shape (Figure 12.35b), cannot be adequately approximated from the measurement data since the accelerometer is at a nodal point for these modes.

Note that, if the response or *excitation* location is at a nodal point for a mode, then information about that mode will be missing from the frequency response function and modal parameter extraction methods may miss this mode. Therefore, the excitation and response

FIGURE 12.35 Profiles of the centerline ($y = 0$) deflections for the 1st, 3rd, and 5th mode shapes given in Figure 12.28. These mode shapes approximate the first three bending modes of an unsupported beam. The markers in (a) and (c) correspond to measured data demonstrating that a mode shape can be approximated by from the peaks of the imaginary part of the frequency response function. The center point has the largest deviation because the mass of the accelerometer affects the response at this location.

locations must be carefully chosen to obtain information about all frequencies of interest. In addition, to obtain more accurate values for the modal parameters at a given natural frequency, the frequency range of the measurement can be centered about this natural frequency.

In some cases, the single-degree-of-freedom modal analysis approximations are not sufficient and therefore multi-degree-of-freedom modal analysis methods must be used to obtain accurate modal parameters. In particular, the single-degree-of-freedom methods assume that the peaks of the frequency response function are well separated. However, if a structure has some closely spaced natural frequencies, this requirement may not be satisfied. In addition, large damping increases the width of the peaks in the frequency response function, which can cause significant peak overlap such that the single-degree-of-freedom methods would not be sufficiently accurate.

Multi-Mode Analysis Methods Multi-degree-of-freedom modal analysis methods estimate the modal parameters of several modes simultaneously. The methods assume that

the measured response data can be approximated by summing contributions from a finite number of modes, as illustrated schematically in Figure 12.32. Equations are used to express this summation in terms of the unknown modal parameters. Estimates for the modal parameters in a specified frequency range are then obtained by curve-fitting these equations to the measurement data.

A wide variety of modal estimation techniques have been developed based on different forms of the equations and different curve fitting techniques. For example, the equations can be expressed in the frequency domain or in the time domain. In addition, the methods can be applied to one set of data (corresponding to one load location and one response location) or to multiple sets of data obtained for a structure, simultaneously. The modal analysis software will determine what methods are available and therefore, specific methods will not be presented here. A full discussion of the different formulations is well beyond the scope of this chapter and therefore only a brief overview is given here. Results from the analysis of one set of experimental measurements will be used to illustrate the process.

At least four quantities need to be specified when using modal analysis software to extract the modal parameters: (1) the frequency range for the analysis, (2) an estimate of the number of resonance frequencies within the specified frequency range, (3) whether to include estimates of residuals from modes outside the analysis frequency range, and (4) the number of response data sets to use (and which ones).

For illustration of the modal parameter estimation process, measurements on the example plate were obtained with an accelerometer at location 10 for roving instrumented hammer excitation at locations 1–35. The resulting frequency response functions are overlaid in Figure 12.36 for the frequency range from 0 Hz to 800 Hz. This frequency range was chosen because it includes frequencies corresponding to the first five modes shown in

FIGURE 12.36 Amplitude of the frequency response functions (FRFs) for the plate shown schematically in Figure 12.27, measured with an accelerometer at location 10 for a hammer excitation at locations 1–35.

Figure 12.28. Because the accelerometer is offset from the centerline ($y = 0$), resonances are observed at the twisting natural frequencies as well as the bending natural frequencies. Recall that the lowest peak at 23 Hz corresponds to the rigid body mode of the plate vibrating on the foam support.

For the plate, identifying the number of resonance peaks in the frequency range of interest is an easy task because there are clearly differentiated peaks at all seven resonance frequencies that fall into this frequency range. With noisy data from a complex structure with many natural frequencies in the frequency range of interest, it may not be easy to determine a precise value to use for the number of degrees of freedom. For example, when two frequencies are close, their peaks may overlap creating one broader peak or there may be extraneous smaller peaks due to noise in the measurement. Also, peaks may be missing from a plot if the response or excitation location is at a nodal point.

Modal indicator functions can be used to help identify the resonance peak locations automatically, by analyzing multiple frequency response functions simultaneously. A plot of the modal indicator function for the plate measurements is shown on the bottom left of Figure 12.37. In the modal indicator function plot, a (gray) dot indicates a potential resonance mode and the plot shows that all seven resonance peaks were identified.

A technique to estimate the modal parameters in the frequency range of interest for the desired number of modes must be chosen. For the plate example, an orthogonal polynomial method accounting for four residuals was used. This method was applied to data from all 35 response locations over the frequency range from 10 Hz to 780 Hz

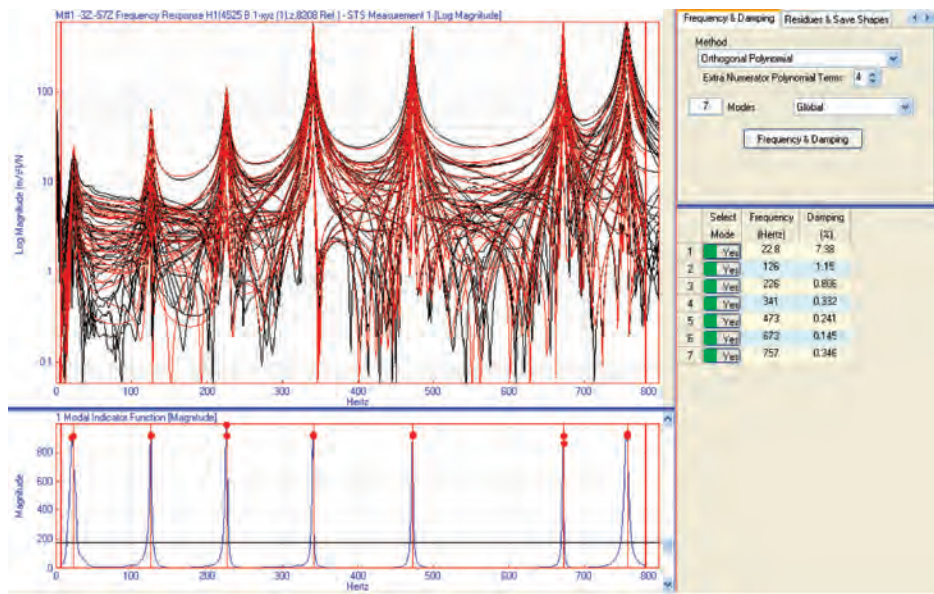

FIGURE 12.37 Modal parameter estimation results for the example plate shown schematically in Figure 12.27. In the upper left, frequency response functions (FRFs) predicted based on the estimated modal parameter are overlaid on the measured frequency response functions for an accelerometer at location 10 for a hammer excitation at locations 1–35. In the lower left, the dots at the peaks of the modal indicator function indicate potential resonance modes. On the upper right, the modal analysis method and parameters are displayed. On the lower right, the predicted modal frequencies and damping are displayed in a table.

FIGURE 12.38 Mode shape estimated from the measured data at 673 Hz. This mode shape looks similar to the mode shape of mode 5 in Figure 12.28 that was predicted at 669 Hz using finite element analysis.

(shown in the top right of Figure 12.37) to estimate the modal parameters for all seven resonance frequencies. Estimated values for the frequency and damping of each of the seven modes for the plate example are shown in the table in the lower right of Figure 12.37.

Mode shapes corresponding to each resonance peak are also obtained from the analysis. The mode shapes can be plotted, as illustrated in Figure 12.38 for one mode or exported to use in verifying/updating a finite element model. The mode shape shown in Figure 12.38 estimated from the measured data at 673 Hz looks similar to the mode shape of mode 5 in Figure 12.28 that was predicted at 669 Hz using finite element analysis. Mode shape animations provide valuable information, for example, critical regions with large displacements or weak regions with large deformations can be identified from the mode shape animations.

To access the accuracy of the modal parameter estimation (i.e., the goodness of fit), frequency response functions predicted based on the estimated parameters can be compared to the measured frequency response functions. For the plate example, these two sets of curves are shown overlaid (in red and black, respectively) in the upper right plot of Figure 12.37. The good agreement is an indication of accurate modal parameter estimation.

The modal assurance criterion (MAC) is another analyzer software function that indicates the accuracy of the estimated modal parameters. The modal assurance criterion uses a correlation coefficient to compare two estimates of a mode shape obtained from experimental data. The modal assurance criterion can also be used to compare mode shapes obtained experimentally to those predicted by finite element analysis. If the two mode shapes are identical, they are perfectly correlated and the modal assurance criterion will equal 1. In practice, values >0.9 are considered good correlations.

Multiple estimates for the modal parameters can be obtained by repeating the modal parameter extraction process using various values for the number of degrees of freedom. Alternatively, the analysis can be repeated for different subsets of the response data or for

FIGURE 12.39 Complexity plot for the mode at 226 Hz, showing that the mode has low complexity (the vectors are nearly collinear).

slightly different frequency ranges that encompass the frequencies of interest. This redundant data can be used to identify modes that are consistently present for most or all choices of analysis parameters and data sets. The consistently determined modes are more likely to be genuine modes rather than artifacts of the analysis method. These modes are called “stable” and stability diagrams can be used to visualize the results of these multiple analyses and identify the genuine resonance frequencies.

A plot of the modal complexity (defined in Section 12.5.1.1) for the mode at ~ 226 Hz is shown in Figure 12.39. Each vector displays the amplitude and phase of one location (1–35) on the example plate of Figure 12.27. If the vectors are collinear, then the modal complexity is zero and the mode will vibrate as a standing wave. Damping is low in the steel plate and nonproportional damping is not present, so the vectors are nearly collinear and the modal complexity is low.

12.5.2 Operational Data Analysis

For the discussion of the modal analysis in Section 12.5.1, it was assumed that the measured response was generated by a single known applied excitation. Data that are gathered for unknown excitations, typically while the structure is in operation, are called *operational data*. Operational data may be the only option if the structure is too large or fragile to excite, or if a machine cannot be completely shut down for vibration testing. Operational loads only excite the modes of interest and therefore operational data may more quickly provide clues needed to solve existing vibration problems. In addition, operational data measurement requires less setup time, because the need for external excitation is eliminated. However, because the excitation is not measured, frequency response functions cannot be obtained explicitly from operational data.

12.5.2.1 Operational Deflection Shapes An *operational deflection shape* is typically defined as the shape of the deflection of a structure when vibrating at a single frequency. For example, an operational deflection shape can be obtained from measurements taken at various points on the structure, when the structure is excited by an unbalanced rotating shaft. Specifically, the shape is obtained from the amplitudes and phases of the peaks in the response data at the shaft rotational frequency. In order to obtain phase data, either all the measurement must be obtained simultaneously, or a reference measurement must be obtained at a fixed location for each additional frequency response function measurement. Operational deflection shapes may be useful in directly determining whether large deflections exist at critical locations of the structure during operation.

Note that operational shapes are different from mode shapes, even though the process of obtaining and displaying the shapes may be similar. In particular, a mode shape is an inherent characteristic of the structure associated with a natural frequency and independent of the applied force, whereas an operational deflection shape can be obtained for any frequency of excitation and depends on the location(s), direction(s), and amplitude(s) of the excitation. When the excitation frequency is near a natural frequency of the structure, then the operation deflection shape may be similar to the mode shape corresponding to that natural frequency.

12.5.2.2 Operational Modal Analysis *Operational modal analysis* (also called *output-only modal analysis* or *ambient modal analysis*) is the process of estimating modal parameters using operational response data only. Operational modal analysis techniques typically assume that the excitation resulting from operation is stationary white noise. Operational excitation that deviates from random, such as excitation due to a rotating shaft, will cause inaccuracies in modal parameter estimates. However, additional techniques have been developed that can be applied to operational data when the excitation also includes harmonic components (Mohanty and Rixen, 2005). These techniques either attempt to filter out the response due to the harmonic excitation or account for this extra response in the analysis. Curve fitting is still required over a modified set of frequency response functions.

Operational modal analysis can be used to estimate the natural frequencies, modal damping, and mode shapes of a structure. However, the modal mass cannot be estimated from operational data, so that frequency response functions cannot be obtained. However, techniques for estimating the modal mass have been developed when data are available from additional experiments with mass added to the structure.

Impact tests can also be performed on a machine that cannot be turned off, such as a very large power generation turbine. Measurements obtained by impacting a running machine with an instrumented hammer include responses to the operational loads superimposed onto the response to the hammer impact. Recordings of the machine's response excited by operational loads alone can be used to "negative average" out the operational responses. In this way the responses due solely to the impact excitation can be approximated. Modal analysis techniques described in Section 12.5.1 can be applied to the frequency response functions thus obtained to estimate the modal parameters.

12.6 APPLICATIONS OF VIBRATION MEASUREMENT

The basic vibration and measurement techniques described in the previous sections can be applied to a broad range of situations, whenever the dynamic response of a system is

important. Applications can be roughly separated into two categories: (1) structural system characterization and (2) machine condition monitoring.

12.6.1 Structural System Characterization

The dynamic response of a structural system or component can either be measured for a specific set of operating conditions or more generally characterized, so that the response of the structure or component to other excitations can be predicted. For the former, the vibration is typically excited by moving elements, for example, rotating shafts, either within or attached to the structure. For the latter, a known force generated by an external source, for example, a shaker, is generally used to excite the structure.

12.6.1.1 Operational Measurements Measurements of a structure's dynamic response during operation can provide a wealth of valuable information. By measuring the motion at critical points on the structure, "sweet spots," that is, speeds that minimize the amplitudes of undesirable vibrations, may be determined. Alternatively, the vibration response at many points on a structure can be measured under constant operating conditions to obtain operational deflection shapes. In this case, typically two accelerometers are used a reference accelerometer that remains at a fixed location and a second roving accelerometer, used to obtain the response at a number of locations on the structure. Operational deflection shapes can be used to identify locations where the structural deformations are largest so that these areas may be stiffened to improve the structure's performance. Alternatively, operational responses may be used to identify resonance conditions that result in high amplitude vibrations at a particular operating frequency, so this frequency can be avoided.

Noise generated by structural vibrations may be a critical factor in some applications. For example, to increase passenger comfort in automobiles, significant effort is put into reducing noise generated by road or engine induced vibrations. Therefore, in the automotive industry, vibration studies are grouped under the broader category of noise, vibration, and harshness (NVH). Vibration analysis tools and standards have been developed around the specific requirements of noise and vibration testing.

Vibrations cause oscillating stresses that can eventually lead to fatigue failure. Durability and fatigue tests can be used to determine the fatigue life of a structure or component. During testing, components are subject to dynamic excitations, either generated in situ by operating conditions or generated by an independent test structure. Accumulated damage and fatigue failures are observed over the duration of the test. Accelerated life testing can be used to reduce the test duration by increasing the test excitation amplitudes. A variety of algorithms exist to compress lifetime loading data into representative short duration loading. Component durability and lifespan are most accurately predicted when the loading conditions during the test closely reproduce the operational loading conditions. Characterizing the dynamic loads a component experiences in operation is critical, not only for durability and fatigue testing but also many other vibrations tests as well.

12.6.1.2 Modal Analysis Measurements Determination of the dynamics characteristics of a structural system or component provides additional information that can be used to investigate design or operational changes that may improve the system's performance. Modal analysis measurements of the structure's natural frequencies and mode shapes are needed to predict and understand its response to more general loadings. For example,

knowledge of the natural frequencies and mode shapes of a structure can be used to tune operating conditions to either enhance or reduce the structure's vibration amplitude.

Models are often used to investigate the effects of modifications of the structure on its dynamic response. Models are especially important when the operation loads cannot be applied directly to test the structure, for example, earthquake loads on a building or bridge and launch loads on a spacecraft or its payload. Traditionally, finite element models have been used. Modal analysis data can be used to validate and refine a finite element model and the refined model can be used to further investigate the structure dynamic response. More recently, structural dynamic modification methods have been incorporated in the modal analysis software that directly use the modal analysis or frequency response function data to predict the effect of design changes on the structural response.

When creating finite element models, many approximation are typically made and therefore, the response of the finite element model will not exactly predict the actual response of the structure. Joints, in particular, are difficult to model precisely. For example, a bearing, connecting a shaft to the main structure, may be modeled with simple linear spring and damper elements that approximate the stiffness and damping of the bearings. Modal analysis data can be used to validate a finite element model by comparing the predicted and measured frequencies and mode shapes. Measures, such as the modal correlation coefficient (MAC), are typically used to quantify the agreement. The modal correlation coefficient has a value between 0 and 1, with 1 implying exact correlation. If there are significant discrepancies between the predicted and measured frequencies and mode shapes, then the finite element model can be refined based on insight gained from the correlation analysis.

Once a sufficiently accurate finite element model has been established, then this model can be used for further predictions. The finite element model can be used to predict the response of the structure to additional loading scenarios that may occur during operation. If the structure is a component of a larger structure, then either a complete or reduced finite element model of the component may be added to a finite element model of the entire structure. This combined model can be used to determine the component's in situ response or its affect on the rest of the structure. If predicted response amplitudes are outside the design specifications for a structure, then finite element models can be used to investigate the effects of design modifications on its response to expected loading scenarios. This type of investigation can be used to identify designs with improved dynamic characteristics that satisfy the design criteria.

12.6.2 Machine Condition Monitoring

Measurements of the vibrations of a machine during operation can often be used to detect defects in machine components and monitor their severity. Often vibration measurements can be used to identify defects in their early stages, long before the defects can be sensed by other methods or before they have a significant effect on the machine's performance. This is true, even though the amplitudes of vibration initially caused by a defect may be orders of magnitude smaller than the amplitudes of other machine vibrations. The advantage of vibration measurement is that these small amplitude vibrations often generate a peak or set of peaks in the vibration spectrum of the machine that can be used to identify the defect. Displaying the vibration spectrum on a logarithmic or dB scale makes it possible to observe these lower amplitude peaks.

Vibrations induced by different components of a machine can be distinguished by the specific characteristics they create in frequency domain representations of the machine's vibrations during operation. For example, information about the peak frequencies and existence of side lobes or harmonics can help differentiate sources of the vibration. In addition, observations of changes in the vibration spectral response with operational speed may also help to distinguish between contributions from difference components.

Vibration measurements can be analyzed to identify a defective component causing a machine error, such as excessive cutter marks in machining, so that steps can be taken to reduce the error. Alternatively, vibration measurements can be used to periodically or continuously monitor a machine so that failing components can be identified and replaced efficiently, for example, before catastrophic failure occurs.

For machine monitoring, peaks in the vibration spectrum corresponding to the component(s) of interest should first be identified. Then, baseline measurements for the machine operating in good condition need to be established. These baseline measurements will depend on transducer type and location, machine operating speed, and any loading on the machine. Therefore, successive measurements need to be made under similar conditions when monitoring the machine performance. As a machine component deteriorates, the amplitude of the peaks in the vibration spectrum corresponding to this component will increase. Criteria for predicting component failure are developed based on accumulated vibration measurements. These criteria are usually defined as a limit on the maximum measured vibration amplitude at a frequency or over a range of frequencies corresponding to the component of interest. If this limit is exceeded, then the component is replaced.

A brief overview of the characteristics of a few common machine components and faults will be discussed in this section to demonstrate how the component geometry and type of defect determine the frequencies of the resulting vibration. Table 12.1 gives a list of a broader range of machine faults and their vibration characteristics. While a complete listing of all potential faults is not possible, additional information about fault detection and condition monitoring can be found in references on machine monitoring such as Rao (2000), Scheffer and Girdhar (2004), and Wowk (1991).

12.6.2.1 Unbalanced, Misaligned, or Bent Shaft No component is perfect, so any rotating shaft will produce some machine vibration. An unbalanced, misaligned, or bent shaft will produce vibration at the shaft rotational frequency, f_{shaft} (in Hz), and/or at its harmonics.

TABLE 12.1 Common Machine Faults and Their Typical Dominant Frequencies of Vibration

Nature of Fault	Frequencies of Dominant Vibration
Unbalanced shaft	f_{shaft}
Misaligned or bent shaft	f_{shaft} , $2f_{\text{shaft}}$, possibly harmonics
Damaged rolling element bearing	See Table 6.2
Damaged or worn gears	$N_{\text{teeth}} \times f_{\text{shaft}}$, N_{teeth} = number of teeth
Faulty belt drive	f_{belt} and harmonics (belt rotation frequency)
Oil-film whirl in journal bearings	$0.42f_{\text{shaft}}$ to $0.48f_{\text{shaft}}$
Mechanical looseness/rubbing	f_{shaft} , plus harmonics and possibly subharmonics

Unbalance of a shaft assembly (shaft with attached components) is the easiest machine defect to understand. For example, an unbalance is created when one blade of a fan or turbine is damaged, so that the blade mass is reduced or its center of mass is shifted. The magnitude of the unbalance is equal to me , where m is the mass of the shaft assembly and e is the eccentricity. The eccentricity is defined as the radial distance between the center of rotation and the center of mass of the shaft assembly. When the shaft is rotating with angular speed $\omega_{\text{shaft}} = 2\pi f_{\text{shaft}}$ (rad/s), this unbalance produces a centrifugal force $F_{\text{un}} = mew_{\text{shaft}}^2$ radially outward and rotating with the shaft. The component of this force in a direction perpendicular to the shaft axis will vary harmonically in time with a frequency equal to the shaft rotational frequency. The machine vibrations generated by this force will have a dominant frequency at the shaft rotation frequency, f_{shaft} .

The need to balance shaft assemblies increases as the rotational speed increases, because the unbalance force is proportional to the square of the shaft rotational speed. Both static and dynamic balancing may be needed to reduce vibrations to acceptable levels. Static balancing reduces the unbalance force by adding a small mass \bar{m} at a radius \bar{e} radially opposed to the unbalance, such that $\bar{m}\bar{e} \approx me$. Alternatively, material can be removed from a radial position at the same angle as the unbalance, for example, by drilling a small hole. Dynamic balancing reduces the moment that exists when the principal axis of inertia of the shaft assembly is not parallel to the axis of rotation. Dynamic balancing can be accomplished by adding two masses in two different planes perpendicular to the axis of rotation so as to align the principal axis of inertia with the axis of rotation. For example, to dynamically balance an automobile tire, a weight is added both to the inside and outside of the rim.

Vibrations caused by misaligned or bent shafts are often dominated by a frequency at one or two times the shaft rotation frequency (f_{shaft} or $2f_{\text{shaft}}$) though some contributions higher harmonics may also be evident. Comparisons of vibration amplitude and phase in the radial and axial directions measured at different locations may be used to distinguish between these sources of vibration. See Scheffer and Girdhar (2004) or Rao (2000) for more details.

12.6.2.2 Rolling-Element Bearing Fault Characteristics Rolling-element bearing failure is a common problem in machinery. The dominant frequency of the resulting vibration depends on the rotational speed, the bearing geometry, and the type of defect. Defects can occur on the inner or outer race, on the balls themselves, and/or on the cage that surrounds the balls to keep them equally spaced. Equations for the frequencies of common rolling-element bearing faults are given in Table 12.2 in terms of the bearing geometry and number of rolling elements, N_{ball} .

If the cage is damaged, then vibration occurs at the frequency of the cage rotation speed, also called the fundamental train frequency. This frequency is approximately equal to half the shaft rotation frequency, $\cong (1/2)f_{\text{shaft}}$, because the cage is typically rotating between a fixed outer race and an inner race rotating at the shaft frequency. A defect on the inner or outer race generates vibration at the ball pass frequency, approximately N_{ball} times the fundamental train frequency, $\cong (N_{\text{ball}}/2)f_{\text{shaft}}$. A defect on a ball, will generate vibration at the ball spin frequency, $\cong (d_{\text{ball}}/2d_{\text{pitch}})f_{\text{shaft}}$, which is a fraction of the fundamental train frequency.

The characteristics of the vibration spectrum produced by a bearing change qualitatively as the bearing defects increase (Scheffer and Girdhar, 2004). For example, the bearing frequencies may appear with sideband frequencies, modulated with the shaft frequency (bearing defect frequency $\pm f_{\text{shaft}}$) or with natural frequencies of the bearing. As

TABLE 12.2 Equations for the Characteristic Bearing Defect Frequencies in Terms of the Shaft Rotation Frequency f_{shaft} , and the Bearing Geometry Where N_{ball} is the Number of Balls, d_{ball} the Ball Diameter, d_{pitch} the Pitch Diameter (Diameter of the Bearing Measured from the Center of Two Opposing Balls), and ψ , the Contact Angle

Defect Location	Dominant Frequency
Cage	$f_C = \frac{f_{\text{shaft}}}{2} \left(1 - \frac{d_{\text{ball}}}{d_{\text{pitch}}} \cos \phi \right)$
Ball	$f_B = \frac{f_{\text{shaft}}}{2} \frac{d_{\text{ball}}}{d_{\text{pitch}}} \left(1 - \left(\frac{d_{\text{ball}}}{d_{\text{pitch}}} \right)^2 \cos \psi \right)$
Outer race	$f_{\text{OR}} = N_{\text{ball}} f_C$
Inner race	$f_{\text{IR}} = N_{\text{ball}} (f_{\text{shaft}} - f_C)$

The rotation rate of the cage, f_C , is called the fundamental train frequency.

the bearing deteriorates further, the peaks may broaden as they increase in amplitude, making it more difficult to identify specific frequency contributions.

12.6.3 Other Machine Fault Characteristics

As illustrated for rolling-element bearing defects, the frequencies of vibration generated by a component defect depend on the speed of operation and geometry of the component. A partial list of frequencies generated by other component defects and machine faults is given in Table 12.1. Such a table should be used with caution, however, because vibration characteristics are machine dependent and can be quite complex. Additional references (e.g., Randall, 2011; Piesol and Paez, 2010; Scheffer and Girdhar, 2004; Rao 2000; Goldman, 1999; Wowk, 1991) can be consulted for additional techniques to identify and analyze machine fault characteristics.

NOMENCLATURE

a	Acceleration (m/s^2)
A_i	Amplitude factor for the i th mode shape (m)
$A(f)$	(Discrete) Fourier transform of $\ddot{x}(t)$ (m/s^2)
c	Viscous damping coefficient (N/s/m)
c_i	i th viscous damping coefficient for a multi-degree-of-freedom system (N/s/m)
C	Viscous damping matrix for a multi-degree-of-freedom system (N/s/m)
d_{ball}	Ball diameter of a bearing
d_{pitch}	Pitch diameter of a bearing
e	Eccentricity (m)
f	Frequency (Hz)

Δf	Frequency resolution (Hz)
f_{belt}	Belt frequency (Hz)
f_{B}	Ball rotation frequency of a ball bearing (Hz)
f_{c}	Cage frequency of a ball bearing (Hz)
f_{d}	Frequency of damped vibration for a one-degree-of-freedom system (Hz)
f_i	i th natural frequency (Hz)
$f_{\text{IR}}, f_{\text{OR}}$	Inner race and outer race frequencies of a ball bearing (Hz)
$f_{\text{L}}, f_{\text{R}}$	Frequencies of the left and right half power points (Hz)
f_{max}	Maximum frequency for the discrete Fourier transform
$f_{\text{n}} = \frac{\omega_{\text{n}}}{2\pi}$	Natural frequency for a one-degree-of-freedom system (Hz)
f_{peak}	Frequency at a peak of a response versus frequency plot (Hz)
$f_{\text{peak}i}$	Frequency at the i th peak of a response versus frequency plot (Hz)
f_{shaft}	Frequency of rotation of a shaft (Hz)
$F(t)$	Force applied to a one-degree-of-freedom system (N)
$F(f)$	(Discrete) Fourier transform of $F(t)$ (N)
$\mathbf{F}(t)$	Force vector for a multi-degree-of-freedom system (N)
$F_i(f)$	(Discrete) Fourier transform of $F_i(t)$ (N)
F_0	Amplitude of a harmonic force applied to a one-degree-of-freedom system (N)
f_{d}	Viscous damping force for a one-degree-of-freedom system (N)
f_{s}	Spring force (N)
F_{un}	Force produced by an unbalance (N)
$H(f)$	Frequency response function (m/N)
$H_{ij}(f)$	Frequency response function for the response at location i due to an excitation at location j
i	Integer index
j	Integer index
j	$\sqrt{-1}$ in Section 12.4.2.1
k	Spring stiffness (N/m)
k_i	i th spring stiffness for a multi-degree-of-freedom system (N/m)
\mathbf{K}	Stiffness matrix for a multi-degree-of-freedom system (N/m)
m	Mass (kg)
m_i	i th mass for a multi-degree-of-freedom system (kg)
me	unbalance magnitude (kg/m)
\mathbf{M}	Mass matrix for a multi-degree-of-freedom system (kg)
n	Positive integer
N	Positive integer: number of degrees of freedom in Section 12.3.2. number of samples in Section 12.3.3
N_{ball}	Integer number of balls in a bearing
N_{teeth}	Integer number of teeth of a gear

Q	Quality factor
t	Time (s)
Δt	Time between samples for a constant sampling rate (s)
t_i	Time at the i th peak of the response for a one-degree-of-freedom system (s)
t_{\max}	Maximum time for sampled data (s)
T_d	Period of vibration for a one-degree-of-freedom system (s)
$T_i(t)$	Time dependence for the i th mode shape
v	Velocity (m/s)
v_0	Initial velocity for a one-degree-of-freedom system (m/s)
\mathbf{v}_0	Initial velocity vector for a multi-degree-of-freedom system (m/s)
$V(f)$	(Discrete) Fourier transform of $\dot{x}(t)$ (m/s)
$w(x, y, t)$	Transverse displacement of a plate (m)
x	Displacement (m)
(x, y, z)	Position vector in rectangular Cartesian coordinates (m)
x_i	Displacement of the i th degree of freedom (m)
x_0	Initial displacement for a one-degree-of-freedom system (m)
x_s	Extension of a spring (m)
$\dot{x} = \frac{dx}{dt}$	Velocity (m/s)
$\ddot{x} = \frac{d^2x}{dt^2}$	Acceleration (m/s ²)
\mathbf{x}	Displacement vector for a multi-degree-of-freedom system (m)
\mathbf{x}_0	Initial displacement vector for a multi-degree-of-freedom system (m)
$\dot{\mathbf{x}}$	Velocity vector for a multi-degree-of-freedom system (m/s)
$\ddot{\mathbf{x}}$	Acceleration vector for a multi-degree-of-freedom system (m/s ²)
X	Harmonic response amplitude for a one-degree-of-freedom system (m)
$X(f)$	(Discrete) Fourier transform of $x(t)$ (m)
$X_i(f)$	(Discrete) Fourier transform of $x_i(t)$ (m)
X_R	Reference used for dB values (m)
δ	Logarithmic decrement
ζ	Nondimensional damping ratio for a one-degree-of-freedom system
ζ_i	i th nondimensional damping ratio
θ_i	i th phase shift (rad)
θ_{err}	Angle misalignment of a measurement transducer
ϕ	Phase (rad)
$\phi_i(f)$	Phase of the (discrete) Fourier transform $X_i(f)$
$\varphi^{(i)}, \boldsymbol{\varphi}^{(i)}$	i th mode shape
ψ	Contact angle in a ball bearing
ω_d	Frequency of damped vibration for a one-degree-of-freedom system (rad/s)
ω_{di}	i th frequency of damped vibration (rad/s)

ω_i	i th natural frequency (rad/s)
ω_n	Natural frequency for a one-degree-of-freedom system (rad/s)
ω_{shaft}	Frequency of rotation of a shaft (rad/s)
AC	Alternating current
AD	Analog to digital
DC	Direct current
DFT	Discrete Fourier transform
FFT	Fast Fourier transform
FRF	Frequency response function
IEPE	Internal electronic piezoelectric
LVDT	Linear variable differential transformer
MAC	Modal assurance criterion
MIMO	Multiple input/multiple output
NVH	Noise, vibration, and harshness
SIMO	Single input/multiple output
SISO	Single input/single output
PE	Piezoelectric
$Re[]$	Real part of a complex number

13.1 INTRODUCTION

As noise continues to grow as a significant design concern, the importance of proper measurement techniques is becoming more crucial. The focus of this chapter is to provide a working knowledge of the basic acoustical or sound measurements and measurement techniques for the practicing engineer. The chapter will also provide a broad overview and introduction to more advanced acoustical measurement methods. There are several published documents including tutorials on the proper methods for measuring sound. This chapter is heavily referenced pointing the reader to these excellent sources of information.

The chapter first provides a discussion of the acoustical quantities that are typically measured. Definitions of the terms, measurement units, and weighting filters are presented. The hardware used to make the measurements is then explained along with principles of calibration and data acquisition. Detailed steps to the measurement of sound pressure are then given. Acoustical measurements important in the areas of sound isolation and room acoustics are then discussed. We then move to measurements of sound intensity and sound power, which are the most advanced measures of a sound field. The chapter is then concluded with a discussion of sound exposure and noise dosage measurements.

13.1.1 Acoustical Measurement Standards

An important source of additional information beyond this chapter is the national and international standards that cover acoustical instruments, measurements, and calculations.

These standards are written by committees of experts on particular topics and represent recommended best practices. Some of the information in this chapter is drawn directly from these standards.

Three organizations that have developed standards related to acoustics instrumentation and measurements are the International Electrotechnical Commission (IEC), the International Organization for Standardization (ISO), and the American National Standards Institute (ANSI). Because these organizations deal with standardization well beyond the scope of acoustics, the specific technical committees that treat acoustical measurement standards are provided. Subcommittees SC1 and SC2 within ISO TC 43 deal with noise and building acoustics, respectively. IEC TC 29 treats the development of instrumentation under the topic of electroacoustics. ANSI Accredited Standards Committees (ASC) S1 (Acoustics) and S12 (Noise) deal specifically with acoustical hardware and measurements. ISO TC 108 and ANSI ASC S2 both treat mechanical vibration and shock, topics related to acoustical measurements. Numerous other organizations related to standardization and regulation of acoustic testing and the development of test codes are provided in Lang and Nobile (1998).

Standards generally begin with an introduction, explanation of the scope, and, in some cases, areas of application. The introductory sections are then usually followed by a list of normative references and definitions that aid in understanding the standardized hardware specifications or measurement procedures. Some example standards from ISO, IEC, and ANSI are described in Table 13.1.

TABLE 13.1 Various Standards Related to Acoustical Measurements

Standard Number	Standard Name	Description
ANSI S1.1-1994 (R2004)	Acoustical Terminology	Provides definitions for a wide variety of terms, abbreviations, and symbols used in acoustics
ANSI S12.19— 1996 (R2006)	Measurement of Occupational Noise Exposure	Presents methods that can be used to measure a person's noise exposure in the work place
ANSI S12.54— 1999/ISO 3744—1994 (R2004)	Acoustics—Determination of sound power levels of noise sources using sound pres- sure—Engineering Method in an Essentially Free Field over a Reflecting Plane	Method for measuring sound pressure levels on a measurement surface enveloping a noise source in order to calculate sound power level produced by the source
ISO 2923:1996	Acoustics—Measurement of noise on board vessels	Techniques and conditions for measurement of noise on board vessels. Results may be used to compare various vessels, and for example, assess audibility of acoustical alarms
ISO 9295:1988	Measurement of high- frequency noise emitted by computer and business equipment	Details four methods for determining sound power levels in the 11.2–22.4 kHz range
IEC 61260 (1995-2008)	Electroacoustics—Octave- band and fractional-octave- band filters	Performance requirements and methods for various implementations of bandpass filters that comprise a filter set or spectrum analyzer
IEC 61672-1 (2002-2005)	Electroacoustics—Sound Level Meters—Part 1: Specifications	Performance specifications for three kinds of sound measuring instruments

13.2 FUNDAMENTAL MEASURES

This section outlines some of the fundamental measures commonly encountered in acoustical measurements. First, the three fundamental measures of sound pressure, sound power, and sound intensity will be discussed. These three terms are discussed in most texts on acoustics (see Hunt, 1992; Pierce, 1989; Beranek, 1993; Kinsler et al., 2000). We will then discuss the decibel scale, frequency weightings, and octave frequency bands. It is crucial that the reader understand these basic fundamental measures before progressing to advanced topics in acoustical measurements.

13.2.1 Sound Pressure

Sound pressure, or acoustic pressure, refers to the small deviations of pressure from the ambient generated by sound waves. To better understand this wave phenomenon, take, for example, a U-shaped tuning fork as shown in Figure 13.1a. The tuning fork is a device used to create a tone at a specific frequency that can then be used to tune various musical instruments. The tone is created by striking one of the tines with a hammer causing the forks to freely vibrate as shown in Figure 13.1b. As the tine moves outward from equilibrium, the air adjacent to the outward moving tine is compressed and accelerated outward. As the air adjacent to the tine is pushed outward, the pressure at that location increases slightly above atmospheric pressure as the density of the air molecules also increases. This local increase in air density is commonly called a condensation. After the tine passes back through equilibrium and displaces in the opposite direction, the adjacent air molecules spread out leaving a pressure slightly lower than atmospheric pressure along with a decreased density of air molecules. This local decrease in air density is commonly

FIGURE 13.1 Illustration of the vibration of a tuning fork, (a) static position, (b) vibrating motion showing tine motion.

TABLE 13.2 Relationship of Sound Pressure and Sound Pressure Level for Various Examples

Sound Source	Sound Pressure (Pa)	Sound Pressure Level (L_p) (dB re 20 μ Pa)
Krakatoa (at 160 km)	20,000	180
M1 Garand being fired	12,000	176
Jet engine (at 30 m)	630	150
Threshold of pain	100	130
Hearing damage (short-term exposure)	20	120
Jet (at 100 m)	6–200	110–140
Jack hammer (at 1 m)	2	100
Hearing damage (8-h exposure)	0.5	88
Major road (at 10 m)	0.2–0.6	80–90
Passenger car (at 10 m)	0.02–0.2	60–80
Normal talking (at 1 m)	0.002–0.02	40–60
Very calm room	0.0002–0.0006	20–30

called a rarefaction. These deviations above and below atmospheric pressure are sound pressure fluctuations.

Everyday sound pressures may take on a very wide range of values (see Table 13.2). For example, the sound pressure from a typical jet engine is on the order of 630 Pa while the threshold of hearing is approximately 2×10^{-5} Pa at 1 kHz. Therefore, the term sound pressure level (L_p) or also referred to as SPL as defined by Equation (13.1) has been developed:

$$L_p = 20 \log \left(\frac{p}{p_{\text{ref}}} \right) \quad (13.1)$$

where p is the measured rms sound pressure, p_{ref} is the reference rms sound pressure usually taken as 20 μ Pa (2×10^{-5} Pa), which is the threshold of hearing for an undamaged ear and also corresponds closely with the reference power of 1×10^{-12} W as shown in a following section. Table 13.2 shows the relationship between sound pressure and sound pressure level for several acoustic environments. Sound pressure level measurements are the most common acoustical measurement made. The measurement can be made with a simple low-cost microphone or an expensive, comprehensive sound level meter. Procedures and methods for sound pressure measurements are discussed in Section 13.4.

13.2.2 Sound Power

Sound power is the term that describes the rate at which sound energy is radiated per unit time. The units of sound power are Joules/second or Watts. As an example of sound power, assume that there is a small spherical sound source. The sound power is a measure of the total amount of sound that the source can produce. Assuming that the source has constant sound power output and that unobstructed radiation occurs, the sound power output of the source is the same at any radius away from the source. A balloon analogy is often used to describe sound power. A balloon has the same amount of material

TABLE 13.3 Relationship Between Sound Power and Sound Power Level for Various Examples

Sound Source	Sound Power (W)	Sound Power Level (L_w) (dB re 1×10^{-12} W)
Saturn rocket	25–40 million	195
Rocket engine	1,000,000	180
Turbojet engine	10,000	160
Siren	1,000	150
Heavy truck engine/rock concert	100	140
75-Piece orchestra pipe organ	10	130
Piano/small aircraft/Jackhammer	1	120
Excavator/trumpet	0.3	115
Chain saw/blaring radio	0.1	110
Helicopter	0.01	100
Auto on highway/loud speech/shouting	0.001	90
Normal speech	1×10^{-5}	70
Refrigerator	1×10^{-7}	50
Auditory threshold	1×10^{-12}	0

surrounding the internal gas whether the balloon is partially or fully inflated. This is the same concept in that the sound power radiating from the source is constant, and is independent of distance from the source.

The range of sound powers encountered can be extremely large. For example, the sound power of a large rocket engine is on the order of 1,000,000 W, whereas the sound power of a soft whisper is approximately 0.000000001 W. Because of this large range in power values, a logarithmic scale known as the decibel scale is widely used in acoustic applications.

When sound power, W , is expressed in terms of decibels, it is called a sound power level, L_w , and is computed as

$$L_w = 10 \log \left(\frac{W}{W_{\text{ref}}} \right) \quad (13.2)$$

where W_{ref} is the standard reference power usually taken to be 1×10^{-12} W or 1 pW. Table 13.3 provides an example of the range of sound power and sound power levels.

Sound power may be measured in various ways depending on the environment in which the measurements are to be made (free-field, diffuse field, hemi anechoic, etc.). The two basic techniques of measuring sound power consist of using an array of pressure microphones placed around the source or using a sound intensity probe. Other comparative techniques also exist where measurements are compared with calibrated sources. The international standards that outline the processes for measuring sound power are ISO 3741, 3742, 3744, and 3745.

13.2.3 Sound Intensity

Sound intensity is defined as the amount of sound power per unit area of a given wave front. Relating this back to the balloon analogy, sound intensity would be a measure of

the balloon wall thickness at a certain location. The thickness of the balloon material will depend on how much the balloon is inflated, with the thickness decreasing as the balloon is further inflated. By analogy, sound intensity decreases as the distance from the source is increased, and vice versa. As previously mentioned, sound power and sound intensity are related by an area. For a spherical wave front, the relationship is expressed as

$$I = \frac{W}{4\pi r^2} \quad (13.3)$$

where I represents sound intensity, $4\pi r^2$ is the surface area of the sphere, and r is the radius of the sphere. From Equation (13.3), it should be noted that the decay of the sound intensity is directly proportional to the square of the radius of the sphere. This relationship is often referred to as the inverse square law.

Sound intensity values are directly related to sound power values by an area term and hence also have a very wide range of values. Again, it is therefore common to express the sound intensity using a decibel scale referred to as a sound intensity level. Sound intensity level is expressed as shown in Equation (13.4), where L_I is the sound intensity level, I is the measured intensity at some distance from the source, and I_{ref} is the reference sound intensity usually taken as $1 \times 10^{-12} \text{ W/m}^2$:

$$L_I = 10 \log \left(\frac{I}{I_{\text{ref}}} \right) \quad (13.4)$$

Sound intensity is the time-averaged product of the pressure and particle velocity. The pressure can simply be measured with a standard microphone. However, the particle velocity is somewhat more difficult to measure. One common method of measurement is to place two similar microphones a known distance apart. By doing this, the pressure gradient can be measured. Then using Euler's equation, the pressure gradient can be used to compute the particle velocity. This topic is expounded upon in the section of this chapter on sound intensity.

13.2.4 Decibel Scale

The decibel scale is a unitless logarithmic scale that is widely used in many fields of science including acoustics, electronics, signals, and communication. The decibel scale is used to describe a ratio of values, which among others may be sound power, sound intensity, sound pressure, and voltage. One main advantage of a logarithmic scale is that a very wide range of values can be reduced to a much smaller range, which provides the user with a better feel for the particular values of interest.

In the field of acoustics, the decibel (dB), which is 1/10 of a bel, is almost exclusively used. Decibels are used over bels to simply increase the sensitivity of the values, similar to using inches instead of feet or centimeters instead of meters when a pencil-sized object is measured. The term bel (in honor of Alexander Graham Bell) refers to the basic logarithm of the ratio of two values. The definition of the base 10 logarithm is shown in Equation (13.5)

$$10^{\log p} = p \quad (13.5)$$

The log of p is the value to which 10 must be raised in order to obtain the value p . The decibel equation can then be expressed as shown in Equation (13.6)

$$N(\text{dB}) = 10 \log \frac{A}{A_{\text{ref}}} \quad (13.6)$$

Two examples using the decibel scale are now provided to better illustrate the significance of the relationship.

EXAMPLE 13.1: *An increase in sound power of a ratio of 2:1 results in what gain in dB?*

Solution

$$N(\text{dB}) = 10 \log 2/1 = 10 \times (0.3010) = 3.01 \text{ dB}$$

Therefore, a doubling of the sound power results in an increase of approximately 3 dB.

EXAMPLE 13.2: *The noise level at a factory property line caused by 12 identical air compressors running simultaneously is 60 dB (assuming they are incoherent noise sources). If the maximum sound pressure level permitted at this location is 57 dB how many compressors can run simultaneously?*

Solution

For 1 compressor: $L_{p1} = 20 \log(P_{\text{rms1}}/P_{\text{ref}})$.

For 12 compressors: $P_{\text{rms12}}^2 = 12P_{\text{rms1}}^2$, therefore $P_{\text{rms12}} = \sqrt{12}P_{\text{rms1}}$, $L_{p12} = 20 \log(\sqrt{12}P_{\text{rms1}}/P_{\text{ref}}) = 20 \log(P_{\text{rms1}}/P_{\text{ref}}) + 20 \log \sqrt{12}$.

Therefore, $L_{p12} - L_{p1} = 20 \log \sqrt{12} = 10.79$ and $L_{p1} = L_{p12} - 10.79 = 60 - 10.79 = 49.21 \text{ dB}$.

Now for x compressors

$$L_{p\text{max}} = 20 \log \sqrt{x} + L_{p1}$$

Therefore, $\log \sqrt{x} = (L_{p\text{max}} - L_{p1})/20 = (57 - 49.21)/20 = 0.3895$ $x = (10^{(0.3895)^2})^2 = 6.01$.

Therefore, six compressors, at most, can be operated in order to meet the 57 dB limit.

13.2.5 Frequency Weightings

Besides the conventional decibel scale, there are other scales have been developed that filter or weight the sound according to how human ears respond to amplitudes at different frequencies. This chapter continues by presenting and discussing several of these filtered scales.

Fletcher and Munson (1933) presented what is typically called the equal loudness contours (see Figure 13.2). This set of contours represents how human ears perceive tones of equal loudness over the frequency range from 20 Hz to 15 kHz. Apparent loudness is given in units of phons. The magnitude for the phon unit comes from the intensity level in dB of a 1 kHz tone with the same perceived loudness as other tones at different

FIGURE 13.2 Equal loudness level contours for sinusoidal sounds. Dashed contour represents the threshold of hearing. (After Robinson and Dadson, 1957; Davis and Silverman, 1978).

frequencies and intensity levels. Therefore, a dB value and a phon value are the same only for a 1 kHz tone. These contours were determined experimentally in an anechoic chamber. The experiment consisted of playing pure tones at a specific intensity level, along with a 1 kHz reference signal. The intensity of the reference signal was increased until the two tones were perceived to be of the same loudness by the listener. Other work, by Robinson and Dadson (1957) and Davis and Silverman (1978), on the development of equal loudness contours has been generated since Fletcher and Munson. The most recent standards can be found in ISO 226:2003.

Weighting filters have been developed to adjust sound pressure levels measured by microphones to mimic how our ears respond according to these equal loudness contours. The first weighting filter to be discussed is called A-weighting and usually carries the associated symbol dBA or dB(A). This weighting was developed to nominally apply the same filter to an incident sound that the human ear applies for tones that lie on the 40-phon equal loudness contour. The 40-phon contour represents relatively quiet tones. It should be noted that the A-weighting curve roughly corresponds to the inverse of the 40-phon equal loudness contour developed by Fletcher and Munson. The A-weighting curve tends to amplify signals in the 1–6 kHz region. Sound outside this frequency range is reduced by the A-weighting. The A-weighting filter is shown in Figure 13.3.

The A-weighting filter is very popular and is used in many applications. Some of these include environmental noise, noise control, construction noise, community noise standards, and so on. The usage of the A-weighting filter for such a wide range of sound pressure levels is in spite of the fact that the A-weighting filter is only appropriate for relatively quiet pure tones (the 40-phon contour).

FIGURE 13.3 Common frequency weighting curves based on equal loudness contours.

The dB(B) and dB(C) scales were developed along similar methods of the dB(A) scale except that they were developed for tones with higher sound pressure levels. The dB(B) scale is seldom used but was developed for tones between the low sound pressure level of the A-weighted scale and the high sound pressure level of the C-weighted scale. The dB (C) scale is used for the high sound pressure levels (based off of the 90 phon curve) and as shown in Figure 13.3 is nearly flat over a large frequency range. The dB(D) scale has been developed for aircraft noise and is depicted in Figure 13.3. The D-weighting curve heavily penalizes high frequencies to which the ear is most sensitive. The equations for the weighting scales are shown in Equation (13.7) where $s = j\omega$, $j = \sqrt{-1}$ and ω is the angular frequency.

$$\begin{aligned}
 G_A(s) &= \frac{k_A \times s^4}{(s + 129.4)^2 (s + 676.7) (s + 4636) (s + 76,655)^2} \\
 G_B(s) &= \frac{k_B \times s^3}{(s + 129.4)^2 (s + 995.9) (s + 76,655)^2} \\
 G_C(s) &= \frac{k_C \times s^2}{(s + 129.4)^2 (s + 76,655)^2} \\
 G_D(s) &= \frac{k_D \times s \times (s^2 + 6532s + 4.0975 \times 10^7)}{(s + 1776.3) (s + 7288.5) (s^2 + 21,514s + 3.8836 \times 10^8)}
 \end{aligned} \tag{13.7}$$

where $k_A \approx 7.39705 \times 10^9$, $k_B \approx 5.99185 \times 10^9$, $k_C \approx 5.91797 \times 10^9$, and $k_D \approx 91104.32$.

Another unit of measure for perceived loudness is the sone. The sone was developed to relate a perceived doubling of loudness in phons to a sones number that doubles. Experiments found that when volunteers were asked to adjust the loudness of a tone until it was perceived to be twice as loud as the original tone that the doubling corresponded to an increase of 10 phons. One sone is arbitrarily equal to 40 phons, and a doubling of the loudness (in sones) corresponds to a doubling of the perceived loudness. The relationship between sones and phons is given in Table 13.4.

TABLE 13.4 Table of Phons to Sones Conversion

Loudness Level (Phones)	Loudness (Sones)
20	0.12
30	0.4
40	1
50	2
60	4
70	8
80	16
90	32
100	64

13.2.6 Octave Frequency Bands

In reference to music theory, the term octave corresponds to a doubling or a halving of frequency. For example, 200 Hz is one octave above 100 Hz and is one octave below 400 Hz. 400 Hz would be considered to be two octaves above 100 Hz and so on.

In acoustics, the term “octave band” is commonly used to represent a range of frequencies where the highest frequency is twice the lowest frequency. These octave bands are commonly used to represent what is going on in the acoustic signal over a band or range of frequencies as compared to discrete frequencies. Many sound level meters will output sound pressure level data in standardized octave bands.

Octave bands are typically specified by a center frequency f_C . The upper frequency limit, f_U , and the lower frequency limit, f_L , of the band are computed as shown in Equation (13.8):

$$f_L = \frac{f_C}{\sqrt{2}}, f_U = \sqrt{2}f_C, \text{ where } f_C = \sqrt{f_L f_U} \quad (13.8)$$

Furthermore, the bandwidth for a given octave can be computed by Equation (13.9).

$$\text{Bandwidth} = f_U - f_L = \frac{f_C}{\sqrt{2}} \quad (13.9)$$

In the field of acoustics, standard octave bands have been defined. The lower frequency, center frequency, and upper frequency for the standard acoustical octave bands are shown in Table 13.5.

In many applications, a higher resolution on the frequency axis is desired. In these cases, the octave band is split into smaller groups. A common way to do this is to split up the octave band into three smaller bands called 1/3-octave bands. The 1/3-octave band scale is commonly used for environmental, noise control, and building acoustics among others. The lower, center, and upper frequencies for the 1/3-octave bands are shown in Table 13.6 and calculated using Equation (13.10).

$$f_L = \frac{f_C}{\sqrt[3]{2}}, f_U = \sqrt[3]{2}f_C, \text{ where } f_C = \sqrt{f_L f_U} \quad \text{Bandwidth} = f_C \left(\sqrt[3]{2} - \frac{1}{\sqrt[3]{2}} \right) \quad (13.10)$$

13.3 MICROPHONES

This section will discuss various types of microphones. It will then cover important considerations in microphone selection, including the sound field in which the microphone will be used and how the physical characteristics of a microphone affect measurements. We will then discuss microphone accuracy specifications. The section will then conclude by discussing various calibration techniques.

A microphone is a device that converts acoustical energy in the form of a compression wave into electrical energy in the form of a time-varying voltage. There are several types of microphones and some of these will be discussed in this section. The most common types of microphones use a thin membrane referred to as a diaphragm to sense the incident wave energy. The compression and expansion of sound waves impinging on the diaphragm causes the diaphragm to vibrate. The mechanical motion of the diaphragm is coupled to a transducer, which then produces a varying voltage proportional to the diaphragm deflection. The coupling mechanism between the diaphragm and the transducer is what distinguishes different types of microphones.

The most common microphones as based on the transducing components are the condenser, electret, and dynamic microphones. This section provides a brief overview of these different microphones and the reader is also referred to the vast amount of information available on the Internet.

13.3.1 Condenser Microphone

Typical elements of a condenser microphone (also called a capacitor microphone or electrostatic microphone) are shown in Figure 13.4. One conducting plate, often referred to as the back plate, is fixed to the microphone casing, although it is electrically isolated from the casing. A metal or metallized plastic diaphragm is placed a small distance away from the back plate and acts as the second (and movable) conducting plate of a dynamic

FIGURE 13.4 Cross section of a condenser microphone (Courtesy of G.R.A.S. Sound and Vibration).

FIGURE 13.5 Illustration of the electrical charge applied to the diaphragm of an electret microphone (Courtesy of G.R.A.S. Sound and Vibration).

capacitor. When the diaphragm vibrates an oscillating voltage appears on the electrical leads attached to the plates. The principal advantage of this type of microphone is that it possesses a uniform frequency response over a wide band of frequencies. The principal disadvantage of these microphones is the need to have a DC bias voltage (e.g., 200 V) across the plates (in order to produce an electrical output signal and to linearize the response of the microphone) and a preamplifier in close proximity to the plates. Condenser microphone designs have typically incorporated a preamplifier in the microphone casing. Condenser microphones are used in research, to produce high-fidelity recordings, and in hearing aids and portable sound equipment.

13.3.2 Electret Condenser Microphones

Technically a subset of condenser microphones, electret microphones (sometimes called a prepolarized microphone) are now in wide use because they offer the advantages of a condenser microphone without the disadvantage of needing a large polarizing DC voltage. Figure 13.5 depicts an illustration of an electret microphone with an electrically charged Teflon diaphragm. The diaphragm consists of an electret plastic foil that has been permanently electrically charged and overlaid with a thin metallic layer. The electret condenser microphone typically employs a preamplifier. It is slightly less sensitive than the condenser microphone and the “permanent” electric charge has a finite life span (e.g., 5 years, but this depends on the design). One should note here that sometimes certain preamplifiers, used in conjunction with electret microphones, require a polarization voltage (e.g., 24 VDC drawing approximately 4 mA of current).

13.3.3 Dynamic Microphone

A dynamic microphone (also called an electrodynamic microphone or a moving-coil microphone) has a coil of wire attached to its diaphragm as shown in Figure 13.6. The transduction in a dynamic microphone is induced when the diaphragm moves its attached coil between the poles of a magnet, inducing an electromotive force (emf) and a

FIGURE 13.6 Illustration of the parts of a dynamic microphone.

corresponding electrical voltage signal (this is known as Faraday's law of induction). Dynamic microphones are capable of a relatively high gain before feedback. They are rugged, and capable of a broad frequency response over a wide dynamic range. Because they are able to withstand the high-intensity sound levels often associated with popular music, they are widely used for live performances and for recording sessions. The principal disadvantage of dynamic microphones is that their frequency response is not as uniform as for condenser microphones.

13.3.4 Microphone Selection

Most microphones are designed to work in one of three sound fields. These sound fields are typically classified as free field, diffuse field, and pressure field. The different microphone designs have been developed to minimize the effect of the microphone in the particular field of measurement. Because the correction for the influence of the microphone in the sound field can be built into the microphone body, care should be taken when selecting microphones for a particular sound field. Using the wrong microphone in a particular field may result in errors of several decibels.

Free-field conditions exist when the sound waves propagate in a specific direction without the effects of any reflections. These conditions could exist in an anechoic chamber, outdoors, or in other places where reflecting surfaces are not present (or provide minimal reflection). The microphone is typically placed in this field with the diaphragm perpendicular to the sound wave as shown in Figure 13.7. When the sound wave is not perpendicular to the diaphragm, corrections can be made if the angle of incidence is known.

A diffuse field, or random field, is created when sound waves from many different directions pass through a point. Statistically, in a diffuse field, sound waves have equal probability of arriving from any direction, and the sound field is considered to be spatially uniform in amplitude for a particular frequency (but not in general equal in amplitude across all frequencies). These sound waves may or may not be generated from the same source but typically multiple reflections are part of the sound field as well. These microphones, sometimes referred to as random incidence microphones (depicted in Figure 13.7

FIGURE 13.7 Illustrations of how free-field, pressure, and random incidence microphones are intended to be used (Image courtesy of G.R.A.S. Sound and Vibration).

as a “Random microphone”), are designed to be direction insensitive. This is achieved by designing their response to compensate for the fact that the presence of the microphone perturbs the sound field. This type of sound field would exist with a steady-state noise source in a closed room with reflecting walls.

Pressure-field conditions exist in enclosures where the dimensions are much smaller than the wavelength of the sound. This is typically achieved with a single source and the resulting field has the same magnitude and phase at all locations. The microphone, sometimes termed a pressure microphone, is typically placed such that the end of the microphone is flush with the enclosure surface (as depicted in Figure 13.7). These microphones are often used to measure the sound waves inside a duct or on a surface. As with the other microphones, pressure-field microphones are designed to account for the changes they make in the sound field.

13.3.5 Microphone Accuracy

Measurement microphones are also rated on a standard scale as given by ANSI S1.12-1967 (R1977). This particular standard rates the microphone on its calibration and type of application. This standard is summarized below and was taken from the Measurement Microphone primer by Brüel and Kjær, which can be found on their website (<http://www.bksv.com/library/primers.aspx> last viewed on February 2, 2011).

Type L: Precisely calibrated reference-standard with a closely specified outer diameter (to enable use in couplers).

Type XL: As above, but with no specified outside diameter.

Type M: For measuring sound-pressure magnitudes of the order 0.1 N/m^2 , or higher. Better high-frequency and high sound pressure performance than for Types L and XL. Copes with relatively large ambient-pressure changes.

Type H: For applications in which diffraction errors in the measurements must be small or in which the sound-pressure magnitude is of the order of 0.5 N/m^2 , or higher. Copes with relatively large ambient-pressure changes.

13.3.6 Calibration

Proper calibration is a vital process when making acoustic measurements. ANSI S1.10-1966 (R1986) gives the standard method for the calibration of microphones, although there are many different methods of microphone calibration. In this section, we provide an overview of the following types of microphone calibration: pistonphone, reciprocity, relative, and switching calibrations. Good resources for further reading on calibration is provided by ANSI S1.12-1967—R1977, ANSI S1.10-1966—R1986 (Burnett and Nedzel-nitsky, 1987; Torr and Jarvis, 1989; Kinsler et al., 2000, pp. 428–430; Maclean, 1940, pp. 140–146; Bobber, 1990).

13.3.7 Pistonphone Calibration

A pistonphone calibrator has an enclosed volume in which the microphone to be calibrated is inserted with an airtight seal. In the pistonphone, a mechanical cam drives a piston, or a pair of pistons, in a sinusoidal motion to create a pressure field at a steady frequency and at steady amplitude. The pressure in the enclosure can be accurately determined by knowing the internal dimensions of the enclosure, the ratio of the specific heats for the gas in the coupler (1.402 for air at 20°C and 1 atm), the atmospheric pressure, the cross section area of the piston(s), and the peak motion of the piston(s). The microphone recordings may then be calibrated by knowing this pressure field inside the pistonphone either electronically within a sound level meter, or in the postprocessing phase of data analysis.

Pistonphones are commercially available from most major microphone manufacturing companies. Given that the sound field is generated with a rotating cam and a moving piston, most pistonphones calibrate at low frequencies at or near 250 Hz (though some operate at 1 kHz). There is a little more variation on the level of pressure generated by a pistonphone but most commercial pistonphones calibrate at levels from 114 dB re 20 μ Pa to 134 dB re 20 μ Pa. One of the main sources of error with a pistonphone calibration is an accurate barometric pressure reading. However, depending on the barometer, pistonphones can be very robust and can be used to calibrate Class 0 and Class 1 systems following IEC standard 942, 1988 Sound Calibrators.

13.3.8 Reciprocity Calibration

Reciprocity calibration has become a very common primary calibration process. The calibration can be performed using an anechoic chamber or in an environment that can be considered to be a free-field environment. The calibration process consists of using three transducers (1–3). The first is the microphone to be calibrated, the second any reversible transducer that may act as both a transmitter or a receiver, and the third a source. The three transducers are organized into three pairs (3-2, 3-1, and 2-1). Each of the three pairs is tested separately. During the first test, the source is placed a distance, r , from the reversible transducer and the open-circuit voltage response is measured at the reversible transducer's terminals, V_2 . The distance r must be sufficiently large so that these measurements are made in the acoustic far field of the transducers used as sources. In the second test, the source outputs the same signal as in the first test and the microphone is put in the place of the reversible transducer. The open-circuit voltage response at the

microphone's terminals, V_1 , is then measured. Finally in the third test, the reversible transducer is used in place of the source and is now operated as a source, while the current through the reversible transducer is measured, I_2 . The open-circuit voltage response is now measured at the microphone's terminals, V'_1 . The open-circuit receiving sensitivity of the microphone, M_{O1} , is then

$$M_{O1} = \sqrt{\frac{2r}{\rho_0 f} \frac{|V_1||V'_1|}{|V_2||I_2|}} \quad (13.11)$$

where ρ_0 is the ambient air density.

13.3.9 Relative Calibration

In cases where one cannot afford expensive precision microphones, one may use lower quality microphones and calibrate them against a microphone with a known sensitivity, M_{KS} . In this method, sometimes referred to as a substitution technique, the precision microphone is placed in a repeatable broadband sound field and its open-circuit voltage response as a function of frequency is then measured, V_{KS} . The microphone of unknown calibration is then put in place of the precision microphone and its open-circuit voltage response is measured, V_{UM} . The sensitivity of the unknown microphone, M_{UM} , may then be determined as

$$M_{UM} = M_{KS} \frac{V_{UM}}{V_{KS}} \quad (13.12)$$

13.3.10 Switching Calibration

In some sound fields it may be desirable to employ multiple microphones. One need not possess multiple precision microphones if a switching calibration is employed, however, the microphones must be stable over the period in which the measurements are made. In the switching calibration technique, the microphones are placed in their desired locations in a sound field and a complex, frequency-dependent transfer function is measured between the two microphones, $H_{I,12}$. The microphones' positions are then interchanged and a second transfer function is measured, $H_{II,12}$. The calibration transfer function, $H_{CAL,12}$, between these two microphones is then

$$H_{CAL,12} = \sqrt{H_{I,12} \times H_{II,12}} \quad (13.13)$$

This calibration transfer function can then be used to determine the open-circuit voltage response of one of the two microphones used for the calibration if the other one is used by dividing the measured open-circuit voltage response by $H_{CAL,12}$.

Another example where the switching calibration technique is useful is in absorption coefficient measurements of acoustic ceiling tiles using a plane wave tube. The absorption

properties are measured in a plane wave tube through a measurement of a complex frequency response between two microphones. This complex frequency response must be calibrated by the measured frequency response by dividing the measured frequency response by $H_{\text{CAL},12}$.

13.4 SOUND PRESSURE LEVEL MEASUREMENTS

Since there is an extremely large range of pressure measurements the results are often presented as a logarithmic measure with units of decibels (reported in terms of dB) as previously discussed. This chapter will discuss the basics of sound level meters and then describe various types of typical quantities measured in field tests that are then used for community noise standards, and to determine worker sound exposure, as will be described in more detail later in this chapter.

13.4.1 Sound Level Meters

Sound pressure level measurements are typically made with a sound pressure level meter or sound level meter, SLM. Many manufacturers provide SLMs that provide a fast and simple method of making sound pressure level measurements. A SLM typically consists of a condenser microphone, preamplifier, data acquisition hardware and software, a display to present the results, and a storage system to save the recorded data. The microphone is typically mounted on a rod extending out past the data acquisition box to minimize sound reflections from the user and system during the test. A photograph of a typical SLM is shown in Figure 13.8.

There is a large range of quality and price on SLMs. A significant cost of the system is associated with the quality of microphone. Another significant cost factor is the capability of the system hardware and software. For example, storage space, real time spectral

FIGURE 13.8 Photograph of a typical sound level meter.

TABLE 13.7 Sound Pressure Level Measurement Standards

3. IEC 61672 : 2003—International Standard for Sound Level Meter Performance

analysis, averaging, sample rate, automatic data logging, filtering, and weighting are some of the capabilities to consider when selecting a SLM.

To help the user select the appropriate SLM, a classification known as types or classes of sound level meters has been set. The two main classes of SLM classifications are Class 1 and Class 2. The basic difference between the two classes is the tolerance limit with which the specifications are met. Class 1 meters are designed to be used for laboratory and field applications where the highest accuracy is required. Class 2 meters can be considerably less expensive but do not provide the same high accuracy and precision, especially in the high frequency range. In general, specifications for Class 1 and Class 2 SLMs have the same design goals and differ mainly in the tolerance limits and the range of operational temperatures. Tolerance limits for Class 2 specifications are greater than, or equal to, those for Class 1 specifications. The details of these classifications can be found in International Standard IEC 61672-1. There are also Class 0 and Class 3 transducers. The Class 0 transducers are used in laboratory applications for the calibration of other meters. Class 3 transducers are used primarily in field studies where accuracy is not of extreme importance. ANSI S1.4-183 is another standard which discusses classifications 0-2. Some manufacturers will designate their microphone, preamp or filter as a certain type or to meet a particular standard. In order to conform, the complete system must be reviewed. The whole system is what must meet the standard, not just one component.

National and international standards exist for making sound pressure level measurements. The ANSI and the IEC are two organizations responsible for developing and maintaining these standards. The standards state both the measurement process which should be followed and the specifications of the equipment required to make the measurements. Several of the standards for sound pressure measurements are listed in Table 13.7.

13.4.2 Sound Pressure Level Metrics

There are numerous ways of representing measured noise. One way is to simply display the A-weighted sound pressure level (L_A) as a function of time. In addition to A-weighted sound pressure level, there are many other single-number metrics that are used to describe noise.

Perhaps, the most common metric is the equivalent continuous sound level (L_{eq}). The L_{eq} is commonly determined from A-weighted sound pressures but it may in general be expressed using other types of weightings (though the weighting used should always be specified, for example, the c-weighted sound pressure level would be L_C). Further it is the level of the steady sound that has the same time-averaged energy as the noise event.

For the time interval, T , which runs between T_1 and T_2 , L_{eq} is calculated as

$$L_{eq} = 10 \log_{10} \left\{ \frac{1}{4 \times 10^{-10}} \frac{1}{T} \int_{T_1}^{T_2} p_A^2(t) dt \right\} \quad (13.14)$$

where p_A is the instantaneous A-weighted sound pressure (a time domain A-weighting filter must be applied to an instantaneous pressure versus time waveform to obtain $p_A[t]$). A running, live update on a sound level meter of L_{eq} is often called a running L_{eq} . The $1/4 \times 10^{-10}$ is the reciprocal of the reference sound pressure squared $(20 \mu\text{Pa})^2$. The L_{eq} gives equal weighting to all noise summed over T irrespective of the time at which it is present. Common values for T include 1 s, 1 min, 1 h, 8 h, and 24 h.

If one has a set of A-weighted, L_{eq} measurements, each taken over a 1-h period of time [expressed as $L_{A,1h}(n)$], for the 24 h of a given day, then we may average these values to arrive at the average $L_{eq,24h}$ for that day

$$L_{eq,24h} = 10 \log_{10} \left\{ \frac{1}{4 \times 10^{-10}} \frac{1}{24} \sum_{n=1}^{24} 10^{0.1L_{A,1h}(n)} \right\} \quad (13.15)$$

L_{eq} measurements are therefore useful to determine average noise exposures over a given period of time.

In order to obtain live readings of sound pressure levels, for example, with a hand held sound level meter in the field, exponential-time-weightings have been developed. Various exponential-time-weightings have been standardized including slow, fast, and impulse. Often a slow exponential time-weighting is called a slow detector for short. Slow and fast exponential-time-weighted sound pressure levels, $L_{A,tw}$, are given by

$$L_{A,tw} = 10 \log_{10} \left\{ \frac{1}{4 \times 10^{-10}} \frac{1}{\tau} \int_{T_1}^{T_2} p_A^2(\xi) e^{-(t-\xi)/\tau} d\xi \right\} \quad (13.16)$$

where $\tau = 1$ s for slow, and $\tau = 0.125$ s for fast weightings. Thus, a slow detector has a longer “memory” than does a fast detector since it gives a higher weighting to previous sound pressures than a fast detector does. The impulse detector is similar in nature to slow and fast detectors, but it has a different time constant depending on whether the sound pressures are rising ($\tau = 0.035$) or falling ($\tau = 1.5$). Thus, the impulse detector responds well to impulsive changes in sound pressure and holds that level fairly constant on the meter so that it can be noted by the operator.

Figure 13.9a displays pressure versus time for an example sound recording that has had a time domain A-weighting filter applied to it. Figure 13.9b shows the instantaneous sound pressure levels using a slow detector and a fast detector. Note the differences in the trailing slopes of the slow and fast detectors when the sound pressures drop suddenly, indicating the respective memories of each type of detector. Figure 13.9c shows a running L_{eq} , and L_{eq} measurements at intervals of 0.125 and 1 s. Recall that, in general, an L_{eq} measurement represents a summation without any time weighting applied.

FIGURE 13.9 (a) A sample microphone recording displayed in A-weighted sound pressure versus time. (b) Instantaneous sound pressure levels with a slow (solid line) and a fast detector (dashed line) for the waveform in (a). (c) Equivalent continuous sound level measurements, L_{eq} , for the waveform in (a) (dashed line represents the running L_{eq} , the solid lines of long and short duration are L_{eq} measurements over the time intervals of 1 s and 1/8 s respectively).

13.5 MEASUREMENT OF SOUND ISOLATION

There are numerous applications where it is desired to measure the isolation that is achieved by placing an acoustic treatment between a source and a receiver location. Such applications include noise barriers, enclosures, partitions or walls, and mufflers among others. While the concepts presented here are applicable to all of these applications, the development will focus specifically on sound isolation in a room or cabin and transmission between two such adjacent spaces. Several metrics have been developed to quantify the effectiveness of such treatments.

13.5.1 Transmission Loss

Conceptually, the ideal metric to quantify the effectiveness of an acoustic treatment is often the *transmission loss*. The transmission loss is defined as

$$TL = 10 \log_{10} \left(\frac{W_i}{W_t} \right) \quad (13.17)$$

where W_i is the total acoustic power incident on the treatment of interest and W_t is the total acoustic power transmitted through the treatment. In practice, this metric can often be difficult to measure, as it requires one to be able to measure the incident power with the treatment in place. A common measurement error encountered occurs when the user measures the sound power radiated by the source without the treatment in place, then puts the treatment in place and measures the sound power radiated through the treatment, and calls the difference between the two measurements the transmission loss. This approach would be correct if the sound power radiated by the source does not change with a changing acoustic load. However, it is often the case that inserting the acoustic treatment also alters the acoustic load on the source and as a result alters the acoustic power radiated from the source. Thus, for an accurate measurement of transmission loss, the incident power must be measured with the acoustic treatment in place.

13.5.2 Insertion Loss

As a result of this difficulty, alternative metrics have also been developed. One of those is the *insertion loss*. The insertion loss is defined as

$$IL = 20 \log_{10} \left(\frac{p_w}{p_{w/O}} \right) \quad (13.18)$$

where $p_{w/O}$ is the pressure at a field point without the treatment in place, and p_w is the pressure at the same field point with the treatment in place.

13.5.3 Noise Reduction

A third metric used when the application of interest is transmission of noise from one reverberant room to a second reverberant room is the *noise reduction*, defined as

$$NR = 10 \log_{10} \left(\frac{I_1}{I_2} \right) = L_{p1} - L_{p2} \quad (13.19)$$

Here, I_1 and I_2 are the acoustic intensities in the source and receiving rooms, respectively, and L_{p1} and L_{p2} are the sound pressure levels in the source and receiving rooms. For Equation (13.19) to be accurate, the sound field in the two rooms must be diffuse—a condition that is approximated in a reverberation chamber. For a more accurate measurement, a spatially averaged sound pressure response should be obtained using an array of microphones (as described in ISO 3741, for example) to reduce the effects of nonuniform distribution of sound energy.

For the case of two coupled reverberant rooms, the noise reduction in Equation (13.19) can be related to the transmission loss in Equation (13.17). The sound power incident on the partition between the rooms can be expressed as $W_i = I_1 S$, where S is the area of the partition. The power transmitted (and subsequently absorbed) in the receiving room can be expressed as $W_t = I_2 A$, where A is the total sound absorption of the receiving room. This leads to

$$TL = NR + 10 \log_{10} \left(\frac{S}{A} \right) \quad (13.20)$$

13.5.4 Sound Isolation of Partitions

A single leaf partition is a partition where both faces of the partition are connected together in a manner such that the cross-section moves as a rigid body. Solid panels would be the simplest example of such a partition. At low frequencies, the transmission loss associated with a single leaf partition placed between two acoustic spaces is governed by the mass per unit area of the partition. The mass law predicts the attenuation of a rigid single leaf partition as

$$TL = 20 \log_{10}(f \rho_S) - 47 \text{ dB} \quad (13.21)$$

where f is the frequency (Hz), and ρ_S is the surface density of the solid partition (kg/m^2). The mass law predicts that the transmission loss increases by 6 dB with a doubling of frequency, or with a doubling of the surface density. This leads to the general rule that low frequencies are harder to isolate than higher frequencies, and if further isolation is needed at low frequencies, it often requires the use of higher surface densities to achieve the desired objective.

In practice, single leaf partitions also exhibit structural wave effects. This causes the transmission loss to deviate from the mass law, due to the interaction of the stiffness, mass, and damping properties of the partition. The critical frequency corresponds to the frequency where the phase speed of bending waves in the partition (which is frequency dependent) matches the phase speed in the surrounding acoustic fluid. Above this critical frequency, the coincidence effect is observed, where waves incident from a particular angle pass through the partition with little attenuation, due to a matching of the phase speeds. This results in a coincidence dip that is observed as reduced transmission loss, typically from frequencies slightly below the critical frequency up to frequencies an octave or more above the critical frequency.

Double leaf partitions are constructed using two single leaf partitions with an acoustic cavity between them. The acoustic cavity may also be filled with an absorptive material. Double leaf partitions have the ability to provide additional transmission loss. These designs offer the potential of increasing the transmission loss at most frequencies. However, they do introduce additional resonance effects, including the coincidence frequencies of both partitions and the mass-air-mass resonances that are established with the partitions providing mass effects and the cavity providing stiffness effects. At these resonances, the transmission loss is typically reduced to levels around that corresponding to the mass law.

13.5.5 Sound Transmission Class

The sound transmission class (STC) is a single number rating system that attempts to characterize the sound isolation associated with an acoustic space. It represents the most common single number metric used in North America for this purpose, and is generally used to rate the sound insulation properties of windows, doors, and partitions. The STC is obtained using the transmission loss values associated with the 1/3-octave bands from 125 to 4000 Hz. The STC is obtained as follows. The measured 1/3-octave band values are compared with a reference contour that is obtained from three straight lines. The first line covers the range from 125 to 400 Hz, and increases by 15 dB over this range. The second line covers the mid-frequency range from 400 to 1250 Hz and increases by 5 dB over this range from the value at 400 Hz. The third line for frequencies above 1250 Hz is

FIGURE 13.10 An example of an STC measurement. Here, the STC = 40.

a horizontal line matching the value of the second line at 1250 Hz. The following guidelines are used to match this reference contour to the measured 1/3-octave band data.

1. No individual transmission loss value can lay more than 8 dB below the reference contour after it is fitted to the data.
2. The total deficiency (obtained as the sum of all deviations below the reference contour) cannot exceed 32 dB. The STC reference contour is fitted to the data to be as high as possible while still meeting these two criteria. The STC value then corresponds to the transmission loss of the STC curve at 500 Hz. An example for determining STC is provided in Figure 13.10, where the STC of this acoustical treatment is 40.

13.6 ROOM ACOUSTICS MEASUREMENTS

13.6.1 Reverberation

One of the first subjective characteristics that a person notices when entering any given room is whether the room is acoustically *live* or *dead*. The degree to which a room is live or dead greatly determines the ability of two people to hold a successfully understood conversation. If a room is too live, it may be difficult to understand speech except at short distances, whereas in a very dead room speech can generally be understood irrespective of distance. This perceptual characteristic is entirely dependent on the amount of reflections off of the walls in the room and the strength of those reflections, which we term room reverberation. For a given sized room, the degree to which the room is live or dead depends on the absorptive qualities of the materials placed on the surfaces of the walls, ceiling, and floor.

Reverberation is quantified through the measurement of an impulse response. An impulsive source, such as a starter pistol or a balloon pop, is used to excite the reverberation in the room and the response of the room due to this impulse may be measured at any selected microphone location. This impulse response may, in general, depend on both the

FIGURE 13.11 (a) Photograph of the Eisenhower Auditorium on the campus of The Pennsylvania State University. (b) Impulse response measurement with the source on stage and the microphone located at the seat location indicated by the arrow. The dotted line indicates the average slope of the impulse response's decay.

locations of the source and the microphone. In a classroom, for example, one may place the impulsive source at the location where the instructor would teach from and then place the microphone at a given seat location.

Reverberation in a room is assumed to decay at a constant rate of dB over time. The reverberation time, RT, is defined as the time it takes for the sound pressure level in a room to decay 60 dB. Figure 13.11a shows a voltage versus time impulse response as measured by a microphone in the Eisenhower Auditorium on the campus of The Pennsylvania State University (2500 seat capacity). The impulsive source was located on the stage while the microphone was placed at an audience seat location. Figure 13.11b shows the magnitude of the impulse response versus time on a dB scale. The initial sound arrival occurs 91 ms into the recording. Note that from approximately the 200 to the 900 ms mark that the sound is decaying at a constant rate. After the 900 ms mark, the sound from the impulse is now into the noise floor (we know it is the noise floor because it matches the level before the initial sound arrival and because the sound level flattens out after that time). The initial arrivals of sound commonly do not follow the steady decay rate. To obtain the RT, we must select a portion of the impulse response with a constant decay. If we conservatively choose the time frame from 250 to 750 ms, we can avoid the initial sound arrivals and any influence of the noise floor. The dashed line in Figure 13.11b displays a line that matches the slope of the decay rate. Over this 500-ms interval, the sound decays 24 dB. Thus, the RT is 1.25 s, since it will take that long for the impulsive sound to decay 60 dB.

The RT can be calculated (in metric units) for a given room if the room's volume, V , total surface area, S , and average absorption coefficient, $\bar{\alpha}$, of the room's surfaces are known:

$$RT = 0.161 \frac{V}{-S \ln(1 - \bar{\alpha})} \quad (13.22)$$

This formula is called the Norris-Eyring reverberation time (see Pierce, 1989, pp. 263–265). The quantity $\bar{\alpha}$ may be determined through an area weighted average of the

many sources. Beranek asserts that numerous inconsistencies in the data given by various authors make these values listed only approximate values.

The optimal RT for a given room depends on the primary intended use for that room. Perceptual studies were conducted to determine the optimal RT for various types of rooms. When the room is primarily used for speech, such as for a classroom, lower reverberation times are desired so that speech may be understood clearly above any reflections and echoes. On the contrary, when a room is used for musical performances, longer reverberation times are desired to give a sense of liveliness of the concert hall. Table 13.10 gives a listing of optimal reverberation times for various types of rooms. Thus if one measures an average RT for a given type of room, one may then use Equations (13.22) and (13.23) to determine how they may change the room surfaces to increase or decrease the RT as needed.

13.6.2 Room Resonances

The Fourier transform of a room's impulse response yields its frequency response. The frequency response of a room provides information about modal resonance frequencies of that room. For smaller rooms, the modes can cause undesirable coloration of the acoustic response at low frequencies (as is experienced when one sings in a typical shower). Thus, the frequency response may be used to identify problematic resonance frequencies. However, in order to reduce the strength of a given modal frequency, one must also know the spatial distribution of that mode.

The resonance frequencies of a rectangular room, of dimensions L_X by L_Y by L_Z , are given by

$$f_{l,m,n} = \frac{c}{2} \sqrt{\left(\frac{l}{L_X}\right)^2 + \left(\frac{m}{L_Y}\right)^2 + \left(\frac{n}{L_Z}\right)^2} \quad (13.24)$$

where l , m , and n are integers (0, 1, 2, 3, . . .). There are three types of room modes: axial, tangential, and oblique. Axial modes have amplitude dependence only along one of

FIGURE 13.12 Illustrations of the spatial variations in axial, tangential, and oblique room modes. Axial mode ($l=3, m=0, n=0$) is shown in the first column, tangential mode ($l=3, m=2, n=0$) is shown in the second column, and oblique mode ($l=3, m=2, n=1$) is shown in the third column.

the axes and they occur when two of the integers are equal to zero. Tangential modes have amplitude dependence in only two dimensions and they occur when one of the integers is equal to zero. Finally, oblique modes have amplitude dependence in all three dimensions and they occur when all integers are non zero. Figure 13.12 gives an example of the spatial distribution of the sound pressure for each of these three types of modes. In the figure, note the lack of Y and Z dependence in the axial mode, and the lack of Z dependence in the tangential mode. If one wishes to characterize a certain modal frequency in a room, both the microphone and the source used in this measurement must be placed away from nodal lines/planes (locations in the room where a mode does not respond).

Each resonance frequency has a finite sized bandwidth associated with it, which depends on the absorption in the room. Increasing absorption decreases the room mode's amplitude and makes the modal frequency response occur over a broader range of frequencies for that mode (so that it is not so apparent). For larger sized rooms, modal frequencies occur within a lower frequency range than for a smaller sized room. Above a frequency called the Schroeder frequency, f_s , modal frequencies overlap to the degree that no one mode dominates the acoustic response of the room. In general, above f_s one need not worry about undesirable coloration of the acoustic response due to a given room resonance. The f_s , valid for most rooms (except for very elongated rooms), is defined in terms of the RT and the volume of the room:

$$f_s = \sqrt{\frac{c^3}{4\ln(10)}} \sqrt{\frac{RT}{V}} = 2090 \sqrt{\frac{RT}{V}} \quad (13.25)$$

where c is the speed of sound (343 m/s).

13.6.3 Critical Distance

Above f_s a room is considered to be spatially uniform in its acoustic response, meaning that any reverberation in a room will be uniformly distributed. However, when two people

are standing close enough to one another, successful communication can still take place. It turns out that there exists a distance at which the direct sound energy from a source equals the reverberant energy (whose energy is created by that source). This distance, for omnidirectional sources (sources without a preferred direction), is called the critical distance, r_C , and is defined as

$$r_C = \sqrt{\frac{\bar{\alpha}S}{16\pi(1 - \bar{\alpha})}} \quad (13.26)$$

This distance increases for directional sources (see Pierce, 1989, pp. 267–270).

13.6.4 Echoes

An echo is a delayed repetition of sound that results in a degradation of speech communication. It has been determined, through perceptual studies, that a reflection of sound which arrives 50 ms later than the direct sound arrival, or any other prominent reflection arrival, is perceived as an echo. This later arrival of sound must also be of sufficient amplitude above the usual constant decay of reverberant energy to be perceived as an echo. Further, this late reflection may only be perceived as an echo if there are no other prominent reflections that precede it by 50 ms. Thus, one way to mask a troublesome echo is to provide other prominent reflections within the 50 ms preceding the troublesome echo. Another way to reduce the echo is to locate the room surface providing the offending echo and treat it with highly sound absorbent materials to reduce the amount of sound energy that is reflected.

13.6.5 Noise Criteria

In the absence of distinct tonal noise, one may define noise criteria, NC, rating for a given room. The NC, given in dB, for a room gives a measure of the perceived background noise since it depends on an overall, A-weighted, sound pressure level measurement, SPL_A :

$$NC = 1.24(SPL_A - 13) \quad (13.27)$$

This SPL_A measurement is made with only background noise present. Table 13.11 gives acceptable NC values for various types of rooms. In some cases, such as a library or a

TABLE 13.11 List of Acceptable Noise Criteria Ratings for Various Room Types

Room Type	Noise Criteria Rating (dB)
Studio	15–20
Concert hall	15–20
Theater	20–25
Auditorium	25–30
Bedroom	25–30
Living room	30–35
Business offices	30–35
Restaurant	35–45

restaurant, spectrally uniform background noise may be desirable to mask the speech of others. An expansive treatment of additional background noise metrics is given by Blazier (1998).

13.7 COMMUNITY AND ENVIRONMENTAL NOISE

Measurement and analysis of the impact of noise on individuals, communities, and the environment are major subfields within acoustics. These topics are inherently fraught with debate, because of the subjectivity of human perception and in the challenge of defining acceptable limits. This section summarizes some of the measurements and calculations commonly carried out in community and environmental noise assessment.

13.7.1 Representations of Community Noise Data

There are numerous ways of representing community noise. Because of the time scales involved, most involve level-based measurements and the tracking of events of significance, rather than detailed time waveform recordings. One possibility is to display the sound pressure level as a function of time, in addition to a calculation of the equivalent sound level (see Equation (13.14)) over the sampling period. The running level measurements can be more helpful in identifying individual noise events than the equivalent level. As an example, the running A-weighted sound pressure level (L_A) and the $L_{A,eq}$ as a function of time is displayed in Figure 13.13. The data, recorded using a Larson Davis 824 Sound Level Meter, include the emptying of several trash dumpsters during the early morning at an apartment complex in Provo, UT. Before the arrival of the garbage truck, major noise sources (>60 dBA) were due to intermittent traffic from the nearby street. After the arrival of the truck (around 8 min into the data shown), the most significant noise events were due to the dumpsters being shaken by the hydraulic arms on the truck before being noisily set back down.

Other representations of community noise are statistical in nature. Using the same garbage truck example, a cumulative distribution function can be calculated. As shown in Figure 13.14, this function shows the percentage of time that the recorded noise levels exceed a given value. From the cumulative distribution function, X-percentile-exceeded noise levels (L_X) can be calculated. In Figure 13.14, lines representing the L_{90} , L_{50} , and L_{10} of 54.4, 60.4, and 75.3 dBA are shown.

FIGURE 13.13 A-weighted sound pressure level and L_{eq} as a function of time before, during, and after the garbage truck arrival.

FIGURE 13.14 Cumulative distribution of the time series in Figure 13.13, showing what fraction of time the sound level exceeds a given sound pressure level.

There are various single-number metrics that are used to describe community noise. These metrics have been the result of attempts to correlate subjective response with objective, albeit empirical, measures. Some of the commonly used metrics are as follows:

- Equivalent continuous sound level (L_{eq}). Although the L_{eq} was defined previously in Equation (13.14) and (13.15), further comments regarding common averaging times are merited. These include hourly levels, day levels (7 A.M.–10 P.M.), evening levels (7–10 P.M.), and night levels (10 P.M.–7 A.M.).
- Day–Night Level (DNL or L_{dn}). The L_{eq} obtained for a 24-h period after a 10-dBA penalty is added to the night levels (10 P.M.–7 A.M.). For individual L_{eq} calculations carried out over 1-h intervals (L_{1h}), L_{dn} may be expressed as

$$L_{dn} = 10 \log_{10} \left\{ \frac{1}{24} \left[\sum_{i=0100}^{0700} 10^{0.1(L_{1h}(i)+10)} + \sum_{i=0800}^{2200} 10^{0.1L_{1h}(i)} + \sum_{i=2300}^{2400} 10^{0.1(L_{1h}(i)+10)} \right] \right\} \quad (13.28)$$

The DNL is important in, for example, land planning around airports and in predicting community annoyance due to transportation noise. The predicted community response in terms of percent of people highly annoyed (see Fidell et al., 1991) as a function of DNL is shown in Figure 13.15.

- *Community Noise Equivalent Level (CNEL)*. CNEL is calculated using the L_{eq} obtained for a 24-h period after 5 dBA is added to the evening levels (7–10 P.M.) and 10 dBA is added to the night levels. It can be calculated similar to L_{dn} , with the appropriate penalty given during the evening (between 2000 and 2200 h).
- *Effective Perceived Noise Level (EPNL)*. This metric was designed for characterizing aircraft noise impact and is used by the Federal Aviation Administration (see FAR Part 36 Sec. A.36) in the certification of commercial aircraft. The metric accounts for (a) the nonuniform response of the human ear as a function of frequency (i.e., the perceived noise level), (b) the additional annoyance due to significant tonal components of the spectrum (the tone-corrected perceived noise level), and (c) the change in perceived noisiness due to the duration of the flyover event. Too involved to be repeated here, calculation procedures for EPNL may be found in FAR Part 36 Sec. A.36.4 or Raney and Cawthorn (1998).

FIGURE 13.15 Percentage of people highly annoyed for a given DNL.

13.7.2 Noise Surveys

In order to document existing community and environmental noise challenges and assist in, for example, land usage planning, properly conducted noise surveys are important. Adequacy of the noise survey parameters will change according to the specific issue and other legal or regulatory requirements. However, careful consideration of number of measurement locations, survey time and duration, appropriate measures, and other measurement parameters is important. In residential surveys, measurements are often made a prescribed distance from a property line. The survey may need to be made during different times of day or seasons and under different meteorological conditions, some of which favor sound propagation to the receiver. A log of individual noise events, such as aircraft flyovers, can form an important part of the survey.

Whatever the specifics of the measurements, an environmental survey report should include not only the data but also information essential to their interpretation. This includes (see Bies and Hansen, 2009, p. 185)

- Reference to the appropriate regulatory document(s)
- Measurement dates, times, and measurement locations
- Local meteorology (wind, temperature, humidity, precipitation) during the survey
- Noise source descriptors
- Instrumentation (type and orientation of meter or microphone and acquisition system, presence of windscreen, etc.)
- Types of noise data recorded
- Impact of extraneous noise sources

13.8 SOUND INTENSITY MEASUREMENTS

13.8.1 Sound Intensity via the “ p - p ” Principle

Although sound pressure measurements are immensely useful in that they yield the sound field magnitude at the measurement location, they may not fully describe the sound

energy transmission for many types of sound fields. The acoustic intensity can be a very important measure in that it is potentially a three-dimensional vector measurement of the net sound energy flux.

Acoustic intensity was defined previously in Equation (13.3) as the sound power per unit area. The instantaneous intensity along direction x , with units of W/m^2 may be written as

$$I_{i,x}(t) = p(t)u_x(t) \quad (13.29)$$

where $p(t)$ and $u_x(t)$ are the time dependent pressure and particle velocity in the x direction. Of more practical measurement interest is the time-averaged intensity, which can be written as

$$I_x(t) = \frac{1}{T} \int_0^T p(t)u_x(t)dt \quad (13.30)$$

The measurement of $p(t)$ is obtained in straightforward fashion with a microphone; however, direct particle velocity measurements are more difficult. Particle velocity measurements have been obtained using ultrasonic transducers or hotwire techniques, and a commercial “ p - u ” probe exists (see Jacobsen and de Bree, 2005). However, the more common technique of obtaining $u_x(t)$ involves processing the pressure signals from closely spaced, well-matched microphones, that is, the “ p - p ” principle (see Fahy, 1995). This is represented schematically in Figure 13.16. The pressure at the center of the two microphones spaced Δx apart is obtained by averaging the pressure signals as

$$p(t) \approx \frac{p_1(t) + p_2(t)}{2} \quad (13.31)$$

FIGURE 13.16 Layout of two microphones used to obtain particle velocity and pressure estimates needed for calculating acoustic intensity.

and the particle velocity is estimated through Euler's equation

$$\frac{\partial p}{\partial x} = -\rho_0 \frac{\partial u_x}{\partial t} \quad (13.32)$$

which results in

$$u_x(t) \approx \frac{1}{\rho \Delta x} \int_{-\infty}^t [p_2(\tau) - p_1(\tau)] d\tau \quad (13.33)$$

For the case of a time-stationary signal, Fahy (1995) shows that the mean intensity in the x direction may be written as

$$I_x = -\frac{1}{\rho \Delta x T} \int_0^T p_1(t) \int_{-\infty}^t p_2(\tau) d\tau dt \quad (13.34)$$

In other words, the average intensity in a time-stationary field is obtained from averaging the product of one microphone's signal and the integrated signal from a second, closely spaced microphone.

Given the prevalence of real-time spectral analyzers, it is helpful to define intensity in terms of the Fourier transforms of the pressure signals. In the frequency domain, the complex intensity is defined as

$$I_C(f) = I(f) + jJ(f) \quad (13.35)$$

In Equation (13.35), $I(f)$ is the mean active intensity, and represents the in-phase components of the pressure and velocity signals, whereas $J(f)$ is the amplitude of the "reactive" intensity and represents the in-quadrature portions of the signals (see Fahy, 1995). The time average of the reactive intensity is zero; for additional information on its calculation and significance (see Fahy 1995; Jacobsen 1991; Mann et al., 1987). For the two microphones in Figure 13.16, the active intensity spectrum [the spectral form of Equation (13.34)] may be written as

$$I_x(f) = \frac{1}{2\pi f \rho \Delta x} \text{Im}\{G_{p_2 p_1}(f)\} \quad (13.36)$$

where $G_{p_2 p_1}(f)$ is the single-sided time-averaged cross spectral density between the two microphones. In the case of a multidimensional intensity probe, calculation of the intensity vector components is geometry-specific, but involves weighting cross-spectral components between various pairs. A method for deriving the calculation process that results in minimized least-square error has been proposed by Pascal and Li (2008).

13.8.2 Intensity Probes

There are several one and multidimensional intensity probes available. These come in various configurations. One- and three-dimensional sound intensity probes are shown in Figure 13.17. Alternate three-dimensional probes are displayed in Figure 13.18, which use four microphones located at the vertices of a regular tetrahedron. The probe at the left

FIGURE 13.17 One (two microphones) and three-dimensional (three orthogonal pairs of microphones) sound intensity probes, with the microphones in the face-to-face configuration and employing a solid spacer.

is the Ono Sokki Tetra-phone[®] and the probe at the right was developed for rocket noise measurements by Brigham Young University and GRAS Sound and Vibration (see Gee et al., 2009, 2010). Other possible configurations exist, such as those described by Pascal and Li (2008).

13.8.3 Systematic Measurement Errors

It is important to understand the possible sources of error in the intensity measurement technique. Some errors that arise include scattering from probe or holder surfaces and environmental effects, such as wind. These errors are field and measurement specific and are not treated further in this section. However, other systematic errors that arise are inherent in the finite-sum averaging and finite-difference that takes place. When the microphone

FIGURE 13.18 (a) Ono Sokki Tetra-phone, which uses four microphones in a side-by-side configuration and arranged in a regular tetrahedron. (b) Spherical intensity probe (along with a U.S. quarter for scale), developed by Brigham Young University and GRAS Sound and Vibration for rocket noise measurements. The microphones are arranged in a tetrahedral configuration on the surface of the sphere.

FIGURE 13.19 Diagram showing the process of finite differencing and summation. (a) for small separation distance, the two pressure estimates (black dots) can be used to accurately represent the pressure at the midpoint between the microphones. (b) the separation distance has increased and although finite-differencing results in a near-accurate slope estimate, the pressure average obtained will underestimate the true pressure.

separation distance is small relative to a wavelength, the two microphones can be used to adequately represent the average pressure and the pressure gradient between the two microphones. However, as frequency and/or separation distance is increased such that the distance relative to a wavelength increases, errors result. Although there are errors associated with both the finite-differencing and summation, it is the latter that primarily causes the estimate of the intensity to be too low, as is illustrated in Figure 13.19.

The error in intensity magnitude for different sensor spacings (Δx) is shown in Figure 13.20. The magnitude errors grow as a function of frequency and microphone

FIGURE 13.20 Error in intensity magnitude for ideal intensity probes with different microphone spacings. This underestimation of acoustic intensity at high frequencies is directly related to an underestimation in the acoustic pressure, based on the separation of the microphones.

spacing. Jacobsen et al. (1998) have found that, in practice, probes that employ solid spacers with the microphones in the face-to-face configuration have a resonance phenomenon that partially counteracts the finite summation bias error and extends the probe's useable bandwidth. It is also worth noting that the phase errors introduced by the “ p - p ” measurement principle are zero for the case of the plane progressive wave and planar interference fields, provided that the sensor separation distance is less than a half wavelength, at which point spatial aliasing begins to occur.

13.8.4 Transducer Mismatch

Another source of error is transducer or instrumentation system mismatch. Any amplitude or phase mismatch will result in errors in the estimation of p or u , which translate into intensity amplitude and/or direction errors. The intensity magnitude error for a progressive plane wave propagating along the probe axis with channel phase mismatch of 0.1° is shown in Figure 13.21. The figure shows the increased error as frequency and sensor spacing decreases, as the acoustic phase difference between channels becomes progressively smaller and the phase error becomes relatively more important. In general, phase errors between measurement channels are frequency dependent and often grow as the low-frequency limit of the microphone is approached. For this reason, commercial intensity probes are sold with solid spacers of various lengths to provide accurate measurements at different frequency ranges.

In a field where both microphones are exposed to the same pressure, amplitude and phase, the time-averaged intensity should be zero. This can be seen from the fact that the imaginary part of the cross-spectrum between the two signals in Equation (13.36) is zero. However, for a real probe with slightly mismatched microphones measuring a uniform sound field in a small cavity, the phase error between the microphones results in a residual or “false” intensity measurement. For a given pressure amplitude, p , phase error, φ_{err} , and

FIGURE 13.21 Intensity magnitude error for plane wave propagation along the probe axis with 0.1° phase error between channels and various sensor spacings.

separation distance relative to wavelength, $k\Delta x$, the residual intensity error, I_{res} , can be expressed as

$$\frac{I_{\text{res}}}{p^2/(\rho c)} = \frac{\varphi_{\text{err}}}{k\Delta x} \quad (13.37)$$

The pressure-residual intensity index, which is a convenient way of expressing the phase error, is calculated as

$$\delta_{pI_{\text{res}}} = 10 \log_{10} \left[\frac{p^2/(\rho c)}{I_{\text{res}}} \right] \quad (13.38)$$

For example, a 0.1° phase error at 100 Hz for a 25-mm microphone spacing results in a pressure-residual intensity index of 14.2 dB. For the 50 Hz one-third-octave band, ANSI standard S1.9-1996 calls for a minimum pressure-residual intensity index of 7.0 dB for a Class 2 measurement system and 13.0 dB for a Class 1 system. Other specifications for probe and calibration and classification are provided within the standard.

13.8.5 Sound Intensity Applications

As discussed below, one application of sound intensity measurements is the measurement of sound power. Other applications include sound source characterization and localization and examination of energy flow. Near-field intensity vectors for the radiated noise from a small solid rocket motor at three different frequencies are shown in Figure 13.22 (see Gee et al., 2010). The intensity vectors reveal the directionality and magnitude of the sources. Another example is the graphical display of an intensity measurement system developed for NASA Glenn Research Center (see Dix et al., 2003). The system involves an intensity probe attached to a computer-controlled motion system that can be rapidly moved around

FIGURE 13.22 Measurement of vector sound intensity made near a rocket plume at three different frequencies. The vectors reveal the directionality and magnitude of the energy flow.

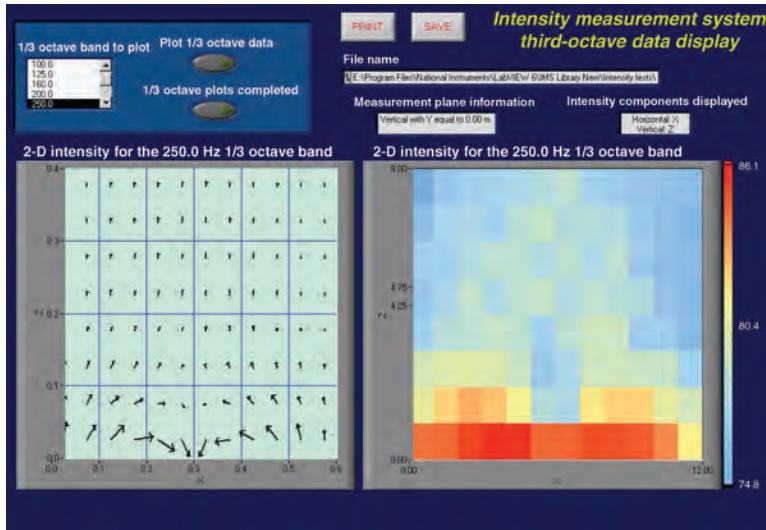

FIGURE 13.23 Graphical display of an automated sound intensity measurement system developed for NASA Glenn Research Center.

to produce results such as those shown in Figure 13.23. The sources in this case comprise three loudspeakers receiving the same source signal but with the middle speaker out of phase with the other two. The intensity vectors clearly reveal the source/sink nature of the near-field energy flow, which the intensity magnitude alone (shown to the right) does not.

13.9 SOUND POWER MEASUREMENTS

When considering acoustic radiation from a source, sound power measurements are often preferable to sound pressure measurements. The sound power corresponds to the amount of acoustic energy radiated per unit time, and can also be expressed as the integral of the acoustic intensity over the area through which the acoustic energy is radiated. It is expressed in units of watts (W). Unlike sound pressure, the measurement of sound power is independent of the distance from the source where the measurement is made. Furthermore, for many sources the sound power radiated is nearly independent of the physical location of the source. Thus, if the sound power is measured outdoors or inside a room the value will be nearly identical; however, if the sound pressure radiated from that same source is measured in those two environments, significantly different results would be expected.

The magnitude of the sound power varies tremendously for normally encountered sources. For this reason, it is convenient to express the sound power on a logarithmic scale and is referred to as the sound power level. The sound power level, L_W , is given by

$$L_W = 10 \log_{10} \left(\frac{W}{W_{\text{ref}}} \right) \quad (13.39)$$

where W is the sound power of the source in watts and W_{ref} is the reference sound power. For airborne applications, the reference sound power is usually taken to be 10^{-12} W.

Most sound power level measurements are obtained using pressure measurements, based on the relationship between the radiated power and the radiated pressure. For these measurements, the measurement can be categorized as a free field or a reverberant field condition.

13.9.1 Measurement of the Sound Power Level in a Free Field

The configuration corresponding to measurement of the sound power level in a free field is generally obtained in an anechoic chamber. An anechoic chamber has the property that there is no appreciable reflection from any of the walls of the chamber, generally obtained by constructing the walls with sound absorbing wedges. For a free field, the sound power can be obtained by integrating the sound intensity over an imaginary spherical surface of area $S = 4\pi r^2$ enclosing the source. If the measurement is in the far field, the intensity is directly related to the acoustic pressure. Thus

$$\begin{aligned} W &= \int_S \vec{I} \cdot d\vec{S} \\ &= \int_S \frac{p^2}{\rho c^2} dS \\ &= \frac{p_{\text{ave}}^2}{\rho c^2} S \end{aligned} \quad (13.40)$$

Using standard reference values (20 μPa for pressure and 10^{-12} W for power) allows the sound power level to be obtained from the *average* sound pressure level as

$$L_W = \bar{L}_p + 10 \log_{10} \left(\frac{S}{S_0} \right) \quad (13.41)$$

where S_0 is the reference area of 1 m^2 . The average sound pressure level is obtained using

$$\bar{L}_p = 10 \log_{10} \left(\frac{1}{N} \sum_{i=1}^N 10^{0.1 L_{pi}} \right) \quad (13.42)$$

Here, L_{pi} is the sound pressure level from the i th measurement location (in dB), usually measured in third-octave or octave bands and typically A-weighted, and N is the total number of measurement locations. The ISO standards outline the number of points that should be included in the measurement. There are also a number of standard measurement surfaces that are used.

For free-field measurements, the measurement surface is generally taken as an imaginary sphere. As the first step, an imaginary box (called the reference box) is constructed that is as small as possible but completely encloses the source of interest. The characteristic distance, d_0 , associated with this box is taken as the distance from the projection of the center of this box on the floor to one of the upper corners of the box. The radius of the measurement sphere, R , should then be at least $2d_0$. If the size of the source is large, relative to the available measurement space, then the measurements can be made on the surface of a large imaginary box surface. The measurement locations are chosen to represent equal area on the sphere or box.

For many sources, it is more practical to measure the sound power in a hemianechoic room or outdoors. The procedure for this measurement parallels that described above for

FIGURE 13.24 Basic sound power measurement positions that should be used for a hemispherical measurement surface. The two measurement locations on the backside of the hemisphere are displayed here in gray.

anechoic conditions, except that the measurement surface corresponds to either a hemisphere or a five-sided box. Several standards are available to guide the measurement of sound power for these conditions. Precision (or grade 1) methods yield reproducibility with a standard deviation of less than 1 dB, while engineering (or grade 2) methods and survey (or grade 3) methods yield reproducibility with a standard deviation of less than 2 dB or 3 dB, respectively.

Figure 13.24 shows the basic measurement positions that should be used for a hemispherical measurement surface. The engineering method described in ISO 3744 normally

Positions 1–10 are used for a hemispherical measurement surface of radius R , and positions 1–20 are used for a spherical measurement surface (the z -axis is the vertical axis).

FIGURE 13.25 The nine measurement positions used for sound power measurements if a box surface is implemented in a hemianechoic environment.

uses the 10 positions shown in this figure, while the survey method described in ISO 3746 only uses positions 4, 5, 6, and 10. The one restriction is that if the difference between any two sound pressure level measurements (in dB) exceeds the number of measurement locations, the number of locations must be increased. If a fully anechoic condition exists, so that a spherical measurement surface is used, the measurements in the lower hemisphere correspond to those on the upper hemisphere. The coordinates for all 20-measurement positions are given in Table 13.12. Figure 13.25 shows the nine-measurement positions used if a box surface is implemented in a hemianechoic environment.

13.9.2 The Reverberation Method

The sound power of an unknown source can also be determined in a reverberant environment. The concept behind this measurement is that the acoustic power radiated in this environment must equal the power absorbed by the surfaces of the test room. If the test room is a reverberation chamber, the sound is considered to be diffuse. For such a field, the sound power can be obtained directly from the sound pressure level in the room if the absorption of the room is known, which can be determined through measuring the reverberation time in the room. Since the room is never truly diffuse, the sound pressure level is obtained through the use of multiple pressure measurements, as outlined in the ISO 3741 standard.

Since the room response is never truly diffuse, the measurement of the sound power is generally more problematic with a narrowband sound source than a broadband source using the reverberation method. Thus, the reverberation method is more accurate for use with broadband noise, with the sound power being measured in octave bands or 1/3-octave bands.

In its simplest form, the sound power is obtained as

$$L_W = \bar{L}_p + 10 \log_{10} \left(\frac{A}{A_0} \right) - 6 \text{ dB} \quad (13.43)$$

where \bar{L}_p is the mean sound pressure level measured in the room (in dB), A is the total absorption in the room (m^2) obtained from measuring the reverberation time, and A_0 is the reference absorption, taken as 1 m^2 .

In practice, several corrections can lead to a more accurate measurement. Since the energy in the room is not truly diffuse, the standard requires the sound pressure

measurements to be at least 1.0 m away from the boundary. However, the energy density is greatest near the walls, so it has been found that the term $10 \log_{10}[1 + Sc/(8Vf)]$ can correct for this underestimate. To correct for air absorption in the room, the term $4.34A/S$ is added. Corrections for meteorological conditions can also be added, resulting in the sound power being obtained as

$$L_W = \bar{L}_p + 10 \log_{10} \left(\frac{A}{A_0} \right) + 10 \log_{10} \left(1 + \frac{Sc}{8Vf} \right) + 4.34 \frac{A}{S} - 6 + C_1 + C_2 \quad (13.44)$$

Here, S is the total surface area of the measurement room (m^2), V is the volume of the measurement room (m^3), f is the center frequency of the frequency band of interest (Hz), c is the speed of sound given by $c = 20.05 \sqrt{273 + \theta} \text{ m/s}$ (where θ is the temperature [$^{\circ}\text{C}$]), $C_1 = -10 \log_{10} \left(\frac{B \sqrt{T_0}}{B_0 \sqrt{T}} \right)$ (where B is the static atmospheric pressure, $B_0 = 1.013 \times 10^5 \text{ Pa}$, T is the temperature in K, and $T_0 = 313.15 \text{ K}$), and $C_2 = -15 \log_{10} \left(\frac{BT_1}{B_0 T} \right)$ (where $T_1 = 296.15 \text{ K}$).

13.9.3 Comparison Method

The sound power can also be determined through the use of the comparison method. This method is simple and accurate, but does require the use of a known reference power source. The reference power source, radiating reference sound power $L_{W,\text{ref}}$, is placed in the measurement volume and the sound pressure level, $L_{p,\text{ref}}$, associated with the reference power source is measured. The unknown source is then operated and the sound pressure level, L_p , is measured. The unknown sound power is then obtained as

$$L_W = L_{W,\text{ref}} + L_p - L_{p,\text{ref}} \quad (13.45)$$

For accurate results, the test room should be hard-walled with no major absorbing surfaces. The volume must exceed 40 times the volume of the reference box, a minimum of three microphones must be used (which remain in the same locations for both measurements), and the sound power should be processed in octave bands or 1/3-octave bands. If the unknown source is not movable, the reference sound source is located on top of the unknown source.

13.10 SOUND EXPOSURE MEASUREMENTS

Two acoustical quantities that are important to determining hearing risk and appropriate conservation procedures are the sound exposure and noise dosage. Additional information on these measurements can be found in Kardous (2007) and Marsh and Richings (1998).

13.10.1 Sound Exposure Level

The sound exposure, with W -type weighting filter applied, is defined for an event occurring over time T as

$$E_W = \int_0^T p_W^2(t) dt \quad (13.46)$$

where $p_w(t)$ is the instantaneous weighted pressure. The most common weighting applied in this situation is A-weighting. Without a weighting filter applied, this quantity is related to the total acoustic energy incident on a receiver. From the sound exposure in Equation (13.46), the W-weighted sound exposure level (SEL) is calculated as

$$\text{SEL}_W = 10 \log_{10} \left(\frac{E_W}{E_{\text{ref}}} \right) \quad (13.47)$$

where E_{ref} is the reference sound exposure of $400 \mu\text{Pa}^2/\text{s}$.

Relationships between sound exposure, the SEL and the L_{eq} defined previously in Equation (13.14) can be stated. First, the SEL can be calculated from the L_{eq} of the same weighting as

$$\text{SEL} = L_{\text{eq}} + 10 \log_{10}(T) \quad (13.48)$$

Alternatively

$$\text{SEL} = p_{\text{ref}}^2 \times T \times 10^{0.1L_{\text{eq}}} \quad (13.49)$$

Although the international standard unit for sound exposure is the squared-pascal second, a second unit, the squared pascal hour (Pa^2/h), is also used. This is a convenient unit for measuring workplace noise exposure, particularly since an A-weighted sound exposure of $1 \text{ Pa}^2/\text{h}$ is nearly equal to a constant level of 85 dB over an 8-h working day.

13.10.2 Noise Dosage

The noise dose is a metric used to quantify noise exposure in the workplace. According to ANSI S1.25, the noise dose for an 8-h workday and exchange rate, Q , is defined as

$$D_Q = \frac{100}{8} \int_0^T 10^{[(L_A(t) - L_C)/q]} dt \quad (13.50)$$

where t is measured in hours and T is the measurement duration. In Equation (13.50), $L_A(t)$ is the slow or fast A-weighted sound level in decibels, provided that the level is greater than a selected threshold level, or is $-\infty$ if below the threshold. The level, L_C , is the criterion sound level that defines 100% noise dosage and $q = Q/\log(2)$, where Q is the exchange rate of 3, 4, or 5 dB. The exchange rate is the change in sound level that corresponds to a doubling or halving of the sound exposure duration while maintaining a constant percentage of criterion exposure. For Occupational Safety and Health Administration (OSHA) regulations, the threshold level is 80 dBA, the criterion level is 90 dBA, and the exchange rate is 5 dB. The exchange rate for the National Institute of Occupational Safety and Health (NIOSH) and most international standards is given as 3 dB.

An alternate method of calculating noise dosage is defined for a workday with noise exposure at different levels for discrete intervals. In this case

$$D = 100 \times \sum_i \frac{t_i}{T_i} \quad (13.51)$$

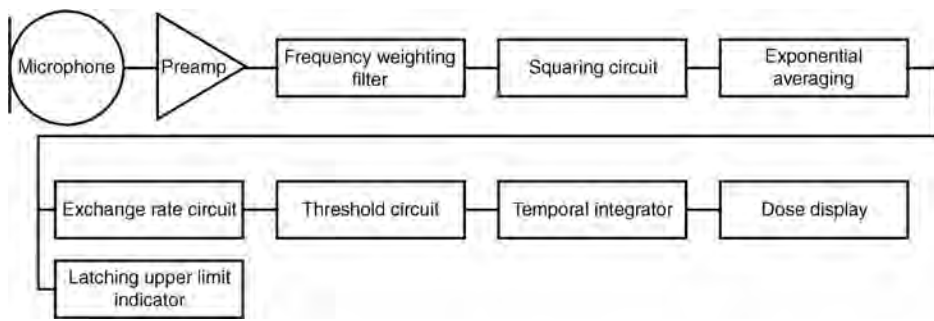

FIGURE 13.26 Elements of a noise dosimeter.

where t_i is the exposure time in hours and T_i is the allowable (100% dosage) duration for exposure at that level. Values for T_i can be calculated for an 8-h workday as

$$T = \frac{8}{2^{[(L-L_c)/Q]}} \quad (13.52)$$

(see Appendix A of OSHA 29CFR 1910.95 regulation).

13.10.3 Equipment

Personal sound exposure meters and noise dosimeters are used to assess noise exposure in the work place. The essential elements of the dosimeter are shown in Figure 13.26 and a typical class-2 dosimeter is displayed in Figure 13.27. ANSI standard S1.25 indicates that a dosimeter should allow for A or C weighting, and fast and slow exponential averaging.

FIGURE 13.27 A Class 2 Larson Davis noise dosimeter with microphone inserted in a calibrator (Photo courtesy of Chuck Kardous, NIOSH).

FIGURE 13.28 Noise dosimeter being worn (Photo courtesy of Churck Kardous, NIOSH).

It should also permit a criterion level of 95, 85, 84, 80, or variable dB, a threshold level of 90, 80, or variable dB, and an adjustable exchange rate of 3, 4, or 5 dB. The standard also specifies that the dosimeter should properly measure impulsive noises up to 140 dB, the maximum allowable peak sound level without hearing protection. NIOSH has shown that many dosimeters have issues with these high-level measurements (Kardous and Willson, 2004).

The noise dosimeter may be used to monitor the noise environment in an area or worn as a personal dosimeter. In this case, the ANSI S12.19 standard specifies that the microphone should be located on the middle-top of a worker's shoulder and should be oriented approximately parallel to the shoulder's plane. This is shown in Figure 13.28. The amount that the person affects the noise level measured depends on, for example, the noise spectrum, absorption due to clothing, angle of incidence, and microphone orientation. The increase may be as much as 5 dB, but an increase in level of around 1 dB is typical.

SUMMARY

The requirement to measure temperature arises in process control, production, environmental observation, and laboratory research. The range of techniques available for measuring temperature is extensive. Many phenomena are dependent on temperature and this can be exploited in instrumentation. A given application may permit direct contact between a measuring device or system and the medium of interest. Alternatively, remote observation of, for example, infrared radiation or fluorescence may be possible using an optical system. This chapter outlines various forms of invasive, semi-invasive, and non-invasive temperature measurement devices and systems. In addition, this chapter describes the fundamental definitions of temperature and the issues that need to be considered in determining the temperature of a given medium, be it a solid body, surface, liquid, or gas.

14.1 INTRODUCTION

Temperature can be defined qualitatively as a measure of hotness of a body. Temperature is the property that determines whether a system is in thermal equilibrium with other systems. If the temperature of two bodies in thermal contact with each other is same, then there will be no net transfer of thermal energy. Quantitatively, temperature can be defined from the second law of thermodynamics in terms of the rate of change of entropy with energy.

To allow the assignment of numerical values to bodies at different temperatures, some form of temperature scale is necessary. The SI unit of the thermodynamic temperature scale is the kelvin, with symbol K. This is defined in terms of the interval between absolute zero, 0 K, and triple point of pure water, 273.16 K. The kelvin is defined as the fraction $1/273.16$ of the temperature of a system exhibiting the triple point of water. Other temperature units are also in common use including the Celsius, Fahrenheit, and Rankine temperature scales. Conversion equations for these are given in Equations (14.1)–(14.3).

$$t = T - 273.15 \quad (14.1)$$

$$T_{\circ F} = 1.8t + 32 \quad (14.2)$$

$$T_{\circ R} = T_{\circ F} + 459.67 \quad (14.3)$$

where, t is the temperature in degrees Celsius ($^{\circ}\text{C}$), T the absolute temperature (K), $T_{\circ F}$ the temperature in degrees Fahrenheit ($^{\circ}\text{F}$), and $T_{\circ R}$ the temperature in Rankine scale ($^{\circ}\text{R}$).

The thermodynamic temperature scale is defined by means of theoretically perfect heat engines. These are not practically realizable, and the International Temperature Scale of 1990, see Preston-Thomas (1990), denoted by ITS-90, was developed as a practical best approximation using available technologies to the thermodynamic temperature scale. Its range of application extends from 0.65 K up to the highest temperature practically measurable using Planck's law of thermal radiation. The ITS-90 is believed to represent thermodynamic temperature to within ± 2 mK from 2 K to 273 K, ± 3.5 mK at 730 K, and ± 7 mK at 900 K (one standard deviation limits; see Mangum and Furukawa, 1990). The ITS-90 is constructed using a number of overlapping temperature ranges. This leads to some ambiguity, albeit small, in the true value of a temperature across an overlapping region but allows greater flexibility in the use of the scale. The ranges are defined between

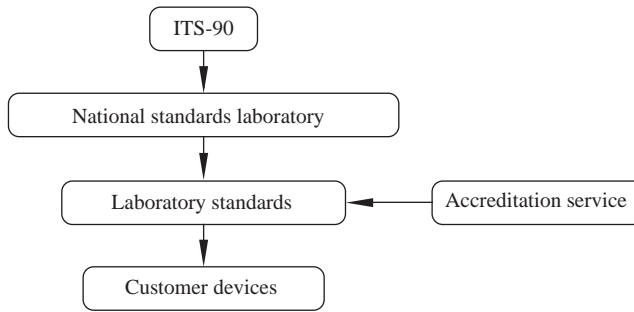

FIGURE 14.1 Traceability between customer devices and the ITS-90.

repeatable conditions using a variety of specified materials at their melting, freezing, and triple points. The ITS-90 was developed under the auspices of the Metric Treaty and the associated consultative committees, BIPM (Bureau International des Poids et Mesures), CIPM (Comité International des Poids et Mesures), and CCT (Comité Consultatif de Thermométrie) and was adopted by the International Committee of Weights and Measures in 1989.

The principal role of the ITS-90 in practical measurement is to allow a means of traceability between the measurement that is actually made and the temperature scale defined by the ITS-90. Thermometers or systems used in defining the ITS-90 are unlikely to be used to measure the temperature of a system of interest. Instead a thermometer can be used that has been calibrated against another device calibrated using guidelines specified in ITS-90. Calibration is the process of relating the output value from a measurement system to a known input value. The schematic given in Figure 14.1 illustrates this process whereby there is a transfer of calibration between practical and specialist devices. The chain between the thermometer in use and the ITS-90 may in practice have more links than those shown in the diagram; each link tending to increase the uncertainty associated with the measurement.

14.1.1 The Measurement Process

A measurement provides information about a property and gives magnitude to that property. Temperature can be measured by observing physical phenomena that is temperature dependent. This may involve inserting a probe containing a transducer into the medium of interest and relating the observed effect on the transducer to temperature. A measurement system may comprise a transducer to convert a temperature-dependent phenomena into a signal that is a function of that temperature, a method to transmit the signal from the transducer, some form of signal processing, a display and method of recording the data. In a given application some of these functions such as data recording may be undertaken by the sensor system itself or by a human operator. A calibration is used to convert the measured quantity into a value of temperature. The significance of temperature can then be considered. The related subject of heat flux measurement is reviewed by Childs et al. (1999).

Whenever a measurement is made it is unlikely that the measured value will equal the true value; the actual or exact value of the measured variable. The difference between the measured value and the true value is the error. There are a number of reasons why a

measured value will not equal the true value and many of these can be inferred by considering the measurement process. The insertion of a transducer, or sometimes even thermal interactions between a remote sensor and an application, will result in disturbance to the temperature distribution in an application. The magnitude of this disturbance will depend on the heat transfer processes involved. Natural instabilities associated with the transducer and signal-measuring devices also contribute to a deviation between the true and measured values. Further deviations between the measured and true values are due to the processing of the signal and data and uncertainties arising from the calibration process.

14.1.2 Calibration

Calibration can be achieved in a number of ways. The sensor to be calibrated can be placed in an environment at a known temperature such as one of the fixed points, for example, the triple point of water. The output from the sensor can be recorded and, within the uncertainties associated with the temperature of the fixed point, taken as an indication of that temperature. The sensor can then be exposed to a different temperature using a different fixed point, for example, the melting point of gallium, and the process repeated. For intermediate values of temperature between the fixed points, the special interpolation equations documented in the ITS-90 can be used. The process described so far is appropriate for producing a sensor with very low uncertainty capability. This, however, is an expensive undertaking and is rarely necessary for the majority of scientific and industrial applications. Instead, a sensor that has been calibrated in this way and is stable is used to calibrate another sensor by comparison. The calibrated and uncalibrated sensors are placed in thermal contact in an enclosure such as a bath of liquid or in a specially constructed heating block or furnace. The medium is heated and the output of both the calibrated and the uncalibrated sensor is recorded. The output from the uncalibrated sensor can then be related to the temperature indicated by the calibrated sensor. In this way a transfer between values of temperatures set up in the ITS-90 and sensors used in practice can be achieved as illustrated schematically in Figure 14.1. It is normally recommended that there should be no more than three or four links between a practical measurement and the ITS-90. The details of the calibration process depend partly on the type of sensor concerned typically involving established procedures for record keeping, inspection and conditioning of the sensor, generic checks, intercomparison either with another sensor or with a medium at a known temperature, analysis of the data, quantification of uncertainties, and completion of records.

Traceability involves ensuring that appropriate procedures have been followed, and in the current industrial setting, this is typically associated with quality standards. Two approaches can be adopted. The first involves following a set of standards and obtaining the appropriate approval and registration certificates for that quality system. The second approach is to accept the principles of the process commended within quality standards and to follow them closely to be able to state that the spirit of the standard has been followed. This latter approach negates the need for registration to a standards system but does require a level of trust.

The difference between a measurement and the true value of temperature is known as the error. The term uncertainty can be used to quantify confidence in the measurement indicated by a sensor. For instance, a sensor may be supplied with a 95% confidence interval uncertainty of $\pm 1.5^\circ\text{C}$. This means that, provided the device does not disturb the temperature distribution in the medium of interest, measurements made will be within 1.5°C of the true value, for 95% of the measurements made. The term uncertainty is used in

preference to accuracy as the latter should generally be reserved for qualitative use. The subject of measurement uncertainty is addressed comprehensively by Figliola and Beasley (2005).

14.2 SELECTION

The selection of a specific sensor or system for temperature measurement can require consideration of a number of aspects including

- uncertainty,
- temperature range,
- thermal disturbance,
- level of contact,
- size of the sensor,
- transient response,
- sensor protection,
- availability,
- cost.

For many applications there is often more than one method that will provide an adequate determination of temperature. A key consideration is application, whether the measurement is of a liquid, gas, solid body, or surface.

The measurement of temperature of a solid material can be achieved in several ways. A transducer can be embedded in the material by forming a hole, inserting the device and, in the case of an electrically based transducer, feeding the wires out through the drill hole. This method can also be used for liquid-in-glass or bimetallic thermometers where the stem of device is inserted to a specific depth bringing the transducer into thermal contact with the region of interest. In the case of a liquid-in-glass thermometer, the device may have to be removed from the application in order to reveal the scale to enable the temperature to be read against the scale. It is important that the transducer is in good thermal contact with the solid body in order to ensure that the transducer takes up the local temperature. Thermal contact can be improved in some cases by filling the hole or pocket with high thermal conductivity oil, or other liquid, which will provide a much better conduction path than if a gas is filling the space between the probe and the hole walls. Errors arising from the effects of unwanted heat conduction along the connecting wires, or the presence of the probe, should be minimized, subject to the requirements of the measurement.

Surface temperatures can be measured by attaching a sensor to the surface, drilling or forming a channel on the underside of the surface and attaching a sensor, by applying a temperature sensitive paint to the surface, or by observing the surface remotely using, say, an infrared thermometer. For approximate assessment of surface temperature, bimetallic thermometers are available with flat bases, spring clips, and permanent magnets. However, if a substantial temperature difference exists between the surface and the immediate surroundings, uncertainties can arise. Thermocouples, platinum resistance thermometers, or thermistors equipped with flat or suitably formed pads can also be considered. To obtain the best uncertainty with applied probes it is usually advantageous if they are small, and perhaps also recessed in shallow grooves. An alternative method of surface

temperature measurement is the noninvasive techniques of infrared radiation or thermal imaging. These techniques may be more expensive to implement. At the other end of the scale, there is frequently a need to obtain a quick and uncomplicated way of checking the temperature of a surface. Temperature indicating paints can be applied very readily to provide an indication of the temperatures that are being encountered. The measurement of the temperature of a surface that is in thermal contact with a gas and also exchanging thermal radiation with its surroundings is subject to a series of processes that could contribute to deviations between the measured temperature and that of the undisturbed object.

The measurement of liquid temperatures usually involves using a transducer that is immersed in the liquid. If a simple visual indication is required a liquid-in-glass thermometer can be considered. Extremely low uncertainty is possible with an appropriate, calibrated instrument. If a larger indicator is required a bimetallic thermometer might be suitable. Bimetallic thermometers are robust and self-contained. However, in many cases, an electrical signal is required for processing, recording, or controlling purposes. Electrically based devices include thermocouples and resistance thermometers. The actual device will be dependent on the temperature range and the precision required. If the temperatures are changing with time, the response characteristics of the sensor and system must be adequate. Thermocouples or resistance temperature detectors will probably be

TABLE 14.1 Approximate Temperature Measurement Range Capabilities for Different Methods

Method	Minimum Temperature (°C)	Maximum Temperature (°C)

the best choice if a particularly rapid response is needed. Infrared thermometers can be used to measure the surface temperature of molten materials such as metals and glass.

Many of the considerations that influence the measurement of liquid temperatures also apply to measuring the temperature of a body of gas. If the gas is moving then there is potential for heat transfer due to conduction along the sensing probe, connection wires, and supports, which can lead to significant errors, unless accounted for. In addition, if the gas is at a different temperature to the surrounding surfaces then thermal radiation exchanges will occur between the sensor and surfaces, again leading to a deviation between the indicated temperature and the gas temperature unless accounted for. High gas velocities can give rise to dynamic heating with an immersed sensor and due allowance must be made for this effect. For simple, isolated measurements, liquid-in-glass or bimetallic thermometers may well be suitable. If electrical signals are required, the choice again lies between thermocouples, platinum resistance thermometers, thermistors, or transistor instruments. If protection has to be added, the increase in thermal mass and thermal resistance will tend to degrade the response of the sensor more seriously in a gas than in a liquid. For some gas temperature measurements, generally associated with combustion processes, it may be undesirable or impossible to use conventional sensors and cooled devices or a noninvasive technique may be suitable.

An indication of the temperature range of a variety of methods is given in Table 14.1.

14.3 INVASIVE TEMPERATURE MEASUREMENT

One option for measuring temperature is to locate the sensor in the medium of interest or on its surface. The sensor will, due to its presence, alter the distribution of temperature within the medium. This is due to differences in the thermal conductivity and heat capacity of the sensing device and the medium of interest. As a result, the installation of sensor in or on a solid or fluid can be classified as invasive. A wide range of invasive sensors are available including liquid-in-glass thermometers, manometric thermometers, bimetallic thermometers, thermocouples, resistance temperature devices such as PRTs and thermistors, noise thermometers, and pyrometric cones. These are described in Sections 14.3.1–14.3.9.

14.3.1 Liquid-in-Glass Thermometers

Liquid-in-glass thermometers exploit the higher volumetric expansion of liquids with temperature in comparison with that of solids. A liquid-in-glass thermometer typically consists of a reservoir and capillary tube containing a thermometric liquid, supported in a stem with a temperature-indicating scale. On heating, the volume of the liquid increases relative to that of the container and the liquid expands up the capillary tube. Liquid-in-glass thermometers can be used from approximately -196°C to 650°C , although no single instrument is capable of measuring temperature across the whole range because of the limitations of the thermometric liquids. Liquid-in-glass thermometers do not require an external power supply and can be relatively inexpensive. As glass is generally chemically stable, these thermometers can be used in a wide variety of chemical environments. Their disadvantages include fragility and the lack of remote logging capability.

In the case of a solid stem thermometer the bulb reservoir is usually a thin glass container with 0.35–0.45 mm thick walls holding a thermometric liquid such as mercury,

ethanol, pentane, toluene, or xylene. The choice of the liquid depends on the desired temperature range

- mercury, -35°C to 510°C ,
- ethanol, -80°C to 60°C ,
- pentane, -200°C to 30°C ,
- toluene, -80°C to 100°C ,
- xylene, -80°C to 50°C .

The space above the thermometric liquid can be evacuated or filled with an inert gas. As the temperature of the liquid in the bulb rises, the liquid will expand and some of it will be forced up the capillary. The temperature of the bulb is indicated by the position of the top of the meniscus, in the case of a mercury thermometer, against markings engraved on the stem.

Liquid-in-glass thermometers can be calibrated at a number of fixed points and a scale subsequently applied to the stem supporting the capillary tube to indicate the value of temperature. The uncertainty of industrial glass thermometers depends on the device concerned with values ranging from $\pm 0.01^{\circ}\text{C}$ to $\pm 4^{\circ}\text{C}$ (see for example BS 1041 (1985)). The use of liquid-in-glass thermometers is reviewed by Ween (1968), Wise (1976), Nicholas and White (1994), Nicholas (1999), and Childs (2001a,b).

Mercury-in-glass thermometers are increasingly being replaced by resistance-based temperature devices, which have cost and environmental advantages, and by infra-red devices, giving a digital readout and noninvasive measurement, or by thermally sensitive paint devices, which give a visible color-based indication of temperature.

14.3.2 Manometric Thermometry

Methods of temperature measurement based on the measurement of pressure are known as manometric thermometry. There are two principal categories: gas thermometry and vapor pressure thermometry.

Gas thermometry is based on the ideal gas law:

$$pV = n\Re T \quad (14.4)$$

where p is the pressure (N/m^2); V the volume (m^3); n the number of moles of the gas ($n = m/M$ (m = mass, M = molar mass)); \Re the universal gas constant (8.314510 J/mol K (Cohen and Taylor, 1987, 1999), and T the temperature (K).

By assuming values for the quantity of mass and for the gas constant, the temperature is obtained by measuring pressure and/or volume. The basic components of a gas thermometer are enclosures to hold the gas sample of interest, under carefully controlled conditions, and a flow circuit to allow the pressure to be measured. Gas thermometers can be used for applications from a few K to 1000 K. The principal application has been in cryogenics, and the gas enclosure, commonly known as the bulb, is usually located within a cryostat. Figure 14.2 illustrates the principal components of a constant volume gas thermometer. Gas thermometry tends to be a specialist activity and is usually confined to standards laboratories and cryogenic applications.

FIGURE 14.2 Principal constant volume gas thermometer components.

Direct use of Equation 14.4 requires knowledge of the gas constant. To reduce uncertainty arising from uncertainty in the gas constant, a number of methods have been devised that eliminate the need for knowing the gas constant, operating on the principle of maintaining either constant pressure, constant volume, and/or constant bulb temperature. Such techniques include

- absolute PV isotherm thermometry,
- constant volume gas thermometry,
- constant pressure gas thermometry,
- constant bulb temperature gas thermometry,
- two bulb gas thermometry.

Uncertainty in the measurement of temperature using gas thermometry is a function of the care taken and the temperature range. Pavese and Steur (1987), for example, report an uncertainty of 0.5 mK for the temperature range 0.5–30 K.

Real gases do not behave exactly according to the ideal gas equation and the nonideal nature of real gases can be modeled using the virial equation

$$p = \left(\frac{\Re T}{V} + \frac{B(T)}{V^2} + \frac{C(T)}{V^3} + \frac{D(T)}{V^4} + \dots \right) \quad (14.5)$$

where $B(T)$, $C(T)$, $D(T)$, etc., are the second, third, fourth virial coefficients, and so on.

The saturation vapor of a pure substance above its liquid phase varies with temperature and is known with low uncertainty for a number of cryogenic liquids such as helium 3 and 4, hydrogen, neon, nitrogen, oxygen, argon, methane, and carbon dioxide. Measurement of the vapor pressure can therefore be used to determine the temperature and this technique provides a method with good sensitivity and requires relatively simple equipment.

Equations quantifying the relationship between pressure and temperature for a variety of cryogenic liquids are given in Pavese (1999), and vapor pressure thermometry is described in detail by Pavese and Molinar (1992).

14.3.3 Bimetallic Thermometers

A bimetallic thermometer consists of two strips of materials, typically two different types of metal that are bonded together. When heated, the assembly will deform due to a mismatch of the coefficient of linear expansion between the two materials. If one end is fixed, then a needle mounted on the other end can be used to indicate the temperature against a calibrated scale. To maximize the bending of the assembly and hence the sensitivity of the device, materials with significantly different coefficients of expansion can be used. Table 14.2 lists some of the materials typically used in bimetallic thermometers.

A bimetallic strip can be coiled in a spiral or helical configuration in order to provide increased sensitivity for a given volume and this form is commonly used in dial thermometers. Dial bimetallic thermometers tend to be reasonable rugged devices and have the advantage that they do not need an independent power supply. A variety of options are typically available for attaching the instrument to an application including magnetic bases and clips.

The uncertainty of typical commercial bimetallic thermometers is 1–2% of the full-scale deflection with an operating range of -70°C to 600°C . The theoretical limit of operation however is from about -270°C to the elastic limit of available materials.

The general equations for defining the curvature of a bimetallic strip are developed in Timoshenko (1953) and Childs (2001a,b). An advanced design device with a sensitivity of $0.0035^{\circ}\text{C}/\text{mm}$ and a repeatability of 0.027°C was demonstrated by Huston (1962). The merits of bimetallic thermometers include that they can be easily read, can be used as an indicator of temperature or as an actuator, are relatively inexpensive and do not require an independent power supply. Their disadvantages include that they are subject to drift, the measurements are usually relatively uncertain in comparison to, say, thermocouples and industrial PRTs and they cannot provide a remote indication of temperature.

FIGURE 14.3 Simple practical thermocouple circuit. T_1 = the temperature at the thermoelectric junction. T_0 = temperature at the terminus connections (Childs, 2001a,b).

14.3.4 Thermocouples

In its simplest practical form a thermocouple can consist of two dissimilar wires connected together at one end with a voltage measurement device across the free ends, as indicated in Figure 14.3. A net electromotive force (emf) due to the Seebeck effect will be indicated by the voltmeter, which is a function of the temperature difference between the joint and the voltmeter connections. Thermocouples are widely used in industry and research with applications from -272°C to 2000°C . The merits of thermocouples are their relatively low cost, small size, rugged nature, versatility, reasonable stability, reproducibility, reasonable uncertainty, and fast speed of response. Although PRTs are more accurate and stable and thermistors are more sensitive, thermocouples are often a more economical solution than PRTs and their temperature range is greater than thermistors. The main disadvantage of thermocouples is their relatively weak signal, which makes the reading sensitive to electrical noise. For example, the output is about 4.1 mV at 100°C for a type K thermocouple. Other disadvantages include a nonlinear output that requires amplification, and calibrations can vary with contamination of the thermocouple materials, cold working, and temperature gradients.

The fundamental physical phenomenon exploited in thermocouples, discovered by Johann Seebeck, is that heat flowing in a conductor produces a movement of electrons and thus an electromotive force (emf). Seebeck demonstrated that a small current flowed through the circuit shown in Figure 14.4 when the temperature of the two junctions was different (Seebeck, 1823). The emf produced is proportional to the temperature difference

FIGURE 14.4 A current will flow through the above circuit that is proportional to the temperature difference between the two junctions (Childs, 2001a,b).

and is called the Seebeck emf or thermoelectric potential. As well as being a function of the net temperature difference, the magnitude of the emf produced is also a function of the materials used.

14.3.4.1 Thermocouple Analysis Thermocouple circuits can consist of the simple forms illustrated in Figures 14.3 and 14.4 or much more complex systems resulting from considerations of data logging and long distances between the point of interest and emf measurement. In this case, the use of thermocouple wire for the whole length may be prohibitively expensive and alternative materials, known as extension and compensation cable, can be used to convey the emf. In order to ensure correct assessment of the signal produced, the circuit must be analyzed. Analysis of a given thermocouple circuit can be undertaken using fundamental physical relationships (see for example Pollock, 1991; Barnard, 1972; Blatt et al., 1976; Bourassa, 1978; Mott and Jones, 1958). Alternatively, thermocouple behavior can be modeled in most applications using a number of laws or an algebraic technique. The thermocouple laws allow a quick common sense approach to be taken to practical temperature measurement and have been developed by a number of authors (e.g., Roeser, 1940; Doebelin, 1990; Childs, 2001a,b; ESDU, 2007a).

14.3.4.2 The Law of Interior Temperatures The thermal emf of a thermocouple with the junction at T_1 and terminus connections at T_0 is unaffected by temperature elsewhere in the circuit provided the properties of the two thermoelements used are homogenous. This requirement means that the physical properties of the wires must be constant with length. If the wire is stretched or strained in a region or the chemical makeup of the wire varies along its length, this will affect the thermoelectric output and could invalidate the law. The law of interior temperatures is illustrated in Figure 14.5. Provided the wire is uniform and homogenous on both sides of the hot spot, then no net emf is generated by the hot spot. The thermocouple will respond only to the temperature difference between the thermoelectric junction and the terminus connections. This result is particularly significant as it means that the emf from a thermocouple is not dependent on intermediate temperatures along a thermoelement.

14.3.4.3 The Law of Inserted Materials If a third homogenous material C is inserted into either thermoelement A or B, then, as long as the two new thermoelectric junctions are at the same temperature, the net emf of the circuit is unchanged irrespective of the

FIGURE 14.5 Illustration of the law of interior temperatures. The thermocouple is unaffected by hot spots along the thermoelement, and the reading is only a function of T_1 and T_0 (Childs, 2001a,b).

FIGURE 14.6 Illustration of the law of inserted materials. The thermocouple is unaffected by the presence of the inserted material and any local hot spot.

temperature in material C away from the thermoelectric junctions. This law is illustrated in Figure 14.6 where a third material is inserted into the thermoelement A and then heated locally. Provided the thermoelectric junctions between C and A are both at the same temperature, the net emf of the thermocouple is unaffected by the presence of the inserted material and any local hot spot as the emf excursion between 2 and 3 is cancelled by that between 3 and 4.

14.3.4.4 The Law of Intermediate Materials If material C is inserted between A and B, the temperature of C at any point away from the junctions A–C and B–C is not significant. This law is illustrated in Figure 14.7. Here an intermediate thermoelectric material is inserted between the two thermoelements. As there is no thermal gradient across the new thermoelectric junctions then the presence of the inserted material does not contribute to the net emf produced by the thermocouple. This law is of great practical significance as it allows us to model the implications of manufacturing techniques used to form thermoelectric junctions. Provided there is no thermal gradient across the thermoelectric junction it does not matter if the thermoelements are joined by a third material such as solder or if local thermoelectric properties are changed at the junction by, for instance, welding.

FIGURE 14.7 Illustration of the law of intermediate materials. As there is no thermal gradient across the new thermoelectric junctions the presence of the inserted material does not contribute to the net emf produced by the thermocouple.

14.3.4.5 Modeling Fundamental Thermoelectric Phenomena An assessment of the fundamental thermoelectric phenomena can be made. These are the Seebeck, Peltier, and Thompson effects but in practical thermocouple circuits, the contribution of the Peltier and Thompson effects is insignificant. The Seebeck effect is the generation of emf in a conductor whenever there is heat transfer and is a consequence of electron movements when heat transfer occurs. An emf will be generated in a material whenever there is a temperature difference in the material and its magnitude will be a function of the temperature difference and the type of material. The Seebeck coefficient is a measure of how the electrons are coupled to the metal lattice and grain structure. It is sensitive to changes in the chemical and physical structure of the solid and will alter if the material is contaminated, oxidized, strained, or heat treated. Data for thermocouple materials normally uses the relative Seebeck coefficient, stating the Seebeck coefficient relative to platinum.

The Seebeck coefficient is defined by Equation (14.6) and is a transport property of all electrically conducting materials.

$$S(T) = \lim_{\Delta T \rightarrow 0} \frac{\Delta E}{\Delta T} = \frac{dE}{dT} \quad (14.6)$$

where S is the Seebeck coefficient ($\mu\text{V/K}$); ΔT the temperature difference across a segment of the conductor (K); and ΔE the absolute Seebeck emf (μV).

The Seebeck coefficient cannot be measured directly. Instead it must be determined by measuring the Thomson coefficient and using a thermodynamic relationship. The Seebeck coefficient varies with temperature so it must be mathematically defined by the gradient dE/dT at a specific temperature.

Rearranging Equation (14.6) allows modeling of the net thermoelectric emf generated by a practical thermocouple circuit:

$$dE = S(T)dT \quad (14.7)$$

If the circuit comprises two materials, A and B, then

$$E = \int_{T_1}^{T_2} S_A dT - \int_{T_1}^{T_2} S_B dT = \int_{T_1}^{T_2} (S_A - S_B) dT \quad (14.8)$$

where E is the thermoelectric emf (μV); S_A the Seebeck coefficient for material A ($\mu\text{V/K}$) and S_B the Seebeck coefficient for material B ($\mu\text{V/K}$).

In Equation (14.8), a difference in the Seebeck coefficients in the two thermoelements appears. It is this difference that is of practical interest in thermocouple thermometry, and it is called the relative Seebeck coefficient. The relative Seebeck coefficient is normally determined with respect to a reference material such as platinum.

$$S_{\text{APt}} = S_A - S_{\text{Pt}} \quad (14.9)$$

$$S_{\text{BPt}} = S_B - S_{\text{Pt}} \quad (14.10)$$

$$S_{\text{AB}} = S_A - S_B = S_{\text{APt}} - S_{\text{BPt}} \quad (14.11)$$

TABLE 14.3 Values of the Seebeck Coefficient for Various Materials.

Material	20°C	1000°C

Source: After Bentley (1998).

where S_{APt} is the Seebeck coefficient for material A relative to platinum ($\mu\text{V/K}$); and S_{BPt} the Seebeck coefficient for material B relative to platinum ($\mu\text{V/K}$).

Values for the Seebeck coefficient relative to platinum are listed in Table 14.3 for a variety of materials.

Substituting for S_A and S_B in Equation (14.11) gives

$$E = \int_{T_1}^{T_2} S_{AB} dT \quad (14.12)$$

and if the relative Seebeck coefficient can be taken as constant over the temperature range then

$$E = S_{AB}(T_2 - T_1) \quad (14.13)$$

Equation (14.13) is particularly useful as it allows the analysis of a wide range of circuits. This can be achieved using loop analysis. In loop analysis the contribution of emf due to the thermal gradient across each element is summed together to produce the total emf that would be indicated by a voltage-measuring device.

The influence of connection leads shown in Figure 14.8 on the output can be analyzed using Equation 14.13. If identical conductors are used, then by using loop analysis

$$E = S_C(T_1 - T_0) + S_A(T_2 - T_1) + S_B(T_1 - T_2) + S_C(T_0 - T_1) \quad (14.14)$$

This simplifies to

$$E = S_{AB}(T_2 - T_1) \quad (14.15)$$

The output emf is therefore dependent only on the temperature difference between the thermoelement junction and the terminus junctions. In other words, the temperature

FIGURE 14.8 Use of connection leads for a thermocouple.

of the connections at the multimeter or data logger does not contribute to the emf produced by the thermocouple circuit. In effect the reference temperature T_1 has been moved from the data logger to the terminus connections.

Use of the circuit illustrated in Figure 14.8 requires the temperature T_1 to be known. This can be achieved by using an alternative method of temperature measurement at this junction such as a thermistor or PRT. Alternatively, the terminus connections can be submerged in an ice bath. The temperature at T_1 will then be known and at 0°C .

In practical use, it is uncommon to need values for the Seebeck coefficients. Instead, the emf temperature characteristics of certain selected thermocouples have been identified under controlled conditions and standardized and this data can be used. If, however, you are involved in the design of a new type of thermocouple or some unusual application, data for Seebeck coefficients of a wide range of materials is tabulated in Pollock (1991) and Mott and Jones (1958).

14.3.4.6 Thermocouple Types There are hundreds of types of thermocouple that have been developed. In principle, almost any dissimilar metals and even semiconductors can be used to form thermocouples. The wide scope of alloys indicates the range possible. Kinzie (1973) for example lists more than 300 combinations of materials for thermocouples. A series of international and national standards are however available for thermocouples listing just eight combinations of materials that are widely used. Stringent guidelines are provided for these thermocouples to ensure that devices that are manufactured to be compatible with the specific standard concerned from one company perform in a similar fashion to those manufactured by another company.

The eight standardized thermocouples fall into three general categories:

1. rare metal thermocouples (types B, R, and S),
2. nickel-based thermocouples (types K and N),
3. constantan negative thermocouples (types E, J, and T).

In the rare metal group, types B, R, and S are based on platinum and its alloys with rhodium. These are the most stable of the standard thermocouples and can be used at high temperatures (up to 1750°C) but are generally more expensive and sensitive to contamination. In nickel-based thermocouples, types N and K are commonly used for applications not requiring the elevated temperature range of the rare metal thermocouples. In constantan negative leg thermocouples, types E, J, and T have high emf outputs as constantan has a strong negative Seebeck coefficient.

TABLE 14.4 Manufacturing Tolerances for ASTM Thermocouples (ASTM E 230-98)

Type	Temperature Range (°C)	Standard Tolerance (°C)	Special Tolerance (°C)
B	870 to 1700	$\pm 0.5\%$	$\pm 0.25\%$
E	0 to 870	± 1.7 or $\pm 0.5\%$	± 1.0 or $\pm 0.4\%$
J	0 to 760	± 2.2 or $\pm 0.75\%$	± 1.1 or $\pm 0.4\%$
K	0 to 1260	± 2.2 or $\pm 0.75\%$	± 1.1 or $\pm 0.4\%$
N	0 to 1260	± 2.2 or $\pm 0.75\%$	± 1.1 or $\pm 0.4\%$
R	0 to 1480	± 1.5 or $\pm 0.25\%$	± 0.6 or $\pm 0.1\%$
S	0 to 1480	± 1.5 or $\pm 0.25\%$	± 0.6 or $\pm 0.1\%$
T	0 to 370	± 1.0 or $\pm 0.75\%$	± 0.5 or $\pm 0.4\%$
E	-200 to 0	± 1.7 or $\pm 1.0\%$	
K	-200 to 0	± 2.2 or $\pm 2.0\%$	
T	-200 to 0	± 1.0 or $\pm 1.5\%$	

The criteria for thermocouple selection include cost, maximum and minimum operating temperatures, chemical stability, material compatibility, atmospheric protection, mechanical limitations, duration of exposure, sensor lifetime, sensitivity, and output emf.

Standards organizations throughout the world have specified allowable tolerances for the deviation of the thermocouple output from standardized tables. Many of the standards are based on the results and research at national laboratories, and there is similarity between the magnitude of tolerances in the standards from one country to another. Tables 14.4 and 14.5 give the manufacturing tolerances for ASTM and British Standard thermocouples. Many countries use the term Class 1 for special tolerance and Class 2 for standard tolerance.

The data for thermoelectric emf versus temperature for two of the standardized thermocouples, types K and T, according to IEC 584.1: 1995 and BS EN 60584.1: 1996 is reproduced in Tables 14.6 and 14.7 and for all the standardized thermocouples plotted in

TABLE 14.5 Manufacturing Tolerances for Thermocouples (BS EN 60584.2)

Type	Tolerance Class 1	Tolerance Class 2
B		$\pm 0.25\%$ (600°C to 1700°C)
E	$\pm 1.5^\circ\text{C}$ (-40°C to 375°C) $\pm 0.4\%$ (375°C to 800°C)	$\pm 2.5^\circ\text{C}$ (-40°C to 333°C) $\pm 0.75\%$ (333°C to 900°C)

14.3.4.7 Thermocouple Assemblies and Installation Temperature measurement can rarely be undertaken using a bare thermocouple wire. Often the thermocouple wires must be electrically isolated from the application and protected from the environment. When measuring the temperature of a moving fluid, it may also be necessary to locate the thermocouple within a specialized assembly to produce a measurement that can be related to the temperature of the flow. A thermocouple assembly therefore involves consideration of

TABLE 14.7 Standard Reference Data to IEC 584.1:1995 and BS EN 60584.1 Part 5: 1996 for Type T Copper/Copper–Nickel Thermocouples giving Thermocouple emf in Microvolts for Various Tip Temperatures Assuming a Cold Junction at 0°C

[illegible]

FIGURE 14.9 emf versus temperature characteristics for the standard thermocouples.

joining the wires at the tip to form the thermoelectric junction, electrical isolation of the wires, protection of the wires, installation of the assembly into the application, and connection of the thermocouple to the voltage-measuring device.

As indicated by the law of intermediate materials, the precise form of connection of the two thermoelements does not significantly affect the output provided the temperature of the bead formed is relatively uniform. Thermocouple beads can therefore be formed by twisting few millimeters of the wires' end together at the tip, which provides only limited strength; crimping; or welding as illustrated in Figure 14.10. The choice of connection depends on the requirements of the application such as the need for strength or high speed of response. For applications requiring high strength of the bead or resistance to vibration, then a welded bead may be most appropriate. The vast majority of commercial thermocouples are welded during manufacture and this need not be a concern for the bulk of users. If, however, thermocouples are being assembled from wire then the bead can be formed by using a discharge-welding machine.

Many applications require the thermocouple wires to be electrically or chemically isolated from the environment or medium of interest. Examples of insulation materials

FIGURE 14.10 Bead formation options: (a) butt welded, (b) welded bead, (c) butt welded and sheathed, (d) grounded and sheathed, (e) twisted wires, and (f) crimped.

FIGURE 14.11 Some protection tube and connector designs.

include PVC (polyvinyl chloride) for temperatures from -30°C to 105°C , Teflon for -273°C to $+250^{\circ}\text{C}$, glass fiber for -50°C to 400°C , and polyimide for -269°C to 400°C . Higher temperatures can be achieved using ceramic sheaths. The requirements of electrical or chemical isolation and good thermal contact are often in conflict, giving rise to thermal disturbance errors.

In addition to the need to electrically isolate the thermocouple, it is also necessary in some applications to protect the thermocouple from exposure to the local environment that could otherwise impair the function of the measurement device. An example is the immersion of a thermocouple into a corrosive fluid. Levels of protection can be achieved by use of a protection tube or sheath around the insulation. An example of a thermocouple assembly with a protecting tube and head is illustrated in Figure 14.11. These tubes and connectors are commercially available. Choice of the insulator and sheath materials depends on the application. The ASTM manual (1993) on the use of thermocouples in temperature measurement lists a wide range of protecting tube materials for different applications. The MIMS (mineral insulated metal sheathed) thermocouple attempts to combine high temperature capability and protection from the environment in a single assembly. In these devices, a mineral such as magnesium oxide is compacted around the thermocouple wires to electrically isolate and support them and this assembly is encapsulated within a metal sheath, Figure 14.12. MIMS thermocouples can be used for the range -200°C to 1250°C .

FIGURE 14.12 A MIMS (mineral insulated metal sheathed) thermocouple for high temperature capability and protection from the local environment.

FIGURE 14.13 Thermocouple installation (Coren et al., 2010).

Thermocouples are useful for determining the temperature for a wide range of applications from surfaces and solid bodies to stationary and flowing fluids. As a thermocouple consists simply of the thermoelectric wires it is usually necessary to insulate the wires and sometimes encapsulate the wires in a protective sheath. In addition, in order to avoid errors caused by heat transfer, it may be necessary to install the thermocouple within a specialized assembly to ensure appropriate measurement of the parameter of interest.

The temperature of a solid surface can be measured using a thermocouple by a variety of means depending on the type of surface and uncertainty desired. Typically the choice is limited to surface mounting or installing the thermocouple in a hole or recess. In the case of surface mounting, an adhesive or shims may be used to secure the thermoelement wires to the surface and to improve thermal contact between the surface of interest and the thermocouple bead. An example of the use of shims for a gas turbine application is shown in Figure 14.13.

Solid temperatures and the temperature of a liquid flowing in a pipe are sometimes measured with the thermocouple immersed in a thermowell. A thermowell is a protecting tube to prevent or minimize damage from harmful atmospheres, corrosive fluids, or mechanical damage; common commercial forms are illustrated in Figure 14.14. As a general rule of thumb, a thermowell should be immersed in the liquid to a depth of 10 times the diameter. Material property requirements for thermowells are documented in ASME PTC 19.3 (1974).

A thermocouple placed in a gas environment will experience heat transfer by conduction along its wires and support, convective heat transfer with the surrounding gas both at the tip and along the length of the wires and support, and radiative heat exchange with the surroundings. The contribution due to conduction is usually relatively small in comparison to convection. Radiative heat transfer tends to be a function of the fourth power of the absolute temperature and can therefore be significant if the temperature of the gas is distinctly different to the temperature of the enclosure. Because of these exchanges of heat

FIGURE 14.14 Thermowells (ASTM, 1993)

the measurement of gas temperature needs to be carefully thought through and undertaken (see Childs, 2001a,b).

14.3.4.8 Extension Leads and Compensation Cable In some applications the measurement location and readout instrumentation are separated by a considerable length. An example is the measurement of temperatures of various different components in an engine on test, with for example, a hundred thermocouples all connected to a data acquisition system some 30 m away. In most applications the thermal gradient and resultant emf is most significant in the first few meters of the wire. The remaining wire length serves the purpose of transmitting the emf to the data acquisition system. The thermoelectric properties of this length of wire are less critical than the part in the region of large thermal gradient. The drive for economy can make the use of a lower specification and hence cheaper wire for this region of wire attractive, and these lengths of wire are known as extension leads or extension wires. There are two types of extension wire: those with similar physical composition to the thermocouple wire itself but manufactured to a less stringent specification and those manufactured using a different material altogether. Some people use the term extension leads for wires manufactured using the same material as the thermocouple and the term compensation lead for wires manufactured using different materials. However, this terminology is not universal and the terms extension and compensation lead, wire and cable are used interchangeably. The use of extension leads in a thermocouple circuit is illustrated in Figure 14.15.

For the configuration shown in Figure 14.15 loop analysis can again be used to analyze the output. If the Seebeck coefficients of the extension leads are S_A , and S_B , respectively, then,

$$E = S_{A'}(T_1 - T_0) + S_A(T_2 - T_1) + S_B(T_1 - T_2) + S_{B'}(T_0 - T_1) \quad (14.16)$$

This simplifies to

$$E = S_{A'B'}(T_1 - T_0) + S_{AB}(T_2 - T_1) \quad (14.17)$$

FIGURE 14.15 The use of extension leads in a thermocouple circuit (Childs, 2001a,b).

If the wire pair A'B' is selected so that it has approximately the same relative Seebeck coefficient as AB, then

$$S_{A'B'} \approx S_{AB} \quad (14.18)$$

and

$$E \approx S_{AB}(T_2 - T_0) \quad (14.19)$$

So the reference junction is effectively located at the connections between the voltmeter or the data logger and the extension leads.

14.3.5 Resistance Temperature Devices

The electrical resistance of a material is a function of temperature, and this phenomena is exploited by the class of instruments called resistance temperature detectors (RTDs). Types of RTD include platinum resistance thermometers (PRTs), thermistors, and a variety of semiconductor-based instruments. RTDs are used in a wide range of applications. Some types such as PRTs can have very low uncertainty, better than 0.002 K (Mangum and Furukawa, 1990) and are used in the definition of the ITS-90, and others such as thermistors and some semiconductor-based devices can be inexpensive in comparison to, say, thermocouples.

In an RTD, the measurement of resistance is made across the length of material. This is usually a metal although germanium and carbon are used in some cryogenic (<273 K) applications. Any metal could in principle be used but stability considerations normally limit the choice to platinum, copper, and nickel. Copper and nickel are useful in the ranges -212°C to 350°C , respectively (Claggett et al., 1995), and are cheap in comparison to platinum. Platinum is more chemically stable and tends to be the preferred material for the majority of metal-based RTDs where low uncertainty is required or a message of quality is important in branding. PRTs are used to define part of the ITS-90.

14.3.5.1 Platinum Resistance Thermometers Platinum resistance thermometers consist of a length of platinum, connection wires, and an instrument to measure the resistance. Platinum resistance thermometers fall into a number of broad categories:

- Standard platinum resistance thermometers (SPRTs) which are used for low uncertainty measurements.
- Industrial platinum resistance thermometers (IPRTs) which are used for practical laboratory and industrial use.
- Secondary SPRTs which are designed for laboratory environments and limited temperature ranges while still providing low uncertainty measurements.

The relationship between resistance and temperature can be approximated by

$$R_t = R_0(t + \alpha t) \quad (14.20)$$

where R_0 is the resistance at 0°C (Ω); R_t the resistance at temperature t (Ω); α the temperature coefficient of resistance (1°C) and t the temperature ($^\circ\text{C}$).

The temperature coefficient of resistance, α , is calculated from

$$\alpha = \frac{R_{100} - R_0}{100^\circ\text{C} \times R_0} \quad (14.21)$$

where R_{100} is the resistance at 100°C (Ω).

Much of the original work on resistance thermometry was undertaken by Siemens (1871) and Callendar (1887, 1891, 1899). Callendar found that the resistance of platinum could fairly accurately be described by a quadratic in the form

$$R_t = R_0(1 + At + Bt^2) \quad (14.22)$$

where A and B are constants.

This equation has traditionally been written in the form given in Equation (14.23), known as Callendar's equation, which simplifies the calculations necessary to determine the calibration constants α and δ .

$$R_t = R_0 \left[1 + \alpha t + \alpha \delta \left(\frac{t}{100} \right) \left(1 - \frac{t}{100} \right) \right] \quad (14.23)$$

where δ is a constant.

For temperatures below 0°C, additional terms are needed and the temperature resistance characteristic is relatively accurately defined by the Callendar–Van Dusen equation, Equation (14.24), which was the basis of the now superseded International Practical Temperature Scales of 1927, 1948, and 1968.

$$R_t = R_0(1 + At + Bt^2 + C(t - 100)t^3) \quad (14.24)$$

TABLE 14.8 Typical Values for the Constants in the Callendar–Van Dusen Equation for an SPRT and an IPRT (Nicholas and White, 1994)

Constant	SPRT	IPRT
A	$3.985 \times 10^{-3}/^{\circ}\text{C}$	$3.908 \times 10^{-3}/^{\circ}\text{C}$
B	$-5.85 \times 10^{-7}/^{\circ}\text{C}^2$	$-5.80 \times 10^{-7}/^{\circ}\text{C}^2$
C	$-4.27 \times 10^{-12}/^{\circ}\text{C}^4$	$-4.27 \times 10^{-12}/^{\circ}\text{C}^4$
α	$3.927 \times 10^{-3}/^{\circ}\text{C}$	$3.85 \times 10^{-3}/^{\circ}\text{C}$

Here C is a constant and is zero above 0°C . Typical values for the coefficients in Equation (14.24) for a standard PRT and an industrial PRT are listed in Table 14.8.

The resistance element may be a coil of fine wire or a track of platinum deposited on a surface. The design of the resistance element depends on the requirements of the thermometer (see ESDU, 2007b). Most materials tend to expand and contract with temperature and this induces strain in a material. This can affect the PRT in a number of ways. Expansion of a track of platinum can alter the cross-sectional area available for conduction and therefore alter the resistance. In addition, repetitive strain cycling can modify the microscopic structure of the platinum and therefore the resistance. A further compounding effect is any variation in the electrical properties of the insulation and connection wires.

Standards (BS 1041: Part 3, 1989; ASTM E1137, 1997; BS EN 60751, 1996) have been produced for PRTs. Values for resistance and the corresponding temperature can be readily interpolated in order to determine a given reading. Two classes of uncertainty are defined for IPRTs: Class A devices where the uncertainty is within $\pm(0.15 + 0.002|t|)$ and Class B devices, with an uncertainty $\pm(0.3 + 0.005|t|)$.

The delicate strain-free designs of an SPRT would not survive the shock and vibration encountered in some industrial environments. The IPRT typically comprises a platinum wire encapsulated within a ceramic housing or a thick film sensor coated onto a ceramic surface. The actual sensing element of an IPRT can be further protected from the environment by a metal sheath. In the design of an IPRT, the constraint for mounting the platinum wire so that strain is minimized is relaxed in favor of producing a robust device. Most designs have just two wires sealed within the sensor body as this reduces the risk of short circuits and makes the device more robust. The ceramic encapsulation used should be selected so that its thermal coefficient of expansion closely matches that of platinum and the former over the temperature range of the PRT. The ceramic material used for encapsulation can include compounds and impurities that react with the platinum and change the transducer's temperature coefficient. The uncertainty achievable for an IPRT is generally of the order of $\pm 0.01^{\circ}\text{C}$ to $\pm 0.2^{\circ}\text{C}$ over the range 0 – 300°C (see Hashemian and Petersen, 1992).

The platinum-sensing element can also be deposited as a thin or thick film on an insulating substrate such as alumina. For a thick film sensor, the surface area can be of the order of 25 mm^2 with an active area of 5 mm^2 . They are mass-produced with each sensor individually trimmed to produce the desired resistance. The thick film structure produces a device that is robust and capable of operating in applications experiencing minor shock or vibration. They are noninductive and therefore insensitive to stray electrical fields. Thick film PRTs are normally designated to Class B of IEC-751 (1993). An innovative

form of temperature measurement is the application of thin film PRTs to polyamide sheet (Jones, 1995). Massed arrays of PRTs can be formed on a polyamide sheet substrate by evaporating or sputtering platinum followed by depositing gold leads using a magnetron. The resulting sheet is flexible and can be glued to the geometry of interest.

In order to obtain a measure of temperature using an RTD, the resistance must be measured. Simplistically, this can be achieved by passing a current through the sensing resistor and measuring the potential across it. If the current is known, then the ratio of potential to current provides the measurement of the resistance from Ohm's law, and the temperature can be determined from the resistance temperature characteristic. However, even if an uncertainty of only 1°C is desired, the resistance must be measured to better than 0.4% and as a result must be undertaken with care (Nicholas and White, 1994). There are two basic methods for measuring resistance commonly used in platinum resistance thermometry, potentiometric methods, and bridge methods, and these are reviewed by Nicholas and White (1994), Connolly (1998), and Wolfendale et al. (1982).

14.3.5.2 Rhodium Iron, Doped Germanium and Carbon Resistors A number of types of RTD are suitable for cryogenic applications including platinum, rhodium iron, doped germanium, and carbon. Although used to define the ITS-90 between 1234.93 K and 13.81 K, the sensitivity of platinum falls off below about 20 K. Rhodium iron alloy has a similar resistance temperature characteristic to platinum at temperatures above 30 K. Below 30 K the sensitivity drops to a minimum between 25 K and 15 K and then rises again giving a RTD with good sensitivity at low temperatures (see Rusby, 1982; Schuster, 1992). Doped germanium resistors are available with a relatively wide temperature range for cryogenic applications, from 0.05 K to 325 K and typically comprise the semiconductor encapsulated in a 3 mm diameter, 8.5-mm long cylinder (example cited is the GR-200A from Lakeshore Cryotronics). Certain carbon resistors produce stable RTDs.

14.3.5.3 Thermistors Thermistors use the variation in resistance with temperature of ceramic semiconductor. Modern thermistors are usually mixtures of oxides of chromium, nickel, manganese, iron, copper, cobalt, titanium, other metals, and doped ceramics. Thermistors can have either a positive temperature coefficient (PTC) or a negative temperature coefficient (NTC). A typical resistance temperature characteristic is 1 Ω/0.01°C. The temperature can be determined approximately from the relationship given in Equation (14.25) (Wood et al., 1978).

$$R_T = R_0 \exp \left[1 - B \left(\frac{1}{T} - \frac{1}{T_0} \right) \right] \quad (14.25)$$

where R_0 is the resistance at T_0 and B a constant for the particular thermistor material.

The resistance characteristic of a thermistor expressed by Equation (14.25) is negative and nonlinear. This can be offset if desired using two or more matched thermistors packaged in a single device so that the nonlinearities of each device negate each other (see Beakley, 1951; Sapoff and Oppenheim, 1964; Sapoff, 1980). Thermistors are usually designated by their resistance at 25°C, with common resistances ranging from 470 Ω to 100 kΩ. The high resistivity of thermistors normally negates the need for a four-wire bridge circuit.

In order to produce a lower uncertainty fit for the resistance temperature characteristic of a thermistor, a polynomial can be used with the degree used depending on the temperature range and the type of thermistor. Equation (14.26) is adequate for most systems.

$$\ln R_T = A_0 + \frac{A_1}{T} + \frac{A_2}{T^2} + \frac{A_3}{T^3} \quad (14.26)$$

Here A_0 , A_1 , A_2 , and A_3 are constants.

Alternatively Equation (14.27) can be used where the second order term has been neglected.

$$\frac{1}{T} = b_0 + b_1 R_T + b_3 (\ln R_T)^3 \quad (14.27)$$

where b_0 , b_1 , and b_3 are constants.

14.3.6 Semiconductor Devices

A forward voltage across a transducer junction can be used to generate a temperature sensing output proportional to absolute temperature. Temperature sensors based on simple transistor circuits can be readily incorporated as a part of an integrated circuit to provide on-board diagnostic or control capability. The majority of semiconductor junction sensors use a diode connected bipolar transistor. If the base of the transistor is shorted to the collector then a constant current flowing in the remaining p-n junction (base to emitter) produces a forward voltage that is proportional to absolute temperature. This can be modeled by Equation (14.28) and in practice has a temperature coefficient of approximately $-2 \text{ mV}/^\circ\text{C}$.

$$V_F = \left(\frac{kT}{q} \right) \ln \left(\frac{I_F}{I_S} \right) \quad (14.28)$$

where k is the Boltzmann's constant ($1.38 \times 10^{-23} \text{ J/K}$); T the temperature (K); q the charge of electron ($1.6 \times 10^{-19} \text{ C}$); I_F the forward current (A); and I_S the junction's reverse saturation current (A).

14.3.7 Diode Thermometers

The forward voltage drop across a p-n junction increases with decreasing temperature. For certain semiconductors the relationship between voltage and temperature is almost linear and in silicon this occurs between 400 K and 25 K with a sensitivity of approximately 2.5 mV/K . Commonly used semiconductors for thermometry are Si and GaAs with the addition of certain elements for stability. The merits of diode thermometers include price, simple voltage temperature relationship, relatively large temperature range (1–400 K), no need for a reference junction, relatively high sensitivity, uncertainty lower than $\pm 50 \text{ mK}$ (Krause and Dodrill, 1986), and simplicity of operation with a constant current source and a digital voltmeter.

14.3.8 Noise Thermometry

The thermal motion of atoms and molecules and charge carriers within an electrical conductor generates broadband electrical noise (Johnson, 1928; Nyquist, 1928). The noise power generated is called Johnson noise and is related to temperature by

$$\text{power} = 4kT\Delta f \quad (14.29)$$

where k is the Boltzmann's constant (J/K); T the absolute temperature (K); and Δf the frequency band (Hz).

In noise thermometry the thermal noise is measured across a resistor. The thermal noise power generated in a resistor is usually very small and sensitive instrumentation is therefore necessary. In principle the temperature range of application is from a few mK to over 2500°C. The circuitry used depends on the temperature range and has been reviewed by Kamper (1972), Blalock and Shepard (1982), and White et al. (1996).

14.3.9 Pyrometric Cones

A number of deforming temperature and heat rate indicating devices have been developed, known as pyrometric cones, thermoscope bars, and Bullers rings, for use in kilns and furnaces. Pyrometric cones, also known as Harrison, Seger, or Orton cones, are slender trihedral pyramids manufactured from mixtures of various mineral oxides (Seger, 1886). On heating the effects of gravity cause the inclined cone to progressively bend as the material softens, see Figure 14.16. Pyrometric cones do not provide a precise indication of temperature as their deformation is a function of both the rate of heating and the temperature cycle. They tend to be used to provide an indication of process completion such as completion of firing.

FIGURE 14.16 Pyrometric cones.

Cones vary in shape, size, and method of use according to the manufacturer. They are an economic means of identifying firing completion and can be distributed at a number of locations in a kiln to indicate local conditions. An alternative is the use of thermocouples, RTDs, or infrared thermometers but these have a higher initial cost. One manufacture, Orton Ceramics, provides cones suitable for temperatures in the range 590–2015°C. Determination of performance equivalents between different manufacturers is standardized in ANSI/ASTM C24-79 and reported by Fairchild and Peters (1926) and Beerman (1956). The practical use of pyrometric cones is described by McGee (1988), Childs (2001a,b), and in manufacturers' guidelines. Thermoscope bars comprise a rod of material mounted on a stand. The bars soften and deform with temperature, and the deformation can be measured and compared with a look up table supplied by the manufacturer to provide an indication of temperature. Bullers rings are dust pressed rings that shrink linearly with temperature rise. Use of thermoscope bars and Bullers rings is outlined in BS 1041 Part 7 (1988).

14.4 SEMI-INVASIVE METHODS

Some temperature measurement scenarios permit the modification of a surface of interest with a thermally sensitive material that can be observed remotely. These techniques can be classed as semi-invasive and include heat-sensitive paints, thermographic phosphors, thermochromic liquid crystals, and variety of crayons and labels. Some of the materials available provide a means of continuously monitoring temperature while others merely provide a means of identifying that a certain temperature has been reached or exceeded. The latter are known as peak temperature indicators.

14.4.1 Peak Temperature-Indicating Devices

A number of products are available that provide an indication that a particular temperature has been attained or exceeded. On heating above some critical temperature the material used for the indicator melts, fuses, or changes composition providing a permanent record that a given temperature has been reached or more likely exceeded. Commercially available products include heat-sensitive crayons, pellets, labels, and paints.

Fuseable material can be applied to a surface by means of a crayon. Applications include identifying temperatures in metal treatment and welding. Self-adhesive labels consisting of a temperature-sensitive indicator sealed under a transparent window are also available. These provide a convenient means of identifying whether a component such as an electronics package has experienced an excessive temperature or in medical applications to validate that a process temperature has been attained. The indicating material permanently changes color from say a light gray to black at the rated temperature, which is printed on the label. Some labels include multiple indicators, sensitive to a range of temperatures, to enable greater resolution of the peak temperature.

14.4.2 Temperature-Sensitive Paints

The same kind of fusible material as used in the peak temperature-indicating crayons is available in paint form. Thermally sensitive paint has also been developed for high temperature applications in order to indicate the peak temperatures on turbine blades

Neumann, 1989. Early work on turbines involved the use of proprietary paints from Thermindex, Faber Castel, and Tempil. The development of a range of multichange paints is reported by Bird et al. (1998). Some paint formulations are available that provide a reversible indication of peak temperature. One principle exploited is to drive water off a colorful salt, thus changing its color. On cooling, the salt can re-absorb water vapor from the atmosphere and revert to its initial color state.

Parameter-sensitive paints (PSPs) are sensitive to a number of physical parameters including pressure and temperature. The paints comprise luminescent molecules and a polymer binder material that can be dissolved in a solvent. Temperature-sensitive paints (TSPs) can be applied by brush or spray and as the paint dries, the solvent evaporates to leave luminescent molecules embedded in a polymer matrix. The principle exploited by TSPs is photoluminescence where a probe molecule is promoted to an excited state by the absorption of a photon of appropriate energy in a fashion comparable to thermographic phosphors. The difference is that the intensity of the luminescence is related to temperature by photophysical processes known as thermal and oxygen quenching (Gallery et al., 1994) and the intensity of luminescence is inversely proportional to the temperature.

14.4.3 Thermographic Phosphors

The luminescent properties of materials, known as thermographic phosphors, such as the lanthanide doped ceramics YAG:Tb, YAG:Dy, or Y₂O₃:Eu, are temperature dependent. In order to measure the temperature of a surface temperature, a thin layer of luminescent materials can be applied, illuminated with UV light, typically from a laser, and the subsequent luminescence observed and analyzed. Thermographic phosphors can be used to indicate temperatures from cryogenic levels to about 2000°C. A phosphor-based thermometry system will generally consist of a source of excitation energy, a method of delivery of energy to the target, a fluorescing medium bonded to the target, optical, detector and data acquisition, and analysis systems. Before excitation phosphor's electronic levels are populated in their ground state. They can be excited by the absorption of energy by, for instance, electromagnetic radiation such as visible or UV light, X- or γ -rays, particle beams, or an electric field. After absorption of energy the atomic configuration of the material may not remain excited but return to its initial or some intermediate state. The intensity of emitted light is an inverse function of temperature. In the case of Europium-based phosphors experiencing continuous illumination, it is given by Equation 14.18 (Fonger and Struck, 1970).

$$I_T = \left[a_j + a_j A e^{-\Delta E/kT} \right]^{-1} \quad (14.30)$$

where I_T is the intensity; a_j the probability rate; A the factor related to a_j ; E the energy (J); T the temperature (K); k the Boltzmann's constant (J/K); and a_{CTS} the charge transfer state rate.

Sensitivities of 0.05°C and an uncertainty of 0.1–5% of the Celsius temperature reading are possible (Allison and Gillies, 1997). Most thermographic phosphors are ceramics and therefore relatively inert. Bonding of the phosphor to the application can be achieved by mixing the phosphor slurry with epoxy, paint, or glue and then applying the mixture

onto the surface by brushing or spraying. For harsh environments subject to, for example, high mechanical shock or large thermal gradients, chemical bonding by vapor deposition, RF sputtering, and laser ablation can also be considered. Thermographic phosphors are reviewed by Heyes (2004, 2009), and the development of a thermal barrier coating for turbomachinery components capable of both sustaining a high thermal gradient and indicating temperature is described by Feist et al. (2001, 2002).

14.4.4 Thermochromic Liquid Crystals

Thermochromic liquid crystals are a class of materials that display significant changes in color over discrete temperature bands. As the temperature rises, a thermochromic liquid crystal mixture will change from colorless, black against a blackened background and pass through the visible spectrum of colors; red to orange to yellow to green to blue to violet, before turning colorless again. The process of color change is reversible with cooling. The colors displayed can be related to temperature by a calibration process. The sensitivity to temperature arises from the structure within the thermochromic liquid crystal with transition between solid and liquid states. In the liquid crystal phase, molecules lose positional order becoming fluid, but retain orientation order and the optical properties of crystalline solids (Kakade et al., 2009a). When a thermochromic liquid crystal is illuminated with white light, it will selectively reflect monochromatic light with wavelength equal to the pitch of the helical molecular structure. The wavelength of the reflected light decreases as the temperature increases and the color observed will therefore change from red through the visible spectrum to blue.

Pure crystals deteriorate rapidly with age and exposure to ultraviolet light but their life can be extended by encapsulation of the crystals within a polymer coating. Thermochromic crystals are commercially available in the form of water-based slurry. This can be sprayed onto a dark or blackened surface using an airbrush (see, for example, Baughn, 1995; Roberts and East, 1996; Kakade et al., 2009a, for practical guidance). They are also available as a pre-formed layer on a blackened substrate of mylar or paper.

The temperature at which a liquid crystal formulation begins to display color is called its red-start temperature. The range of temperature over which the crystals display color is often referred to as the color play bandwidth or the temperature event range. The range of temperature over which a liquid crystal displays a single color is called the isochrome bandwidth and this can be as little as 0.1°C . For narrow band thermochromic liquid crystals the color changes over a range about 1°C and these can be used to determine surface temperature with an uncertainty of about 0.1°C . Wideband thermochromic liquid crystals are typically active across a range 5°C to 20°C and can be used to determine the distribution of surface temperature. The value of the red-start temperature and the color play bandwidth can be controlled by selecting appropriate cholesteric esters and their proportions.

A number of approaches have been adopted in determining the value of temperature from color in the use of thermochromic crystals. For instance in the use of forehead clinical thermometers, human eyesight and judgement is used comparing the displayed color to a look-up table or identifying the most significant illumination in a panel. A CCD camera can also be used to capture the images produced by liquid crystals and the resulting RGB image processed to hue, and a calibration used to convert this to a corresponding temperature (see Kakade et al., 2009a,b).

Applications of thermochromic liquid crystals have included forehead and fish-tank thermometers, novelty stickers, turbine heat transfer experiments (for example Campbell and Molezzi, 1996; Ou et al., 2000), jet engine nacelles, and vehicle interiors (Lee and Yoon, 1998).

14.5 NONINVASIVE METHODS

A number of temperature-dependent phenomena such as the emission of radiation, scattering, and luminescence can be observed remotely thereby providing the possibility of measuring temperature without disturbing the medium of interest. Remote observation can under certain circumstances be classed as noninvasive to the medium of interest or target. It should however be noted that optical techniques, particularly for methods requiring use of a laser system can involve use of bulky and complicated equipment, and while this may not require machining or installation of a measurement device on the surface of interest or location of a sensor in a fluid, the equipment may nevertheless be bulky and will likely require optical access through, say, special windows. Noninvasive methods are potentially attractive for a variety of reasons and applications including

- targets in motion,
- fragile targets,
- remote targets,
- unsteady temperature applications,
- harsh environments,
- temperature distribution required.

Noninvasive methods of temperature measurement have developed with the advances in semiconductor fabrication technology and the availability of lasers as a source of excitation. Use of infrared thermometers is now commonplace for inspection in industry and retail. Temperature measurement techniques based on infrared radiation are reviewed in Sections 14.5.1 and 14.5.2.

A series of sophisticated methods for noninvasive measurement of gas temperature are available such as index of refraction; absorption, and emission spectroscopy; line reversal; scattering; laser-induced fluorescence; light polarization; speed of sound; and speckle methods. Some of the techniques, such as laser-induced fluorescence, are highly specialized and expensive requiring extensive expertise and high-cost capital equipment. This type of method is not available off the shelf and its use should be carefully justified in terms of the value of the data it would produce. These methods are reviewed in ESDU (2002) and Childs (2001a,b).

14.5.1 Infrared Thermometry

Infrared thermometers measure the thermal radiation emitted by a body due to its temperature and have found applications from cryogenic temperatures to over 6000 K. Infrared thermometers are widely available with examples used in industry and retail where the cost is the same order of magnitude as, for example, a thermocouple indicator to highly sophisticated traceable devices for high temperature gas or surface measurement, suitable

for laboratory and research use. Any body will emit energy in the form of thermal radiation due to its temperature with the quantity of radiation rising with increasing temperature. The energy emitted over the electromagnetic spectrum due to temperature by a blackbody is modeled by Planck's law (Equation 14.31). The energy radiated reduces with temperature but the wavelength distribution shifts toward those with longer wavelengths.

$$E_{\lambda b} = \frac{C_1}{\lambda^5 [\exp(C_2/\lambda T) - 1]} \quad (14.31)$$

where $E_{\lambda b}$ is the spectral emissive power for a blackbody (W/m^3); C_1 the first radiation constant ($3.7417749 \times 10^{-16} \text{ Wm}^2$, Cohen and Taylor, 1987); λ the wavelength (m); C_2 the second radiation constant (0.01438769 m K , Cohen and Taylor, 1987); and T the absolute temperature (K).

Integration of Equation (14.31) over all wavelengths gives the total thermal radiation emitted by a blackbody, Equation (14.32).

$$E_b = \sigma T^4 \quad (14.32)$$

where σ is the Stefan–Boltzmann constant. $\sigma = 5.67051 \times 10^{-8} \text{ W/m}^2 \text{ K}^4$ (Cohen and Taylor, 1987).

An infrared system consists of three basic elements, the source, propagation medium, and measuring device. The infrared-measuring device may comprise an optical system, a detector, processing circuit, and display. The purpose of the optical system is to focus the energy emitted by the target onto the sensitive surface of the infrared detector, which usually converts the energy into an electrical signal. There are a number of types of infrared thermometer depending on whether the device is sensitive to all or a specific band of wavelengths. Those sensitive to all wavelengths are classed as total radiation or broadband thermometers. Those sensitive to radiation in a specific band of wavelengths are classed as spectral band thermometers, ratio thermometers, and thermal imagers.

The radiation emitted by real targets does not match the ideal simplification of Equations (14.31) and (14.32). Radiation emitted by real bodies is a function of both the surface temperature and surface properties. The surface property limiting the quantity of radiation is called the emissivity, ϵ , and is the ratio of the electromagnetic flux that is emitted from a surface to that emitted from a blackbody at the same temperature. Emissivity is a function of the dielectric constant and subsequently its refractive index and is generally wavelength dependent. Quantification and accounting for the effects of emissivity in undertaking a temperature measurement using an infrared thermometer is usually necessary. Target surfaces can be classified into three categories:

1. blackbodies,
2. graybodies,
3. nongraybodies.

Information about the emissivity of a wide range of materials is documented in the reference texts edited by Touloukian et al. (1970, 1972a,b) and also tends to be available from infrared thermometer suppliers.

The medium across which the radiation is transmitted can attenuate the radiation due to absorption, scattering, and turbulence with absorption and emission dependent on the energy structure of the constituent molecules. As well as nitrogen and oxygen, air typically contains a proportion of water vapor and CO₂ along with a number of trace molecules. The strong dipole moment and light hydrogen atoms in water vapor result in strong and broad absorption bands. In addition, water vapor is an asymmetric top and this gives an irregular absorption spectrum. The properties of water vapor and CO₂ along with those of other trace substances in air act to absorb a proportion of the radiation emitted from a target at specific wavelengths and even make air opaque at some frequencies. This means that using Equation (14.31) without modification to account for the radiation not transmitted would lead to an error. Information concerning the transmissive properties of air, which varies with distance and local composition, has been published by Yates and Taylor (1960) and is also modeled in a number of software packages such as LOWTRAN (Selby et al., 1972, 1975, 1976, 1978), MODTRAN, HITRAN, and FASCODE. These codes represent long-running research development and are reviewed in Smith (1993) and are available on-line (see, for example, www.cfa.harvard.edu/hitran/, HITRAN, 2010). When dealing with other transmission mediums or specific particulates such as smoke, the transmission characteristics for the system concerned must be identified in order to allow for the temperature reading to be correctly interpreted.

An approach to negate the impact of nontransmission of thermal radiation is to use spectrally sensitive detectors. These operate across a specific waveband only and a detector can be selected to match the characteristics of a given application. For example, there are a number of wavelengths, known as windows, near 0.65 μm , 0.9 μm , 1.05 μm , 1.35 μm , 1.6 μm , 2.2 μm , 4 μm , and 10 μm , where the transmittance is high and air is effectively transparent to thermal radiation. A large number of detectors have now been identified that are sensitive to thermal radiation such as PbS, PbSe, InSb, HgCdTe, and PbSnTe (for further data see for example Rogatto, 1993). As a general rule instruments used for measuring hot targets operate at shorter wavelengths (for example 0.9–1.1 μm) and those for cooler objects operate at longer wavelengths (3–5 μm or 8–14 μm). A further issue arises from the use of optical devices and windows between the target and the detector as materials used for lenses and windows also have their own spectral characteristics and only transmit a proportion of the incident radiation at specific wavelengths. An infrared sensor should only be operated when the spectral range over which a target and the media transmit and over which the detector is sensitive all overlap.

A compounding problem affecting a temperature measurement using an infrared thermometer is background radiation. An infrared thermometer will read any radiation incident on the detector whether it is emitted, transmitted, or reflected from a target. If a surface is not a perfect absorber of incident radiation then a proportion of the incident radiation can be reflected, and this can distort the indicated temperature. If, for example, a target surface is at a temperature, say 300 K, but is in close proximity to a hotter object, then it is possible for an infrared thermometer to read the radiation emitted from both the surface and a proportion of radiation from the hotter object that is reflected off the surface of the target. The temperature indicated for the target will be artificially high, without appropriate offsetting. A number of strategies are available to minimize such effects involving repositioning the detector or using screens. The practical use of infrared thermometers is described by Kaplan (1999).

When an infrared thermometer is aimed at a target it collects energy within a collecting beam, or zone, whose shape is determined by the optical system and detector and is typically conical. The cross section of the collecting beam is called the field of view and this determines the spot size; the area on the target over which a temperature measurement is made.

In principle, it is possible to side step the requirement of knowing the surface emissivity by using ratio thermometers. These measure the radiation emitted from a surface around two fixed wavelengths. The ratio of the radiation emitted is given by

$$R = \frac{\varepsilon(\lambda_1)\lambda_2^5(e^{C_2/\lambda_2 T} - 1)}{\varepsilon(\lambda_2)\lambda_1^5(e^{C_2/\lambda_1 T} - 1)} \quad (14.33)$$

If the emissivity is not spectrally sensitive and is near unity the emissivities will cancel, and provided the target temperature is low, then,

$$T = \frac{C_2(\lambda_1 - \lambda_2)/\lambda_1\lambda_2}{\ln \left[R \left(\frac{\lambda_1}{\lambda_2} \right)^5 \right]} \quad (14.34)$$

An optical fiber can be used to convey thermal radiation into a narrow wavelength band from a location of interest or a convenient viewing point to a detector. This enables the detector to be remote from the target and is particularly useful in monitoring very hot applications such as combustion processes. Optical fiber-based devices are useful for temperatures in the range 100–4000 °C. The use of this technique is reported by Dils (1983), Saaski and Hartl (1992), Sun (1992), Ewan (1998), Zhang et al. (1992), Grattan and Zhang (1995), and Krohn (2000).

14.5.2 Thermal Imaging

Infrared radiation principles can be used to measure the spatial distribution of temperature on a target surface and this is known as thermal imaging or thermography. Applications of thermal imaging are extensive ranging from plant condition monitoring, diagnostics, materials testing, process control, energy auditing for structures, and surveillance. The developments in semiconductor technology have resulted in the wider availability of thermal imaging devices, including reasonably priced items for process control. Thermal imagers typically comprise an optical system, a detector, processing electronics, and a display and are extensions of infrared thermometer technologies combined with some form of scanning optics. Thermal imagers do not require any form of additional illumination in order to operate and this makes them highly attractive in surveillance applications. It should be noted that military and surveillance thermal imagers tend to be configured to produce an image rather than quantitative information on the distribution of temperatures.

It is possible to make use of a single detector with some form of scanner to transmit the radiation signal from specific regions of the optical system to enable a two-dimensional image of the temperature distribution to be built up. The disadvantage of single detector scanners is the trade-off between the speed of response of the instrument and the signal-

to-noise ratio of the detector. The detector typically needs to be cooled and operated at performance limits in order to achieve the desired time response. Multidetector scanners comprising a linear detector array or a two-dimensional array of detectors, known as a staring array enable the temporal to spatial burden to be reduced. Cooling of the detectors can be achieved in a number of ways such as use of liquid nitrogen, Peltier coolers, or a miniature Sterling engine.

The optimum waveband for a thermal imager as for most other infrared thermometers is dictated by the wavelength distribution of the emitted radiation, the transmission characteristics of the atmospheric environment between the imager and the target and by the characteristics of the available detector technology. The following optical bands for air are defined as

- short wavelength infrared imaging band (SWIR), 1.1 to 2.5 μm ;
- medium wavelength infrared imaging band (MWIR), 2.5 to 7 μm , with a notch at 4.2 μm due to CO_2 absorption;
- long wavelength imaging band (LWIR), 5 to 15 μm ;
- further bands beyond 15 μm are classed as far infrared (FIR) and very long wave infrared (VLWIR).

The emissivity of most naturally occurring objects and organic paints is high in the long wave infrared but is lower and more variable in the medium wave infrared. Metallic surfaces tend to have lower emissivity in either band. As such, the use of a thermal imager to provide quantitative information for the temperature distribution, particularly for a surface comprising different materials has to be carefully managed. Without correction for local emissivity values the thermal imager will assume a default value and apply this to the whole image. However, basing the choice of thermal imager on emissivity alone ignores attenuation in the transmission medium. Fog particles, for example, attenuate radiation by scattering with the magnitude dependent on the particulate size. If moderately sized particulates are present, scattering affects the MWIR region more than the LWIR, and a LWIR system can generally provide better range performance.

A number of performance parameters can be used for thermal imagers, allowing different systems to be compared (see also Holst, 1995, 2000; Runciman, 1999).

- Thermal sensitivity (NEDT, noise equivalent differential temperature) refers to the smallest temperature differential that can be detected and depends on the optical system, the responsivity of the detector, and the noise of the system.
- Spatial resolution defines the smallest quantity that can be discerned and is often quantified by Airy disc size.
- Minimum resolvable temperature (MRT).
- Minimum detectable temperature (MDT).

The price of a thermal imager usually reflects the performance, ruggedness, and image processing capability. Some compact imagers can be readily handheld while other systems are designed to be mounted on a platform weighing as much as 100 kg. The availability of uncooled and Sterling engine-cooled detector arrays has made battery-powered portable devices viable. The uncertainty associated with the temperature measurement is specific to the device but typical figures are $\pm 2\text{ K}$ or $\pm 2\%$ full-scale output. Modern

thermal imagers can be particularly easy to use needing simply to be aimed at the target of interest and the image captured by pressing a button.

14.6 CONCLUSIONS

A wide variety of methods are available for measuring temperature. Despite the many types of temperature measuring systems, the choice for a given application is typically limited by a number of factors including uncertainty, temperature range, thermal disturbance, level of contact, size of the sensor, transient response, sensor protection, availability, and cost. This chapter has provided a review of a range of invasive, semi-invasive, and noninvasive instrumentation along with an introduction to the measurement process, calibration, and traceability. Some applications permit the installation of a sensor on or within the medium of interest. Alternatively, it may be desirable to observe the target remotely using an infrared pyrometer, a thermal imager, or other form of noninvasive method.

NOMENCLATURE

a_{CTS}	charge transfer state rate
a_j	probability rate
$B(T)$	second virial coefficient (cm^3/mol)
$C(T)$	third virial coefficient (cm^6/mol^2)
C_1	first radiation constant ($3.7417749 \times 10^{-16} \text{ W m}^2$, Cohen and Taylor, 1987)
C_2	second radiation constant (0.01438769 m K , Cohen and Taylor, 1987)
$D(T)$	fourth virial coefficient (cm^9/mol^3)
E	thermoelectric emf (μV); energy (J)
$E_{\lambda,b}$	spectral emissive power for a blackbody (W/m^3)
E_b	emissive power for a blackbody (W/m^2)
I_F	forward current (A)
I_S	junction's reverse saturation current (A)
I_T	intensity
k	Boltzmann's constant ($1.380658 \times 10^{-23} \text{ J/K}$, Cohen and Taylor, 1987)
n	number of moles of the gas
p	pressure (N/m^2)
q	charge of electron ($1.6 \times 10^{-19} \text{ C}$)
\mathcal{R}	universal gas constant (8.314510 J/mol K , Cohen and Taylor, 1987)
R_0	resistance at 0°C (Ω)
R_t	resistance at temperature t (Ω)
R_T	resistance at temperature T (Ω)
R_{100}	resistance at 100°C (Ω)
S	Seebeck coefficient ($\mu\text{V/K}$)
S_A	Seebeck coefficient for material A ($\mu\text{V/K}$)

S_B	Seebeck coefficient for material B ($\mu\text{V/K}$)
S_{AB}	relative Seebeck coefficient ($\mu\text{V/K}$)
S_{APt}	Seebeck coefficient for material A relative to platinum ($\mu\text{V/K}$)
S_{BPt}	Seebeck coefficient for material B relative to platinum ($\mu\text{V/K}$)
t	temperature ($^{\circ}\text{C}$)
T	temperature (K)
$T_{^{\circ}F}$	the temperature in degree Fahrenheit ($^{\circ}\text{F}$)
$T_{^{\circ}R}$	the Rankine temperature ($^{\circ}\text{R}$)
T_0	temperature at a reference condition (K)
V	volume (m^3)
V_F	forward voltage (V)
α	temperature coefficient of resistance ($\Omega\Omega^{-1}^{\circ}\text{C}^{-1}$ or $^{\circ}\text{C}^{-1}$)
δ	constant
ε	emissivity
λ	wavelength (m)
σ	Stefan–Boltzmann constant and is equal to $5.67051 \times 10^{-8} \text{W/m}^2 \text{K}^4$ (Cohen and Taylor, 1987)
ΔE	absolute Seebeck emf (μV)
Δf	frequency interval (Hz)
ΔT	temperature difference across a segment of a conductor (K),
ANSI	American National Standards Institute
ASTM	American Society for Testing of Materials
BS	British Standard
FIR	far infrared
IPRT	industrial platinum resistance thermometer
IR	infrared
ITS-90	International Temperature Scale of 1990
MDT	minimum detectable temperature
MRT	minimum resolvable temperature
MWIR	medium wavelength infrared
NEDT	noise equivalent differential temperature
NTC	negative temperature coefficient
PRT	platinum resistance thermometer
PSP	parameter-sensitive paint
PTC	positive temperature coefficient
RTD	resistance temperature detector
SPRT	standard platinum resistance thermometer
SWIR	short wavelength infrared
TSP	temperature-sensitive paints
UV	ultra violet
VLWIR	very long wave infrared

15.1 PRESSURE CONCEPTS

Pressure represents a contact force per unit area. It acts inwardly, and normally to a surface. To better understand the origin and nature of pressure, consider the measurement of pressure at the wall of a vessel containing an ideal gas. As a gas molecule with some amount of momentum collides with this solid boundary, it rebounds off in a different direction. From Newton's second law, we know that this change in linear momentum of the molecule produces an equal but opposite (normal, inward) force on the boundary. It is the net effect of these collisions averaged over brief instants in time that yields the pressure sensed at the boundary surface. Because there are so many molecules per unit volume involved (e.g., in a gas there are roughly 10^{16} molecules per mm^3), pressure is usually considered to be continuous. Factors that affect the frequency or the number of the collisions, such as temperature and fluid density, affect the pressure. In fact, this reasoning is the basis of the kinetic theory from which the ideal gas equation of state is derived.

A pressure scale must be related to molecular activity, since a lack of any molecular activity must form the limit of absolute zero pressure. A pure vacuum, which contains no molecules, provides the limit for a primary standard for absolute zero pressure. As shown in Figure 15.1, the absolute pressure scale is quantified relative to this absolute

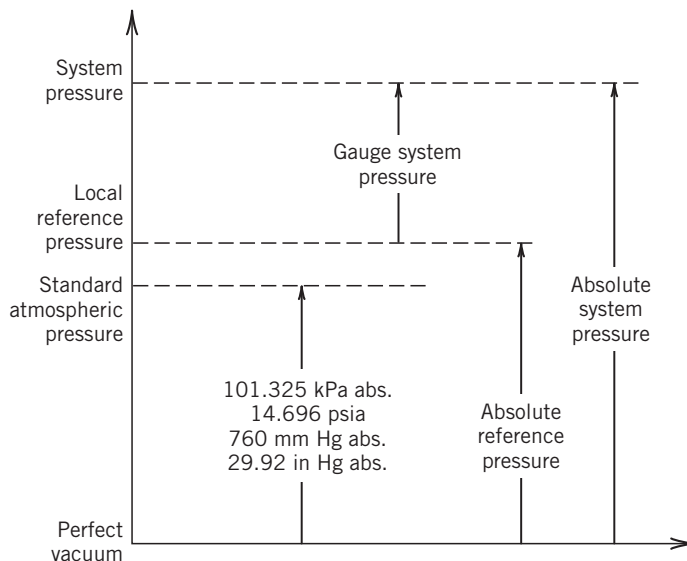

FIGURE 15.1 Relative pressure scales.

zero pressure. The pressure under standard atmospheric conditions is defined as 1.01320×10^5 Pa absolute (where $1 \text{ Pa} = 1 \text{ N/m}^2$) (Brombacher et al.,). This is equivalent to

- 101.32 kPa absolute
- 1 atm absolute
- 14.696 lb/in.² absolute (written as psia)
- 1.013 bar absolute (where 1 bar = 100 kPa)

The term “absolute” can be abbreviated as “a” or “abs.”

Also indicated in Figure 15.1 is a gauge pressure scale. The gauge pressure scale is measured relative to some absolute reference pressure, which is defined in a manner convenient to the measurement. The relation between an absolute pressure, p_{abs} , and its corresponding gauge pressure, p_{gauge} , is given by

$$p_{\text{gauge}} = p_{\text{abs}} - p_0 \quad (15.1)$$

where p_0 is a reference pressure. A commonly used reference pressure is the local absolute atmospheric pressure. Absolute pressure is a positive number. Gauge pressure can be positive or negative depending on the value of measured pressure relative to the reference pressure. A differential pressure, such as $p_1 - p_2$, is a relative measure of pressure.

Pressure can also be described in terms of the pressure exerted on a surface that is submerged in a column of fluid at depth h , as depicted in Figure 15.2. From hydrostatics, the pressure at any depth within a fluid of specific weight γ can be written as

$$p_{\text{abs}}(h) = p(h_0) + \gamma h = p_0 + \gamma h \quad (15.2)$$

FIGURE 15.2 Hydrostatic-equivalent pressure head and pressure.

where p_0 is the pressure at an arbitrary datum line at h_0 , and h is measured relative to h_0 . The fluid specific weight is given by $\gamma = \rho g$ where ρ is the density. When Equation (15.2) is rearranged, the equivalent head of fluid at depth h becomes

$$h = [p_{\text{abs}}(h) - p(h)]/\gamma = (p_{\text{abs}} - p_0)/\gamma \quad (15.3)$$

The equivalent pressure head at one standard atmosphere ($p_0 = 0$ absolute) is

$$\begin{aligned} 760 \text{ mm Hg abs} &= 760 \text{ torr abs} = 1 \text{ atm abs} \\ &= 10,350.8 \text{ mm H}_2\text{O abs} = 29.92 \text{ in Hg abs} \\ &= 407.513 \text{ in H}_2\text{O abs} \end{aligned}$$

The standard is based on mercury (Hg) with a density of $0.0135951 \text{ kg/cm}^3$ at 0°C and water at $0.000998207 \text{ kg/cm}^3$ at 20°C (Brombacher et al.,).

15.2 PRESSURE REFERENCE INSTRUMENTS

The units of pressure can be defined through the standards of the fundamental dimensions of mass, length, and time. In practice, pressure transducers are calibrated by comparison against certain reference instruments, which also serve as pressure measuring instruments. This section discusses several basic pressure reference instruments that can serve either as working standards or as laboratory instruments.

15.2.1 McLeod Gauge

The McLeod gauge, originally devised by Herbert McLeod in 1874 (McLeod, 1874), is a pressure-measuring instrument and laboratory reference standard used to establish gas pressures in the subatmospheric range of 1 mmHg abs down to 0.1 mmHg abs. A pressure that is below atmospheric pressure is also called a vacuum pressure. One variation of this instrument is sketched in Figure 15.3a, in which the gauge is connected directly to the low-pressure source. The glass tubing is arranged so that a sample of the gas at an unknown low pressure can be trapped by inverting the gauge from the sensing position, depicted as Figure 15.3a, to that of the measuring position, depicted as Figure 15.3b. In this way, the gas trapped within the capillary is isothermally compressed by a rising column of mercury. Boyle's law is then used to relate the two pressures on either side of the mercury to the distance of travel of the mercury within the capillary. Mercury is the preferred working fluid because of its high density and very low vapor pressure.

At the equilibrium and measuring position, the capillary pressure, p_2 , is related to the unknown gas pressure to be determined, p_1 , by $p_2 = p_1(\forall_1/\forall_2)$ where \forall_1 is the gas volume of the gauge in Figure 15.3a (a constant for a gauge at any pressure), and \forall_2 is the capillary volume in Figure 15.3b. But $\forall_2 = Ay$, where A is the known cross-sectional area of the capillary and y is the vertical length of the capillary occupied by the gas. With γ as the specific weight of the mercury, the difference in pressures is related by $p_2 - p_1 = \gamma y$ such that the unknown gas pressure is just a function of y :

$$p_1 = \gamma Ay^2/(\forall_1 - Ay) \quad (15.4)$$

FIGURE 15.3 McLeod gauge: (a) sensing position and (b) Indicating position.

In practice, a commercial McLeod gauge has the capillary etched and calibrated to indicate either pressure, p_1 , or its equivalent head, p_1/γ , directly. The McLeod gauge generally does not require correction. The reference stem offsets capillary forces acting in the measuring capillary. Instrument systematic uncertainty is on the order of 0.5% (95%) at 1 mm Hg abs and increases to 3% (95%) at 0.1 mm Hg abs.

15.2.2 Barometer

A barometer consists of an inverted tube containing a fluid and is used to measure atmospheric pressure. To create the barometer, the tube, which is sealed at only one end, is evacuated to zero absolute pressure. The tube is immersed with the open end down within a liquid-filled reservoir as shown in the illustration of the Fortin barometer in Figure 15.4. The reservoir is open to atmospheric pressure, which forces the liquid to rise up the tube.

From Equations (15.2) and (15.3), the resulting height of the liquid column above the reservoir free surface is a measure of the absolute atmospheric pressure in the equivalent head (Eq. 15.3). Evangelista Torricelli (1608–1647), a colleague of Galileo, can be credited with developing and interpreting the working principles of the barometer in 1644.

As Figure 15.4 shows, the closed end of the tube is at the vapor pressure of the barometric liquid at room temperature. So the indicated pressure is the atmospheric pressure minus the liquid vapor pressure. Mercury is the most common liquid used because it has a very low vapor pressure, and so, for practical use, the indicated pressure can be taken as the local absolute barometric pressure. However, for very accurate work the barometer needs to be corrected for temperature effects, which change the vapor pressure, for temperature and altitude effects on the weight of mercury, and for deviations from standard

FIGURE 15.4 Fortin barometer.

gravity (9.80665 m/s^2 or 32.17405 ft/s^2). Correction curves are provided by instrument manufacturers.

Barometers are used as local standards for the measurement of absolute atmospheric pressure. Under standard conditions for pressure temperature and gravity, the mercury rises 760 mm (29.92 in.) above the reservoir surface. The U.S. National Weather Service always reports a barometric pressure that has been corrected to sea-level elevation.

15.2.3 Manometer

A manometer is an instrument used to measure differential pressure based on the relationship between pressure and the hydrostatic equivalent head of fluid. Several design variations are available, allowing measurements ranging from the order of 0.001 mm of manometer fluid to several meters.

The U-tube manometer in Figure 15.5 consists of a transparent tube filled with an indicating liquid of specific weight γ_m . This forms two free surfaces of the manometer liquid. The difference in pressures p_1 and p_2 applied across the two free surfaces brings about a deflection, H , in the level of the manometer liquid. For a measured fluid of specific weight γ , the hydrostatic equation can be applied to the manometer of Figure 15.5 as

$$p_1 = p_2 + \gamma x + \gamma_m H - \gamma(H + x)$$

which yields the relation between the manometer deflection and applied differential pressure,

$$p_1 - p_2 = (\gamma_m - \gamma)H \quad (15.5)$$

From Equation (15.5), the static sensitivity of the U-tube manometer is given by $K = 1/(\gamma_m - \gamma)$. To maximize manometer sensitivity, we want to choose manometer liquids that minimize the value of $(\gamma_m - \gamma)$. From a practical standpoint, the manometer fluid must not be soluble with the working fluid. The manometer fluid should be selected to provide a deflection that is measurable yet not so great that it becomes awkward to observe.

A variation in the U-tube manometer is the micromanometer shown in Figure 15.6. These special-purpose instruments are used to measure very small differential pressures, down to 0.005 mm H₂O (0.0002 in. H₂O). In the micromanometer, the manometer

FIGURE 15.5 U-tube manometer.

FIGURE 15.6 Micromanometer.

reservoir is moved up or down until the level of the manometer fluid within the reservoir is at the same level as a set mark within a magnifying sight glass. At that point the manometer meniscus is at the set mark, and this serves as a reference position. Changes in pressure bring about fluid displacement so that the reservoir must be moved up or down to bring the meniscus back to the set mark. The amount of this repositioning is equal to the change in the equivalent pressure head. The position of the reservoir is controlled by a micrometer or other calibrated displacement measuring device so that relative changes in pressure can be measured with high resolution.

The inclined tube manometer is also used to measure small changes in pressure. It is essentially a U-tube manometer with one leg inclined at an angle θ , typically from 10° to 30° relative to the horizontal. As indicated in Figure 15.7, a change in pressure equivalent to a deflection of height H in a U-tube manometer would bring about a change in position of the meniscus in the inclined leg of $L = H/\sin \theta$. This provides an increased sensitivity over the conventional U-tube by the factor of $1/\sin \theta$.

A number of elemental errors affect the instrument uncertainty of all types of manometers. These include scale and alignment errors, zero error, temperature error, gravity error, and capillary, and meniscus errors. The specific weight of the manometer fluid varies with temperature but can be corrected. For example, the common manometer fluid of mercury has a temperature dependence approximated by

$$\gamma_{\text{Hg}} \frac{133.084}{1 + 0.000067T} (\text{N/m}^3) = \frac{848.707}{1 + 0.000101(T - 32)} (\text{lb/ft}^3)$$

FIGURE 15.7 Inclined tube manometer.

with T in $^{\circ}\text{C}$ or $^{\circ}\text{F}$, respectively. A gravity correction for elevation z and latitude ϕ corrects for gravity error effects using the dimensionless correction,

$$e_1 = -(2.637 \times 10^{-3} \cos 2\phi + 9.6 \times 10^{-8} z + 5 \times 10^{-5})_{\text{US}} \quad (15.6a)$$

$$= -(2.637 \times 10^{-3} \cos 2\phi + 2.9 \times 10^{-8} z + 5 \times 10^{-5})_{\text{metric}} \quad (15.6b)$$

where ϕ is in degrees and z is in feet for Equation (15.6a) and meters in Equation (15.6b). Tube-to-liquid capillary forces lead to the development of a meniscus. Although the actual effect varies with purity of the manometer liquid, these effects can be minimized by using manometer tube bores of greater than about 6 mm (0.25 in.). In general, the instrument uncertainty in measuring pressure can be as low as 0.02–0.2% of the reading.

15.2.4 Deadweight Testers

The deadweight tester makes direct use of the fundamental definition of pressure as a force per unit area to create and to determine the pressure within a sealed chamber. These devices are a common laboratory standard for the calibration of pressure-measuring devices over the pressure range from 70 to $7 \times 10^7 \text{ N/m}^2$ (0.01–10,000 psi). A deadweight tester, such as that shown in Figure 15.8, consists of an internal chamber filled with an oil and a close-fitting piston and cylinder. Chamber pressure acts on the end of the carefully machined piston. A static equilibrium exists when the external pressure exerted by the piston on the fluid balances the chamber pressure. This external piston pressure is created by a downward force acting over the equivalent area A_e of the piston. The weight of the piston plus the additional weight of calibrated masses are used to provide this external force F . At static equilibrium the piston floats and the chamber pressure can be deduced as

$$p = \frac{F}{A_e} + \sum \text{error corrections} \quad (15.7)$$

A pressure transducer can be connected to a reference port and calibrated by comparison to the chamber pressure. For most calibrations, the error corrections can be ignored.

FIGURE 15.8 Deadweight tester.

When error corrections are applied, the instrument uncertainty in the chamber pressure using a deadweight tester can be as low as 0.005–0.01% of the reading. A number of elemental errors contribute to Equation (15.7), including air buoyancy effects, variations in local gravity, uncertainty in the known mass of the piston and added masses, shear effects, thermal expansion of the piston area, and elastic deformation of the piston (American Society of Mechanical Engineers (ASME), 1987).

An indicated pressure, p_i , can be corrected for gravity effects, e_1 , from Equation (15.6a) or (15.6b), and for air buoyancy effects, e_2 , by

$$p = p_i(1 + e_1 + e_2) \quad (15.8)$$

where

$$e_2 = -\gamma_{\text{air}}/\gamma_{\text{masses}} \quad (15.9)$$

The tester fluid lubricates the piston so that the piston is partially supported by the shear forces in the oil in the gap separating the piston and the cylinder. This error varies inversely with the tester fluid viscosity, so high-viscosity fluids are preferred. In a typical tester, the uncertainty due to this error is less than 0.01% of the reading. At high pressures, elastic deformation of the piston affects the actual piston area. For this reason, the effective area is based on the average of the piston and cylinder diameters.

15.3 PRESSURE TRANSDUCERS

A pressure transducer is a device that converts a measured pressure into a mechanical or electrical signal. The transducer is actually a hybrid sensor-transducer. The primary sensor is usually an elastic element that deforms or deflects under the measured pressure relative to a reference pressure. Several common elastic elements used, as shown in Figure 15.9, include the Bourdon tube, bellows, capsule, and diaphragm. A secondary transducer element converts the elastic element deflection into a readily measurable signal

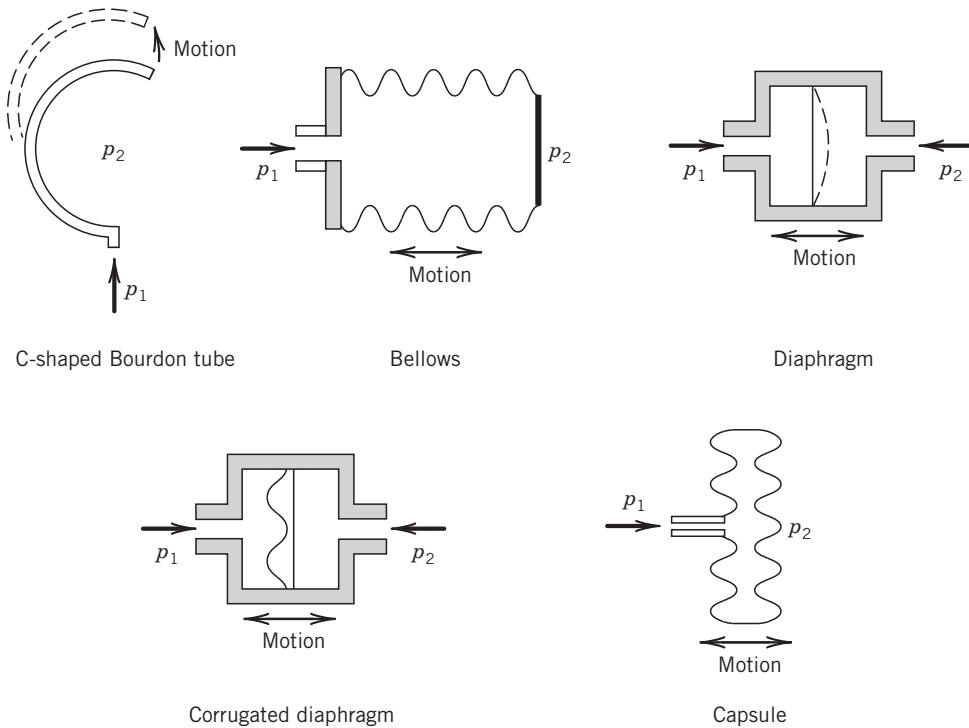

FIGURE 15.9 Elastic elements used as pressure sensors.

such as an electrical voltage or mechanical rotation of a pointer. There are many methods available to perform this transducer function, and we examine a few common ones.

General categories for pressure transducers are absolute, gauge, vacuum, and differential. These categories reflect the application and reference pressure used. Absolute transducers have a sealed reference cavity held at a pressure of absolute zero, enabling absolute pressure measurements. Gauge transducers have the reference cavity open to atmospheric pressure and are intended to measure above or below atmospheric pressure or both. Differential transducers measure the difference between two applied pressures. Vacuum transducers are a special form of absolute transducer for low-pressure measurements.

Pressure transducers are subject to some or all of the following elemental errors: resolution, zero shift error, linearity error, sensitivity error, hysteresis, noise, and drift due to environmental temperature changes. Electrical transducers are also subject to loading error between the transducer output and its indicating device (see Chapter 6). Loading errors increase the transducer nonlinearity over its operating range. When this is a consideration, a voltage follower (see Chapter 6) can be inserted at the output of the transducer to isolate transducer load.

15.3.1 Bourdon Tube

The Bourdon tube is a curved metal tube having an elliptical cross section that mechanically deforms under pressure. In practice, one end of the tube is held fixed and the input pressure is applied internally. A pressure difference between the outside and the inside of

FIGURE 15.10 Bourdon tube pressure gauge.

the tube brings about tube deformation and a deflection of the tube free end. This action of the tube under pressure can be likened to the action of a deflated balloon that is subsequently inflated. The magnitude of the deflection of the tube end is proportional to the magnitude of the pressure difference. Several variations exist, such as the C shape (Figure 15.9), the spiral, and the twisted tube. The exterior of the tube is usually open to atmosphere (hence, the origin of the term “gauge” pressure referring to pressure referenced to atmospheric pressure), but in some variations the tube may be placed within a sealed housing and the tube exterior exposed to some other reference pressure, allowing for absolute and for differential designs.

The Bourdon tube mechanical dial gauge is a commonly used pressure transducer. A typical design is shown in Figure 15.10, in which the secondary element is a mechanical linkage that converts the tube displacement into a rotation of a pointer. Designs exist for low or high pressures, including vacuum pressures, and selections span a wide choice in range. The best Bourdon tube gauges have instrument uncertainties as low as 0.1% of the full-scale deflection of the gauge, with values of 0.5–2% more common. But the attractiveness of this device is that it is simple, portable, and robust, lasting for years of use.

15.3.2 Bellows and Capsule Elements

A bellows sensing element is a thin-walled, flexible metal tube formed into deep convolutions and sealed at one end (Figure 15.9). One end is held fixed and pressure is applied

FIGURE 15.11 Potentiometer pressure transducer.

internally. A difference between the internal and external pressures causes the bellows to change in length. The bellows is housed within a chamber that can be sealed and evacuated for absolute measurements, vented through a reference pressure port for differential measurements, or opened to atmosphere for gauge pressure measurements. A similar design, the capsule sensing element, is also a thin-walled, flexible metal tube whose length changes with pressure, but its shape tends to be wider in diameter and shorter in length (Figure 15.9).

A mechanical linkage is used to convert the translational displacement of the bellows or capsule sensors into a measurable form. A common transducer is the sliding arm potentiometer (voltage-divider, Chapter 6) found in the potentiometric pressure transducer shown in Figure 15.11. Another type uses a linear variable displacement transducer (LVDT; see Chapter 12) to measure the bellows or capsule displacement. The LVDT design has a high sensitivity and is commonly found in pressure transducers rated for low pressures and for small pressure ranges, such as zero to several hundred mm Hg absolute, gauge, or differential.

15.3.3 Diaphragms

An effective primary pressure element is a diaphragm (Figure 15.9), which is a thin elastic circular plate supported about its circumference. The action of a diaphragm within a pressure transducer is similar to the action of a trampoline; a pressure differential on the top and bottom diaphragm faces acts to deform it. The magnitude of the deformation is proportional to the pressure difference. Both membrane and corrugated designs are used. Membranes are made of metal or nonmetallic material, such as plastic or neoprene. The material chosen depends on the pressure range anticipated and the fluid in contact with it. Corrugated diaphragms contain a number of corrugations that serve to increase diaphragm stiffness and to increase the diaphragm effective surface area.

Pressure transducers that use a diaphragm sensor are well suited for either static or dynamic pressure measurements. They have good linearity and resolution over their useful range. An advantage of the diaphragm sensor is that the very low mass and relative stiffness of the thin diaphragm give the sensor a very high natural frequency with a small damping ratio. Hence, these transducers can have a very wide frequency response and very short 90% rise and settling times. The natural frequency (rad/s) of a circular

diaphragm can be estimated by (Hetenyi, 1950)

$$\omega_n = 10.21 \sqrt{\frac{E_m t^2}{12(1 - \nu_p^2) r^4}} \quad (15.10)$$

where E_m is the material bulk modulus (psi or N/m²), t the thickness (in. or m), r the radius (in. or m), ρ the material density (lb_m/in.³ or kg/m³), and ν_p the Poisson's ratio for the diaphragm material. The maximum elastic deflection of a uniformly loaded, circular diaphragm supported about its circumference occurs at its center and can be estimated by

$$y_{\max} = \frac{3(p_1 - p_2)(1 - \nu_p^2)r^4}{16E_m t^3} \quad (15.11)$$

provided that the deflection does not exceed one-third the diaphragm thickness. Diaphragms should be selected so as to not exceed this maximum deflection over the anticipated operating range.

Various secondary elements are available to translate this displacement of the diaphragm into a measurable signal. Several methods are discussed below.

15.3.4 Strain Gauge Elements

A common method for converting diaphragm displacement into a measurable signal is to sense the strain induced on the diaphragm surface as it is displaced. Strain gauges, devices whose measurable resistance is proportional to their sensed strain (see Chapter 11), can be bonded directly onto the diaphragm, integrated within the diaphragm material or onto a deforming element (such as a thin beam) attached to the diaphragm so as to deform with the diaphragm and to sense strain. Metal strain gauges can be used with liquids. Strain gauge resistance is reasonably linear over a wide range of strain and can be directly related to the sensed pressure (Way, 1934). A diaphragm transducer using strain gauge detection is depicted in Figure 15.12.

By using semiconductor technology in pressure transducer construction, we now have a variety of very fast, very small, highly sensitive strain gauge diaphragm transducers. Silicone piezoresistive strain gauges can be diffused into a single crystal of silicone wafer, which forms the diaphragm. Semiconductor strain gauges have a static sensitivity that is 50times greater than conventional metallic strain gauges. Because the piezoresistive gauges are integral to the diaphragm, they are relatively immune to the thermoelastic strains prevalent in conventional metallic strain gauge–diaphragm constructions. Furthermore, a silicone diaphragm does not creep with age (as does a metallic gauge), thus minimizing calibration drift over time. However, uncoated silicone does not tolerate liquids.

15.3.5 Capacitance Elements

Another common method to convert diaphragm displacement to a measurable signal is a capacitance sensor. One version uses a thin metallic diaphragm as one plate of a capacitor paired with a fixed plate to complete the capacitor. The diaphragm is exposed to the process pressure on one side and to a reference pressure on the other or to a differential

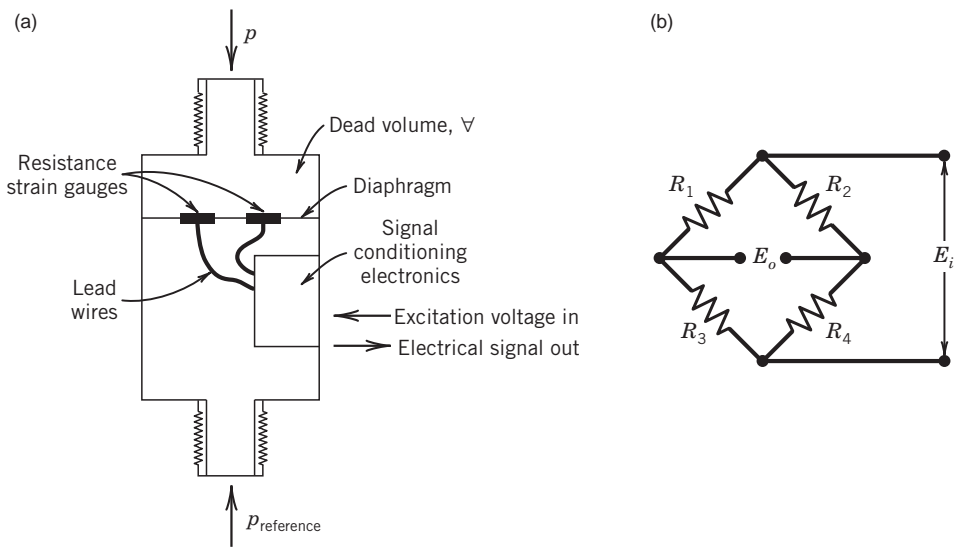

FIGURE 15.12 Diaphragm pressure transducer: (a) sensing scheme and (b) bridge–strain gauge circuit for pressure diaphragms.

pressure. When pressure changes, so as to deflect the diaphragm, the gap between the plates changes, which causes a change in capacitance.

To illustrate this, a transducer using this method is depicted in Figure 15.13. The capacitance C developed between two parallel plates separated by average gap t is determined by

$$C = c\epsilon A/t \quad (15.12)$$

FIGURE 15.13 Capacitance pressure transducer. In this schematic, the diaphragm is conductive and its deflection exaggerated.

where the product $c\epsilon$ is the permittivity of the material between the plates relative to a vacuum ($\epsilon = 8.85 \times 10^{-12}$ F/m; c = dielectric constant), and A is the overlapping area of the two plates. The dielectric constant depends on the material in the gap, which for air is $c = 1$ but for water is $c = 80$. The capacitance responds to an instantaneous change in the area-averaged plate gap separation from which the time-dependent pressure is determined. However, the capacitance change is small relative to the absolute capacitance. Oscillator and bridge circuits are commonly used to operate the circuit and to measure the small capacitance change providing an output voltage E_0 .

The capacitance pressure transducer has the attractive features of other diaphragm transducers, including small size and a wide operating range. Many common and inexpensive pressure transducers use this measuring principle and are suitable for many engineering measurement demands, including a niche as the on-board car tire pressure sensor of choice. However, the principle is sensitive to temperature changes and has a relatively high impedance output. If attention is paid to these shortcomings, an accurate and stable transducer can be made.

15.3.6 Piezoelectric Crystal Elements

Piezoelectric crystals form effective secondary elements for dynamic (transient) pressure measurements. Under the action of compression, tension, or shear, a piezoelectric crystal deforms and develops a surface charge q , which is proportional to the force acting to bring about the deformation. In a piezoelectric pressure transducer, a preloaded crystal is mounted to the diaphragm sensor, as indicated in Figure 15.14. Pressure acts normal to the crystal axis and changes the crystal thickness t by a small amount Δt . This sets up a charge, $q = K_q p A$, where p is the pressure acting over the electrode area A and K_q is the crystal charge sensitivity, a material property. A charge amplifier (see Chapter 6) is used to convert charge to voltage so that the voltage developed across the electrodes is

$$E_o = q/C \quad (15.13)$$

FIGURE 15.14 Piezoelectric pressure transducer.

where C is the capacitance of the crystal–electrode combination, again given by Equation (15.12). The operating equation becomes

$$E_o = K_q tp / c\epsilon = Kp \quad (15.14)$$

where K is the overall transducer gain. The crystal sensitivity for quartz, the most common material used, is $K_q = 2.2 \times 10^{-9}$ coulombs/N.

15.4 PRESSURE TRANSDUCER CALIBRATION

15.4.1 Static Calibration

A static calibration of a pressure transducer is usually accomplished either by direct comparison against any of the pressure reference instruments discussed (Section 15.3) or against the output from a certified laboratory standard transducer. For the low-pressure range, the McLeod gauge or the appropriate manometric instruments along with the laboratory barometer serve as convenient working standards. The approach is to pressurize (or evacuate) a chamber and expose both the reference instrument, which serves as the standard, and the candidate transducer to the same pressure for a side-by-side measurement. For the high-pressure range, the deadweight tester is a commonly used pressure reference standard.

15.4.2 Dynamic Calibration

The rise time and frequency response of a pressure transducer are found by dynamic calibration, and there are a number of clever ways to accomplish this (Instrument Society of America (ISA), 2002). As discussed in Chapter 3, the rise time of an instrument is found through a step change in input. For under-damped systems, natural frequency and damping ratio can be measured based on the ringing behavior (see Chapter 3), giving the frequency response. The frequency response can be found directly by applying a constant amplitude periodic input signal and varying its frequency. A flush-mounted transducer places the sensor in direct contact with the fluid at the measurement site. Because pressure transducers could also be attached by means of a pressure tap or by connecting tubing to the tap, this length (called the transmission line) affects the overall response and should be included as part of the dynamic calibration.

An electrical switching valve or flow control valve can create a step change in pressure. But the mechanical lag of the valve limits its use to transducers having an expected rise time of 50 ms or more. Faster applications might use a shock tube calibration or some equivalent diaphragm burst test.

As shown in Figure 15.15, the shock tube consists of a long pipe separated into two chambers by a thin diaphragm. The transducer is mounted into the pipe wall of one chamber, the expansion section, at pressure p_1 . The pressure in the other chamber, the driver section, is raised from p_1 to p_2 . Some mechanism, such as a mechanically controlled needle, is used to burst the diaphragm on command. Upon bursting, the pressure differential causes a pressure shock wave to move down the low-pressure chamber. A shock wave has a thickness on the order of $1 \mu\text{m}$ and moves at the speed of sound, a . So as the shock passes the transducer, the transducer experiences a change in pressure from p_1 to p_3 over a time $t = d/a$, where d is the diameter

FIGURE 15.15 Schematic of a shock tube facility.

of the transducer pressure port, and pressure p_3 is

$$p_3 = p_1[1 + (2k/k + 1)(M_1^2 - 1)] \quad (15.15)$$

where k is the gas-specific heat ratio and M_1 is the Mach number calculated using normal shock wave tables and absolute pressure p_1 . The velocity of the shock wave can also be deduced from the output of fast-acting standard pressure sensors mounted in the shock tube wall. Typical values of t are on the order of 1–10 μs , so this method is at least four orders of magnitude faster than a switching valve. The transducer rise time is calculated from the output record.

A common verification check for system response is the “pop test,” which is well suited for liquids or gases and systems needing just moderate response times. In this situation, the transducer and connecting tubing are pressurized to a steady value, perhaps by using a small syringe or hand pump. The system is suddenly vented to atmosphere. The recorded transducer response gives an indication of the system rise time and ringing behavior. One variation of this approach attaches a balloon or similar flexible material to one end of the connecting tubing/transducer system. After pressurizing, the balloon is popped to suddenly vent the system.

A reciprocating piston within a cylinder can generate a sinusoidal variation in pressure for frequency-response calibration. The piston can be driven by a variable speed motor and its displacement measured by a fast-responding transducer, such as an LVDT (see Chapter 12). Under properly controlled conditions (Ex. 1.2), the actual pressure variation can be estimated from the piston displacement. Other techniques include an encased loud-speaker or an acoustically resonant enclosure, which serves as a frequency driver instead of a piston, or using an oscillating flow control valve to vary system pressure with time (Instrument Society of America (ISA), 2002).

15.5 PRESSURE MEASUREMENTS IN MOVING FLUIDS

Pressure measurements in moving fluids warrant special consideration. Consider the flow over the bluff body shown in Figure 15.16. Assume that the upstream flow is uniform and

FIGURE 15.16 Streamline flow over a bluff body.

steady with negligible losses. Along streamline A, the upstream flow moves with a velocity U_1 , such as at point 1. As the flow approaches point 2, it must slow down and finally stop at the front end of the body. Above streamline A, flow moves over the top of the bluff body, and below streamline A, flow moves under the body. Point 2 is known as the stagnation point and streamline A the stagnation streamline for this flow. Along streamline B, the velocity at point 3 is U_3 and because the upstream flow is considered to be uniform it follows that $U_1 = U_3$. As the flow along B approaches the body, it is deflected around the body. From the conservation of mass principles, $U_4 > U_3$. Application of conservation of energy between points 1 and 2 and between 3 and 4 yields

$$\begin{aligned} p_1 + \rho U_1^2/2 &= p_2 + \rho U_2^2/2 \\ p_3 + \rho U_3^2/2 &= p_4 + \rho U_4^2/2 \end{aligned} \quad (15.16)$$

However, because point 2 is the stagnation point, $U_2 = 0$, and

$$p_2 = p_t = p_1 + \rho U_1^2/2 \quad (15.17)$$

Hence, it follows that $p_2 > p_1$ by an amount equal to $p_v = \rho U_1^2/2$, called the *dynamic pressure*, an amount equivalent to the kinetic energy per unit mass of the flow as it moves along the streamline. If no energy is lost through irreversible processes, such as through a transfer of heat,¹ this translational kinetic energy is transferred completely into p_2 . The value of p_2 is known as the *stagnation* or the *total pressure* and is noted as p_t . The total pressure can be determined by bringing the flow to rest at a point in an isentropic manner.

The pressures at 1, 3, and 4 are known as static pressures² of the flow. The *static pressure* is that pressure sensed by a fluid particle as it moves with the same velocity as the

¹This is a realistic assumption for subsonic flows. In supersonic flows, the assumption is not valid across a shock wave.

²The term “static pressure” is a misnomer in moving fluids, but its use here conforms to common expression. “Stream pressure” is more appropriate and is sometimes used.

FIGURE 15.17 Total pressure measurement devices. (a) Impact cylinder. (b) Pitot tube. (c) Kiel probe.

local flow. The static pressure and velocity at points 1 and 3 are given the special names of the “freestream static pressure” and “freestream velocity.” Since $U_4 > U_3$, Equation (15.16) shows that $p_4 < p_3$. It follows from Equation (15.17) that the total pressure is the sum of the static and dynamic pressures anywhere in the flow.

15.5.1 Total Pressure Measurement

In practice, the total pressure is measured using an impact probe, such as those depicted in Figure 15.17. A small hole in the impact probe is aligned with the flow so as to cause the flow to come to rest at the hole. The sensed pressure is transferred through the impact probe to a pressure transducer or other pressure-sensing device such as a manometer. Alignment with the flow is somewhat critical, although the probes in Figure 15.17a and b are relatively insensitive (within $\sim 1\%$ error in indicated reading) to misalignment within a $\pm 7^\circ$ angle (American Society of Mechanical Engineers (ASME), 1987). A special type of impact probe shown in Figure 15.17c, known as a Kiel probe, uses a shroud around the impact port. The effect of the shroud is to force the local flow to align itself with the shroud axis so as to impact directly onto the impact port. This effectively eliminates total pressure sensitivity to misalignment up to $\pm 40^\circ$ (American Society of Mechanical Engineers (ASME), 1987).

15.5.2 Static Pressure Measurement

The local value of static pressure in a moving stream is measured by sensing the pressure in the direction that is normal to the flow streamline. Within ducted flows, static pressure is sensed by wall taps, which are small, burr-free, holes drilled into the duct wall perpendicular to the flow direction at the measurement point. The tap is fitted with a hose or tube, which is connected to a pressure gauge or transducer. A recommended design for a wall tap is shown in Figure 15.18. The tap hole diameter d is typically between 1% and 10% of the pipe diameter, with the smaller size preferred (Franklin and Wallace, 1970). The tap must be perpendicular to the local tangent to the wall with no drilling burrs (Rayle, 1959).

Alternatively, a static pressure probe can be inserted into the flow to measure local stream pressure. It should be a streamlined design to minimize the disturbance of the

FIGURE 15.18 Anatomy of a static pressure wall tap.

flow. It should be physically small so as not to cause more than a negligible increase in velocity in the vicinity of measurement. As a rule, the frontal area of the probe should not exceed 5% of the pipe flow area. The static pressure sensing port should be located well downstream of the leading edge of the probe so as to allow the streamlines to realign themselves parallel with the probe. Such a concept is built into the improved Prandtl tube design shown in Figure 15.19a.

FIGURE 15.19 Improved Prandtl tube for static pressure. (a) Design. (b) Relative static error along tube length.

A Prandtl tube probe consists of eight holes arranged about the probe circumference and positioned 8–16 probe diameters downstream of the probe leading edge and 16 probe diameters upstream of its support stem. A pressure transducer or manometer is connected to the probe stem to measure the sensed pressure. The hole positions are chosen to minimize static pressure error caused by the disturbance to the flow streamlines due to the probe's leading edge and stem. This is illustrated in Figure 15.19b, where the relative static error, $p_e/p_v = (p_i - p)/(\frac{1}{2}\rho U^2)$, is plotted as a function of tap location along the probe body. Real viscous effects around the static probe cause a slight discrepancy between the actual static pressure and the indicated static pressure. To account for this, a correction factor, C_0 , is used with $p = C_0 p_i$ where $0.99 < C_0 < 0.995$ and p_i is the indicated (measured) pressure.

15.6 MODELING PRESSURE AND FLUID SYSTEMS

Fluid systems can be modeled using lumped parameter ideal elements just as common resistor–inductor–capacitor electrical loops and mass–damper–spring mechanical systems are used. The common elements are inertance, resistance, and compliance.

Inertance describes the inertial properties of a mass in motion, such as that of a mass of fluid moving within a vessel. For a fluid of density ρ and a vessel of cross-sectional area A and length ℓ the inertance is written as

$$L_f = \rho\ell/A \quad (15.18)$$

When modeling inertial forces in laminar flows, this value should be increased by a factor of $\frac{4}{3}$. Inertance is the direct analog to electrical inductance.

Fluid *resistance* describes the opposition to motion. This is the pressure change required to move a volume of fluid per unit time, Q . It is written

$$R = \Delta p^n / Q = \Delta E / I \quad (15.19)$$

where $n = 1$ for laminar and $n = 0.5$ for turbulent flows. Hence, $Q = \frac{1}{R} \Delta p^n$.

The resistance of the laminar flow of a Newtonian fluid through a circular pipe is $R = \frac{128\mu\ell}{\pi d^4}$, where μ is the fluid viscosity. In electrical systems, it has the analogous meaning as the opposition to current flow for an imposed voltage potential, such as an electrical resistor.

Compliance describes a measure of the volume change associated with a corresponding pressure change, such as

$$C_{vp} = \Delta v / \Delta p \quad (15.20)$$

It is a measure of the flexibility in a structure, component, or substance, and so it is the inverse of the system *stiffness*. Compliance is the direct analog to electrical capacitance.

15.7 DESIGN AND INSTALLATION: TRANSMISSION EFFECTS

Consider the configuration depicted in Figure 15.20 in which a tube of volume \forall_t with length ℓ and diameter d is used to connect a pressure tap to a pressure transducer of internal dead volume \forall (e.g., Figure 15.12). Under static conditions, the pressure transducer

FIGURE 15.20 Wall tap to pressure transducer connection: the transmission line.

indicates the static pressure at the tap. But if the pressure at the tap is a time-dependent pressure, $p_a(t)$, the response behavior of the tubing influences the time-indicated output from the transducer, $p(t)$.

By considering the one-dimensional pressure forces acting on a lumped mass of fluid within the connecting tube, balancing inertance, compliance, and resistance against forcing function, we can develop a model for the pressure system response. A network model is shown in Figure 15.21a in which the circuit is driven between two pressures, the applied pressure $p_a(t)$ at the tap and the measured pressure $p_m(t)$ at the transducer sensor. Using the electrical analog, inertance is modeled by the inductor, fluid resistance by a resistor, and compliance by a capacitor (Figure 15.21b). The circuit analysis of the two loops gives

$$L\ddot{I} + RI + \frac{1}{C} \int Idt = E_a \quad \text{and} \quad \frac{1}{C} \int Idt = E_m \quad (15.21)$$

FIGURE 15.21 An equivalent lumped parameter network of the pressure transmission line model of Figure 15.20 using an electrical analogy.

Taking the derivative of the second loop to get \dot{E}_m and \ddot{E}_m in terms of \dot{I} and \ddot{I} , then substituting these back into Equation (15.21) with $E_a = p_a$, $E_m = p_m$, $L = L_f$, and $C = C_{vp}$ gives

$$L_f C_{vp} \ddot{p}_m + R C_{vp} \dot{p}_m + p_m = p_a(t) \quad (15.22)$$

Substituting Equations (15.18) to (15.20) into Equation (15.22) gives the working system response equation for the applied and measured pressures,

$$\frac{16\ell\rho C_{vp}}{3\pi d^2} \ddot{p}_m + \frac{128\mu\ell C_{vp}}{\pi d^4} \dot{p}_m + p_m = p_a(t) \quad (15.23)$$

in which we have augmented the fluid inertial force by $\frac{4}{3}$ (Munson et al., 2009).

In this simple model, the system compliance lumps the compliance of the fluid, tube walls, and transducer into a single value, C_{vp} . As these individual compliances could be modeled separately by using capacitors in parallel, the total capacitance is simply the sum of each. If one compliance dominates, the others can be neglected. Further, the inertance and resistance of the connecting tube and the transducer cavity are lumped into single values. Improved models use distributed, lumped parameters, such as are commonly used to model physiological vascular systems (Migliavacca, 2006). A long-standing approach to modeling the transmission line (Delio et al., 1949) examines the forces acting on a fluid element. In this model, small pressure changes act on the element, moving it back and forth by a distance x within the tube. Summing the forces and substituting for p_m again results in Equation (15.23) (Doebelin, 2003). Be aware that models are based on simplifying assumptions and should be used only as a guide in the design of a system, not as a replacement for *in situ* calibration.

We can study the transient and frequency response of the system represented by Equation (15.23) by extracting values for ω_n and ζ ,

$$\omega_n = \frac{d}{4} \sqrt{3\pi/\rho\ell C_{vp}} \quad (15.24)$$

$$\zeta = \frac{16\mu}{d^3} \sqrt{3\ell C_{vp}/\pi\rho} \quad (15.25)$$

The total system compliance could be measured using Equation (15.20) by closing the pressure tap, increasing the fluid volume in the tubing by a small known amount, such as by syringe, and measuring the corresponding pressure change.

15.7.1 Liquids

Liquids are relatively incompressible, so that the compression–restoring force in the transmission line is due primarily to the compliance in the transducer, which is a transducer specification, for use in Equations (15.24) and (15.25). Connecting tubing can usually be considered rigid for the underlying assumptions of the above lumped parameter analysis. Thick-walled, flexible tubing is often used, but this is fairly rigid and its compliance can be ignored. If need be, the compliance can be measured.

15.7.2 Gases

For gases, we simplify by assuming that the system is rigid relative to the compressibility of the gas. Compliance is then modeled in terms of the fluid's adiabatic bulk modulus of elasticity, $E_m = \forall / C_{vp}$. This gives

$$\omega_n = \frac{d}{4} \sqrt{3\pi E_m / \rho \ell \forall} \quad (15.26)$$

$$\zeta = \frac{16\mu}{d^3} \sqrt{3\ell \forall / \pi \rho E_m} \quad (15.27)$$

Equations (15.26) and (15.27) can also be written in terms of the speed of sound for the gas, a , which is related to its compressibility by $a = \sqrt{E_m / \rho}$ and for a perfect gas by $a = \sqrt{kRT}$, where T is the gas absolute temperature, giving

$$\omega_n = \frac{ad}{4} \sqrt{3\pi / \ell \forall} \quad (15.28)$$

$$\zeta = \frac{16\mu}{ad^3} \sqrt{3\ell \forall / \pi} \quad (15.29)$$

When the tube volume, $\forall_t \gg \forall$, then a series of standing pressure waves develop and we can expect $\omega \sim O(a/\ell)$. Hougén et al. (1963) discuss an improved prediction as

$$\omega_n = \frac{a}{\ell \sqrt{0.5 + \forall / \forall_t}} \quad (15.30)$$

$$\zeta = \frac{16\mu \ell}{\rho a d^2} \sqrt{0.5 + \forall / \forall_t} \quad (15.31)$$

Note that in all cases, larger diameter and shorter length tubes improve pressure system response.

15.7.3 Heavily Damped Systems

In systems in which we estimate a damping ratio greater than 1.5, the frequency response model can be simplified further. The behavior of the pressure-measuring system closely follows that of a first-order system. Again, the typical pressure transducer-tubing system has a compliance C_{vp} , which is a measure of the transducer and tubing volume change relative to an applied pressure change. The response of the first-order system is indicated through its time constant, which is estimated by neglecting the second-order term in Equation 15.23 so that (Doebelin, 2003)

$$\tau = \frac{128\mu \ell C_{vp}}{\pi d^4} \quad (15.32)$$

Equation 15.32 shows that the time constant is proportional to ℓ/d^4 . Long- and small-diameter connecting tubes promote a more sluggish system response to changes in pressure.

15.8 FLUID VELOCITY MEASURING SYSTEMS

Velocity measuring systems are used to measure the local velocity in a moving fluid. Desirable information can consist of the mean velocity, as well as any of the dynamic components of the velocity. Dynamic components are found in pulsating, phasic, or oscillating flows, or in turbulent flows. For most general engineering applications, information about the mean flow velocity is usually sufficient. The dynamic velocity information is often sought during applied and basic fluid mechanics research and development, such as in attempting to study airplane wing response to air turbulence, a complex periodic waveform as the wing sees it. In general, the instantaneous velocity can be written as

$$U(t) = \bar{U} + u \quad (15.33)$$

where \bar{U} is the mean velocity and u is the time-dependent dynamic (fluctuating) component of the velocity. The instantaneous velocity can also be expressed in terms of a Fourier series:

$$U(t) = \bar{U} + \sum_i C_i \sin(\omega_i t + \phi'_i) \quad (15.34)$$

so that the mean velocity and the amplitude and frequency information concerning the dynamic velocity component can be resolved with a Fourier analysis of the time-dependent velocity signal.

15.8.1 Pitot-Static Pressure Probe

For a steady, incompressible, isentropic flow, Equation 15.16 can be written at any arbitrary point x in the flow field as

$$p_t = p_x + \frac{1}{2} \rho U_x^2 \quad (15.35)$$

or, rearranging,

$$p_v = p_t - p_x + \frac{1}{2} \rho U_x^2 \quad (15.36)$$

Again p_v , the difference between the total and static pressures at any point in the flow, is the *dynamic pressure*. Hence, measuring the dynamic pressure of a moving fluid at a point provides a method for estimating the local velocity,

$$U_x = \sqrt{\frac{2p_v}{\rho}} = \sqrt{\frac{2(p_t - p_x)}{\rho}} \quad (15.37)$$

In practice, Equation 15.37 is utilized through a device known as a *pitot-static pressure probe*. Such an instrument has an outward appearance similar to that of an improved Prandtl static pressure probe (Figure 15.19a), except that the pitot-static probe contains an interior pressure tube attached to an impact port at the leading edge of the probe, as shown in Figure 15.22. This creates two coaxial internal cavities within

FIGURE 15.22 Pitot-static pressure probe.

the probe, one exposed to the total pressure and the second exposed to the static pressure. The two pressures are typically measured using a differential pressure transducer so as to indicate p_v directly.

The pitot-static pressure probe is relatively insensitive to misalignment over the yaw angle range of ± 15 degrees (American Society of Mechanical Engineers (ASME), 1987). When possible, the probe can be rotated until a maximum signal is measured, a condition that indicates that it is aligned with the mean flow direction. However, the probes have a lower velocity limit of use that is brought about by strong viscous effects in the entry regions of the pressure ports. In general, viscous effects should not be a concern, provided that the Reynolds number based on the probe radius, $Re_r = \bar{U}r/\nu$, is greater than 500, where ν is the kinematic viscosity of the fluid. For $10 < Re_r < 500$, a correction to the dynamic pressure should be applied, $p_v = C_v p_i$, where

$$C_v = 1 + (4/Re_r) \quad (15.38)$$

and p_i is the indicated dynamic pressure from the probe. However, even with this correction, the measured dynamic pressure has a systematic uncertainty on the order of 40% at $Re_r \approx 10$ but decreases to 1% for $Re_r \geq 500$.

In high-speed gas flows, compressibility effects near the probe leading edge require a closer inspection of the governing equation for a pitot-static pressure probe. An energy balance along a streamline for a perfect gas between any point x and the stagnation point can be written as

$$\frac{U^2}{2} = c_p(T_t - T_\infty) \quad (8.34)$$

For an isentropic process, the relationship between temperature and pressure can be stated as

$$\frac{T_x}{T_t} = \left(\frac{p_x}{p_t} \right)^{(k-1)/k} \quad (15.39)$$

where k is the ratio of specific heats for the gas, $k = c_p/c_v$. The Mach number of a moving fluid relates its local velocity to the local speed of sound,

$$M = U/a \quad (15.40)$$

where the speed of sound, also called the acoustic wave speed, for a perfect gas is $a = \sqrt{kRT_x}$ where T_x is the absolute temperature of the gas at the point of interest. Combining these equations and using a binomial expansion gives a relationship between total pressure and static pressure at any point x in a moving compressible flow,

$$p_v = p_t - p_x = \frac{1}{2} \rho U_x^2 \left[1 + M^2/4 + (2-k)M^4/24 + \dots \right] \quad (15.41)$$

Equation 15.41 reduces to Equation 15.36 when $M \ll 1$. The error in the estimate of p_v , based on the use of Equation 15.36 relative to the true dynamic pressure, becomes significant for $M > 0.3$, as shown in Figure 15.23. Thus, $M \sim 0.3$ is used as the incompressible limit for perfect gas flows.

For $M > 1$, the local velocity is found through iteration using the Rayleigh relation:

$$p_t/p = \left(\frac{(k+1)^2 M^2}{4kM^2 - 2(k-1)} \right)^{k/k-1} \left(\frac{1-k+2kM^2}{k+1} \right) \quad (15.42)$$

and Equation 15.40 where both p and p_t are the measured values.

FIGURE 15.23 Relative error in the dynamic pressure between using Equations 15.36 and 15.41 at increasing flow speeds.

15.8.2 Thermal Anemometry

The rate at which energy, \dot{Q} , is transferred between a warm body at T_s and a cooler moving fluid at T_f is proportional both to the temperature difference between them and to the thermal conductance of the heat transfer path, hA . This thermal conductance increases with fluid velocity, thereby increasing the rate of heat transfer at any given temperature difference. Hence, a relationship between the rate of heat transfer and velocity exists forming the working basis of a thermal anemometer.

A thermal anemometer utilizes a sensor, a metallic resistance temperature detector (RTD) element, that makes up one active leg of a Wheatstone bridge circuit, as indicated in Figure 15.24. The resistance–temperature relation for such a sensor was shown in Chapter 8 to be well represented by

$$R_s = R_0[1 + \alpha(T_s - T_0)] \quad (15.43)$$

so that sensor temperature T_s can be inferred through a resistance measurement. A current is passed through the sensor to heat it to some desired temperature above that of the host fluid. The relationship between the rate of heat transfer from the sensor and the cooling fluid velocity is given by King's law (King, 1914) as

$$\dot{Q} = I^2 R = A + BU^n \quad (15.44)$$

where A and B are constants that depend on the fluid and sensor physical properties and operating temperatures, and n is a constant that depends on sensor dimensions (Hinze, 1959). Typically, $0.45 \leq n \leq 0.52$ (Collis and Williams,). A , B , and n are found through calibration.

Two types of sensors are common: the hot-wire and the hot-film. As shown in Figure 15.25, the hot-wire sensor consists of a tungsten or platinum wire ranging from 1 to 4 mm in length and from 1.5 to 15 μm in diameter. The wire is supported between two rigid needles that protrude from a ceramic tube that houses the lead wires. A hot-film sensor usually consists of a thin (2 μm) platinum or gold film deposited onto a glass substrate and covered with a high thermal conductivity coating. The coating acts to electrically insulate the film and offers some mechanical protection. Hot wires are generally used in electrically nonconducting fluids, while hot films can be used in conducting fluids or in nonconducting fluids when a more rugged sensor is needed.

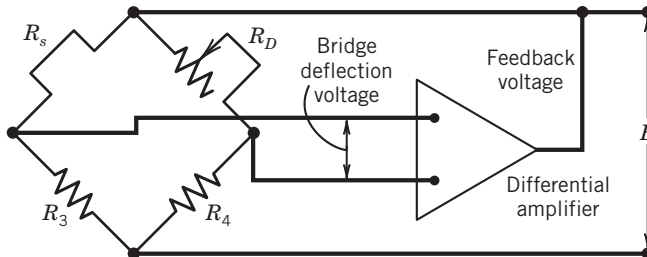

FIGURE 15.24 Thermal anemometer circuit, shown in constant resistance mode.

FIGURE 15.25 Schematic of a hot-wire probe.

Two anemometer bridge operating modes are possible: (1) constant current and (2) constant resistance. In constant-current operation, a fixed current is passed through the sensor to heat it. The sensor resistance and therefore its temperature, based on Equation 15.43, are permitted to vary with the rate of heat transfer between the sensor and its environment. Bridge-deflection voltage provides a measure of the cooling velocity. The more common mode of operation for velocity measurements is constant resistance. In constant-resistance operation, the sensor resistance of Equation 15.43 is originally set by adjusting the bridge balance. The sensor resistance is then maintained constant by using a differential feedback amplifier to sense small changes in bridge balance, which would be equivalent to sensing changes in the sensor set-point resistance; that is, the circuit acts as a closed loop controller using the bridge balance as the error signal. The feedback amplifier rapidly readjusts the bridge applied voltage, thereby adjusting the sensor current to bring the sensor back to its set-point resistance and corresponding temperature. Because the current through the sensor varies with changes in the velocity, the instantaneous power ($I^2 R_s$) required to maintain this constant temperature is equivalent to the instantaneous rate of heat transfer from the sensor (\dot{Q}). In terms of the instantaneous applied bridge voltage, E , required to maintain a constant sensor resistance, the velocity is found by the general correlation

$$E^2 = C + DU^n \quad (15.45)$$

where the values of C , D , and n are found by calibration under a fixed sensor and fluid temperature condition. An electronic or digital linearizing scheme is usually employed to condition the signal by performing the transformation

$$E_1 = K \left(\frac{E^2 - C}{D} \right)^{1/n} \quad (15.46)$$

such that the measured output from the linearizer, E_1 , is

$$E_1 = KU \quad (15.47)$$

where K is found through a static calibration.

For mean velocity measurements, the thermal anemometer is a straightforward device to use. It has a better usable sensitivity than the pitot-static tube at lower velocities. Multiple velocity components can be measured by using multiple sensors, each sensor aligned differently to the mean flow direction and operated by independent anemometer circuits (Hinze, 1959; Rodi, 1975). Because it has a high-frequency response, fluctuating (dynamic) velocities can be measured. In highly turbulent flows with root-mean-square (rms) fluctuations of $\sqrt{u^2} \geq 0.1\bar{U}$, signal interpretation can become complicated, but it has been well investigated (Rodi, 1975). Low-frequency fluid temperature fluctuations can be compensated for by placing resistor R_3 directly adjacent to the sensor and exposed to the flow. An extensive bibliography of thermal anemometry theory and signal interpretation can be found elsewhere (Freymuth, 1978).

In constant temperature mode using a fast-responding differential feedback amplifier, a hotwire system can attain a frequency response that is flat up to 100,000 Hz, which makes it particularly useful in fluid mechanics turbulence research. However, less expensive and more rugged systems are commonly used for industrial flow monitoring, where a fast dynamic response is desirable. There is a natural upper frequency limit on a cylindrical sensor of diameter d that is brought about by the natural oscillation in the flow immediately downstream of a body. This vibrates the sensor. The frequency of this oscillation, known as the Strouhal frequency (and explained further in Section 10.6), occurs at approximately

$$f \approx 0.22[\bar{U}/d](10^2 < \text{Re}_d < 10^7) \quad (15.48)$$

The heated sensor warms the fluid within its proximity. Under flowing conditions this does not cause any measurable problems so long as the condition

$$\text{Re}_d \geq Gr^{1/3} \quad (15.49)$$

is met where $\text{Re}_d = \bar{U}d/\nu$, $Gr = d^3 g \beta (T_s - T_{\text{fluid}})/\nu^2$, and β is the coefficient of thermal expansion of the fluid. Equation 15.49 ensures that the inertial forces of the moving fluid dominate over the buoyant forces brought on by the heated sensor. This forms a lower velocity limit on the order of 0.6 m/s for using hot-wire sensors in air.

15.8.3 Doppler Anemometry

The Doppler effect describes the phenomenon experienced by an observer whereby the frequency of light or sound waves emitted from a source that is traveling away from or toward the observer is shifted from its original value and by an amount proportional to its speed. Most readers are familiar with the change in pitch of a train as heard by an observer as the train changes from approaching to receding. Any radiant energy wave, such as a sound or light wave, experiences a Doppler effect. The effect was recognized and modeled by Christian Johann Doppler (1803–1853). The observed shift in frequency, called the Doppler shift, is directly related to the speed of the emitter relative to the observer. To an independent observer, the frequency of emission is perceived to be higher than actual if the emitter is moving toward the observer and lower if moving away, because the arrival of the emission at the observer location is affected by the relative velocity of the emission source. The Doppler effect is used in astrophysics to measure the velocity of distant objects by monitoring the frequency of light emitted from a particular

gas, usually hydrogen. Since, in the visible light spectrum, frequency is related to color, the common terms of red shift or blue shift refer to frequency shifts toward the red side of the spectrum or toward the blue side.

Doppler anemometry refers to a class of techniques that utilize the Doppler effect to measure the local velocity in a moving fluid. In these techniques, the emission source and the observer remain stationary. However, small scattering particles suspended in and moving with the fluid can be used to generate the Doppler effect. The emission source is a coherent narrow incident wave. Either acoustic waves or light waves are used.

When a laser beam is used as the incident wave source, the velocity measuring device is called a laser Doppler anemometer (LDA). LDA measures the time-dependent velocity at a point in the flow. Yeh and Cummins (1964) in 1964 discussed the first practical laser Doppler anemometer system. A laser beam provides a ready emission source that is monochromatic and remains coherent over long distances. As a moving particle suspended in the fluid passes through the laser beam, it scatters light in all directions. An observer viewing this encounter between the particle and the beam perceives the scattered light at a frequency, f_s :

$$f_s = f_i \pm f_D \quad (15.50)$$

where f_i is the frequency of the incident laser beam and f_D is the Doppler shift frequency. Using visible light, an incident laser beam frequency is on the order of 10^{14} Hz. For most engineering applications, the velocities are such that the Doppler shift frequency, f_D , is on the order of 10^3 – 10^7 Hz. Such a small shift in the incident frequency can be difficult to detect in a practical instrument. An operating mode that overcomes this difficulty is the dual-beam mode shown in Figure 15.26. In this mode, a single laser beam is divided into two coherent beams of equal intensity using an optical beam splitter. These incident beams are passed through a focusing lens that focuses the beams to a point in the flow. The focal point forms the effective measuring volume (sensor) of the instrument. Particles suspended in and moving with the fluid scatter light as they pass through the beams. The frequency of the scattered light is that given by Equation 15.50 everywhere but at the measuring volume. There, the two beams cross and the incident information from the two beams mix, a process known as optical heterodyne. The outcome of this mixing is a separation of the incident frequency from the Doppler frequency. A stationary observer, such as an optical photodiode, focused on the measuring volume, sees two distinct frequencies, the Doppler shift frequency and the unshifted incident frequency, instead of seeing their sum. It is a simple matter to separate the much smaller Doppler frequency from the incident frequency by filtering.

FIGURE 15.26 Laser Doppler anemometer, shown here in the dual-beam mode of operation.

FIGURE 15.27 Oscilloscope trace of a photodiode output showing the Doppler frequency from a single particle moving through the measuring volume.

For the setup shown in Figure 15.26, the velocity is related directly to the Doppler shift by

$$U = \frac{\lambda}{2\sin\theta/2} f_D = d_f f_D \quad (15.51)$$

where the component of the velocity measured is that which is in the plane of and bisector to the crossing beams. In theory, by using beams of different color or polarization, different velocity components can be measured simultaneously. However, the dependence of the lens focal length on color causes a small displacement between the different measuring volumes formed by the different colors. For most applications this can be corrected. The LDA technique requires no direct calibration beyond explicit determination of the parameters in d_f and the ability to measure f_D .

In dual-beam mode, the output from the photodiode transducer is a current of a magnitude proportional to the square of the amplitude of the scattered light seen and of a frequency equal to f_D . This effect is seen as a Doppler “burst” shown in the typical oscilloscope trace of Figure 15.27. The Doppler burst is the frequency signal created by a particle moving through the measuring volume. If the instantaneous velocity of a dynamic flow varies with time, the Doppler shift from successive scatters will vary with time. This time-dependent frequency information can be extracted by any variety of processing equipment that can interpret the signal current. The most common is the burst analyzer.

Burst analyzers extract Doppler frequency information by performing a Fourier analysis (see Chapter 2) on the input signal. This is done by first discretizing the photodetector analog signal at a high sample rate and then analyzing the signal.

The analysis can work in one of two ways. In the first approach, the analyzer performs the fast Fourier transform (FFT) continuously on small blocks of data from which the Doppler frequency is directly determined. In the second mode, the correlation mode, the sampled signal is correlated with itself through a mathematical transformation of the form

$$R_j = \sum_{i=1}^n x(i)x(i+j) \quad (15.52)$$

where i refers to the sample value at time t and j to the sample value at time delay Δt . This operation improves the signal-to-noise ratio (SNR) of the signal; the frequency is

determined from the correlation function and the sample rate. From Equation 15.51, the Doppler frequency can be converted to a velocity and provided as an output signal. The acquisition and analysis occur rapidly so that the signal appears nearly continuous in time and with only a short time lag.

All methods output a voltage that is proportional to the instantaneous velocity, which makes their signal easy to process, or a digital output path to a digital file for signal analysis. At very low light levels and very few scattering particles, the signal level to noise level can be very low. In such cases, photon correlation techniques are successful (Cummins and Pike, 1973; Durst et al., 1976).

The LDA technique measures velocity at a point. Thus, its probe volume needs to be moved around to map out the flow field. If the SNR and seeding is good, the LDA can measure time-dependent velocities well. The LDA technique is particularly useful where probe blockage effects render other methods unsuitable, where fluid density and temperature fluctuations occur, or where environments hostile to physical sensors exist. An extended discussion of LDA techniques can be found elsewhere (Durst et al., 1976; Goldstein, 1996).

15.8.4 Particle Image Velocimetry

Particle image velocimetry (PIV) measures the full-field instantaneous velocities in a planar cross section of a flow. The technique tracks the time displacement of particles, which are assumed to follow the flow. Principle components for the technique are a coherent light source (laser beam), optics, a CCD-camera, and dedicated signal interrogation software.

In a simple overview, the image of particles suspended in the flow are illuminated and recorded during very-short-duration repetitive flashes of a laser beam. These images are recorded and compared. The distance traveled by any particle during the period between flashes is a measure of its velocity. By repeatedly flashing the laser, in the manner of a strobe light, the particle positions can be tracked and velocity as a function of time obtained.

In a typical layout, such as shown in Figure 15.28, a pulsed flash laser beam is passed through a cylindrical lens, which converts the beam into a two-dimensional (2-D) sheet of light. This laser sheet is mechanically situated to illuminate an appropriate cross section of the flow field. The camera is positioned and focused to record the view of the illuminated field. The laser flash and camera shutter are synchronized to capture the flow image. The acquired digital image is stored and processed by interrogation software, resulting in a full-field instantaneous velocity mapping of the flow.

FIGURE 15.28 Basic layout of a digital particle image velocimeter.

The operating principle is based on particle displacement with time

$$\vec{U} = \Delta \vec{x} / \Delta t \quad (15.53)$$

where \vec{U} where \vec{U} is the instantaneous particle velocity vector based on its spatial position $\vec{x}(x,y,z,t)$. The camera records particle position at each flash into separate image frames. To obtain velocity data in a rapid manner, each image is divided into small areas, called interrogation areas. The corresponding interrogation areas between two images, I_1 and I_2 , are cross-correlated with each other, on a pixel-by-pixel basis. A particular particle movement from position \vec{x}^1 to \vec{x}^2 shows up as a signal peak in the correlation $R_{12}(\Delta \vec{x})$, where

$$R_{12}(\Delta \vec{x}) = \int_A \int I_1(\Delta \vec{x}) I_2(\vec{x} + \Delta \vec{x}) d\vec{x} \quad (15.54)$$

so identifying the common particle and allowing the estimate of the particle displacement $\Delta \vec{x}$. By repeating the cross-correlation between images for each interrogation area, a velocity vector map of the full area results.

A number of variations of this process have been developed but the concept remains the same. The technique works in gases or liquids. Three-dimensional information can be obtained by using two cameras. As with LDA, particle size and properties should be chosen relative to the fluid and flow velocities expected so that the particles move with the fluid, but large enough relative to camera pixel size to avoid peak-locking errors (Raffel et al., 2007). The maximum flow speed measurable is limited by the interrogation area size. The resolution depends on laser flash width and separation time, flow velocity, camera recording time, and image magnification. Raffel et al. (2007) discuss the technique, its variations, and error estimates.

15.8.5 Selection of Velocity Measuring Methods

Selecting the best velocity measuring system for a particular application involves a number of factors that an engineer needs to weight accordingly:

1. Required spatial resolution
2. Required velocity range
3. Sensitivity to velocity changes only
4. Required need to quantify dynamic velocity
5. Acceptable probe blockage of flow
6. Ability to be used in hostile environments
7. Calibration requirements
8. Low cost and ease of use.

When used under appropriate conditions, the uncertainty in velocity determined by any of the discussed methods can be as low as 1% of the measured velocity, although under special conditions LDA methods can have an uncertainty one order of magnitude lower (Goldstein and Kried, 1967).

15.8.6 Pitot-Static Pressure Methods

The pressure probe methods are best suited for finding the mean velocity in fluids of constant density. Relative to other methods, they are the simplest and cheapest method available to measure velocity at a point. Probe blockage of the flow is not a problem in large ducts and away from walls. Fluid particulate blocks the impact ports, but aspirating models are available for such situations. They are subject to mean flow misalignment errors. They require no calibration and are frequently used in the field and laboratory alike.

15.8.7 Thermal Anemometer

Thermal anemometers are best suited for use in clean fluids of constant temperature and density. They are well suited for measuring dynamic velocities with very high resolution. However, signal interpretation in strongly dynamic flows can be complicated (Rodi, 1975; Yavuzkurt, 1984). Hot-film sensors are less fragile and less susceptible to contamination than hot-wire sensors. Probe blockage is not significant in large ducts and away from walls. Thermal anemometers are 180° directionally ambiguous (i.e., flows from the left or right directions give the same output signal), an important factor in flows that may contain flow reversal regions. An industrial-grade system can be built rather inexpensively. The thermal anemometer is usually calibrated against either pressure probes or an LDA.

15.8.8 Laser Doppler Anemometer

The laser Doppler anemometer (LDA) is a relatively expensive and technically advanced point velocity measuring technique that can be used for most types of flows but is also well suited to hostile, combusting, or highly dynamic (unsteady, pulsatile, or highly turbulent) flow environments. It offers good frequency response, small spatial resolution, no probe blockage, and simple signal interpretation, but requires optical access and the presence of scattering particles. This method provides very good temporal resolution for time-accurate measurements in turbulent flows. The method measures the velocity of particles suspended in the moving fluid, not the fluid velocity, so careful planning is required in particle selection to ensure that the particle velocities represent the fluid velocity exactly. The size and concentration of the particles govern the system frequency response (Maxwell and Seaholtz, 1974; Dring and Suo, 1982).

15.8.9 Particle Image Velocimetry

Particle image velocimetry (PIV) is a relatively expensive and technically advanced full-field velocity measuring technique that can be used for most types of flows, including hostile and combusting flows. There is no probe blockage of the flow, but it requires optical access and the presence of scattering particles. The method provides an instantaneous snapshot of the flow, providing excellent views of flow structures. Time-dependent quantification of such dynamic flows is possible, but frequency bandwidth is limited to camera frame rate and spatial resolution. As with LDA, this method measures the velocity of particles suspended in the moving fluid, not the fluid velocity, so careful planning is required in particle selection to ensure that the particle velocities represent the fluid velocity exactly.

NOMENCLATURE

d	diameter (l)
e_i	elemental errors
d_f	fringe spacing (l)
f_D	Doppler frequency (Hz)
h	depth (l)
h_0	reference depth (l)
k	ratio of specific heats
p	pressure ($m^{-1}lt^{-2}$)
p_a	applied pressure ($m^{-1}lt^{-2}$)
p_{abs}	absolute pressure ($m^{-1}lt^{-2}$)
p_e	relative static pressure error ($m^{-1}lt^{-2}$)
p_i	indicated pressure ($m^{-1}lt^{-2}$)
p_m	measured pressure ($m^{-1}lt^{-2}$)
p_t	total or stagnation pressure ($m^{-1}lt^{-2}$)
p_v	dynamic pressure ($m^{-1}lt^{-2}$)
q	charge (C)
r	radius (l)
t	thickness (l)
y	displacement (l)
ρ	density (ml^{-3})
ι	time constant (t)
ϕ	latitude
ω_n	natural frequency (t^{-1})
z	altitude (l)
C	capacitance (F)
E	voltage (V)
E_m	bulk modulus of elasticity ($m^{-1}lt^{-2}$)
Gr	Grash of number
H	manometer deflection height (l)
K	static sensitivity
K_q	charge sensitivity ($m^{-1}lt^{-2}$)
K_E	voltage sensitivity ($Vm^{-1}t^{-2}$)
M	Mach number
Re_d	Reynolds number, $Re = Vd/\nu$
S	specific gravity
U	velocity (lt^{-1})
\forall	volume (l^3)
γ	specific weight ($MI^{-2}T^{-2}$)
ϵ	dielectric constant

λ	wavelength (l)
μ	absolute viscosity ($\text{MT}^{-1}\text{L}^{-1}$)
ν	kinematic viscosity (l^2/t)
ν_p	Poisson ratio

16.1 INTRODUCTION

Conjugated organic and organometallic molecules such as pyrene, ruthenium complexes, and platinum porphyrins exhibit luminescence quenching by oxygen (Birks, 1970; Khalil et al., 1989; Wolfbeis, 1991). These oxygen-sensitive luminophore can be

used to monitor oxygen concentrations in various environments through luminescence intensity or luminescence decay (lifetime) rate measurements. A number of oxygen sensors based on these luminophore are now commercially available, and are commonly used in a wide variety of applications (Hach Company, *Hach 9182 Dissolved Oxygen Analyzer*, Loveland, CO; Ocean Optics, Inc., *FOXY Fiber Optic Oxygen Sensors*, Dunedin, FL; Oxford Optronix, Ltd, *OxyLiteTM/OxyLabTMpO2 Sensors*, Oxford, UK). The University of Washington research group pioneered the combination of these luminophore with oxygen-permeable polymer matrices, commonly referred to as binders, to form pressure-sensitive paint. PSP made it possible to obtain high resolution, two-dimensional pressure distributions over aerodynamic surfaces in wind tunnel environments (Kavandi et al., 1990; Demas et al., 1999; Bell et al., 2001). PSP has a number of advantages over discrete pressure taps traditionally used on conventional wind tunnel models: (i) PSP measures pressure distributions over a surface area thereby allowing visualization of dynamic flow processes with high spatial resolution limited only by the imaging system, (ii) PSP allows measurement in regions where conventional pressure taps cannot be used, such as leading and trailing edges, (iii) PSP allows for experimentally guided Computational Fluid Dynamics, resulting in accurate simulations, and (iv) PSP allows for studies of surface flow features, such as shock location and boundary layer separation and reattachment. The experimental setup requires that the paint be either sprayed or airbrushed onto the surface of interest, and a light source emitting blue or UV light to excite the dye. The surface is imaged through a filter that isolates the excitation light from the pressure-sensitive luminescence of the paint. Each pixel on the camera then acts as a pressure tap, and therefore, continuous distributions of the pressure on the painted surface are acquired. Standard pressure paints can be used for mean measurements with response times of about 1 Hz, and fast response (Gregory et al., 2008) systems can be used for high frequency measurements, with a bandwidth of over 100 kHz.

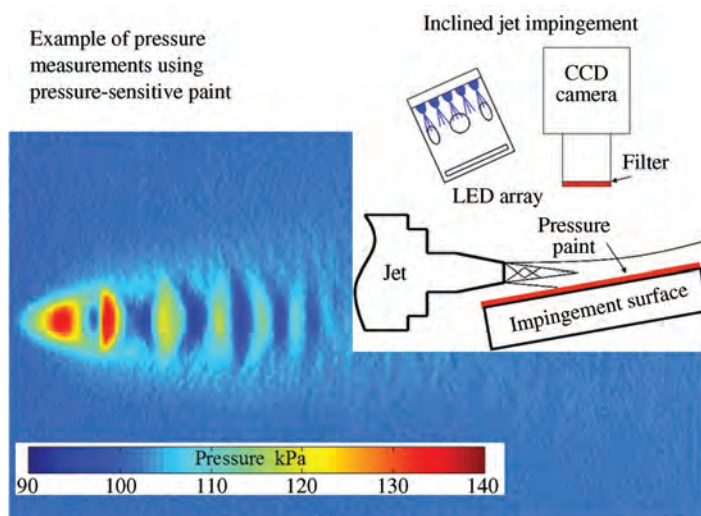

FIGURE 16.1 Example of PSP setup. (See the color version of this figure in Color Plates Section.)

An example of the utility of PSP is shown in Figure 16.1. Here, a jet is impinging onto a flat surface at an inclined angle. While this is a simple experimental setup, the resulting flow-field can produce a complex series of shock and expansion waves on the impingement surface if the jet is operated in the sonic under-expanded regime. In this under-expanded regime, slight changes in the jet pressure ratio can have a dramatic effect on the magnitude and location of these waves. It would be impractical and intrusive to pressure tap the impingement surface. PSP, however, can easily be applied to this problem and produce data with the spatial resolution necessary to resolve the pressure field.

The use of PSP is becoming more common in large transonic tunnels, with production systems in use in several facilities such as AEDC (Ruyten and Sellers, 2004), ARA (Vardaki et al., 2010), TsAGI (Mosharov et al., 1998), and DLR (Engler et al., 2005). Fast-responding PSP has been used in unsteady aerodynamic applications, such as airflow over rotor blades (Bencic, 1998). An excellent review of unsteady aerodynamic applications of PSP has been recently presented by Gregory et al. (2008). The PSP for insect flight has also been evaluated in the Callis laboratory (McGraw, 2004.) with the ultimate goal of mapping the pressure distribution over an insect's wings in flight. Paint formulations, test equipment, and software are now available commercially by Innovative Scientific Solutions, Inc. (Dayton, OH).

16.2 PRINCIPLES OF PRESSURE-SENSITIVE PAINT

PSP is made of an oxygen-sensitive luminescent molecule that is incorporated into an oxygen-permeable polymer binder and dissolved in a volatile solvent to form a paint that can be easily applied to surfaces (Figure 16.2). Exposing the luminescent molecule, or luminophor, to light of an appropriate wavelength places it in an excited state with a finite lifetime. The excited-state luminophor will eventually release its energy primarily by emitting photons or by transferring its energy to a diatomic oxygen molecule. The energetics of this process is presented in a Jablonski diagram in Figure 16.3. The luminophor begins in a singlet ground state, 1S_0 , and is excited into a singlet excited state, 1S_x , upon exposure to UV radiation. It then rapidly decays nonradiatively to its lowest singlet excited state, 1S_1 . From here, the luminophor can transfer its energy in one of three ways. First, it can lose the energy nonradiatively in the form of heat through a first order rate process represented by the rate constant, k_1 . It can also

FIGURE 16.2 A schematic depicting the application of pressure-sensitive paint. (See the color version of this figure in Color Plates Section.)

FIGURE 16.3 A general Jablonski diagram for oxygen-sensitive luminophors.

lose its energy by emitting photons in a process known as fluorescence (k_f). Alternatively, the energy can be transferred from the singlet excited state to a triplet excited state ($3T_1$), through intersystem crossing (k_2).

At this point, the luminophor will relax back to its singlet ground state through non-radiative heat transfer (k_{nr}), through the emission of photons in the form of luminescent (k_p), or through energy transfer to molecular oxygen. Many oxygen-sensitive luminophors are organometallic compounds that feature a heavy, metallic central atom surrounded by an organic ligand. The direct result of this arrangement is strong spin-orbital coupling which helps the molecule to overcome the forbidden transition. Because of this, the triplet state is a relatively long-lived species, and the luminescent decay can occur over a period approaching milliseconds, depending on the exact luminophor (Lakowicz, 1983). This long lifetime allows energy transfer to molecular oxygen to take place through molecular collisions. The rate of energy transfer is directly proportional to the concentration of oxygen present in the surrounding environment, and can be represented by $\kappa_q(O_2)$, where κ_q is the pseudo-first order bimolecular quenching constant and (O_2) is the concentration of oxygen. When the concentration of oxygen is high, collision quenching of the triplet state molecule with oxygen becomes significant. As a result, more energy is transferred to oxygen than is released as photons. Therefore, the triplet state lifetime, τ , can be defined as the inverse of the sum of the three energy decay processes:

$$\tau = (k_{nr} + k_p + \kappa_q[O_2])^{-1} \quad (16.1)$$

The concentration of oxygen, in turn, can be directly related to pressure through Henry's law:

$$[O_2] = \sigma P_{O_2} \quad (16.2)$$

where σ is the Henry's Law constant for oxygen, and P_{O_2} is the partial pressure of oxygen. There are two common ways of quantifying the amount of luminescent intensity being emitted by the luminophor, and both will be described in Section 16.5.

16.3 PRESSURE-SENSITIVE LUMINESCENT DYES

Different types of luminescent dyes are available for measuring oxygen concentration and, hence, pressure. By selecting the appropriate dye to be incorporated in the particular matrix, one can produce PSP for the specific application. This method is based on using the dyes with different excited state lifetime. The rate of the luminescent quenching is directly proportional to the oxygen concentration and the luminescent dye in the excited state. Therefore, the longer the lifetime of the luminescent dye, the higher the probability of being quenched by an oxygen molecule. Similarly, a higher concentration of oxygen dissolved in the polymer corresponds to a higher probability of collisional quenching. Thus, a luminescent dye with a long excited state lifetime is more optimal for lower oxygen concentration, while a short-lived luminescent dye is more optimal for higher oxygen concentration. In principal, it is thereby possible to “tune” the sensitivity for detecting a certain oxygen level by the proper choice of the particular polymer or matrix that has certain oxygen concentration and matching it to a particular dye. The lifetime of the luminophor and the diffusion rate of oxygen in the polymer are matched so that there is a measurable change in the luminescence level for the pressure range to be monitored.

University of Washington has done much research on the particular class of luminescent dyes known as porphyrins. Porphyrins and their derivatives have gained much momentum in chemical sensors application (McDonagh et al., 2008; Di Natale et al., 2010; Amao and Okura, 2009; Khalil et al., 2010; Gewehr, and Delpy, 1993). The electronic structure of the inner 16-membered ring with 18 electrons is responsible for the main features of their optical properties (Khalil et al., 1989). Porphyrin is highly symmetrical molecule with two pairs of low energy excited states, the quasi-forbidden Q states in the visible (650–500 nm) and the strongly allowed B states in the near UV (440–380 nm). Any chemical substitution on the porphyrin ring will reduce the symmetry and has the possibility of affecting the Q-transition intensity as well as its spectral position, displacing the transition to a longer wavelength. Symmetry breaking and symmetry reduction have immediate effects on the spectral properties of porphyrin ring. An important discovery was the high quantum yield and short lifetime of the triplet state of platinum (II) porphyrins (PtP), which has promoted many practical applications. It is believed that the strong electronic interaction between the platinum filled *d* orbital and the porphyrin empty $\pi\pi$ molecular orbitals, and the strong spin of Pt coupling produced approximately 100% triplet quantum yield and 90% phosphorescent emission yield. The concept of using PtP phosphorescence emission changes to study oxygen concentration was originally developed to monitor the oxygen concentration in blood (Khalil et al., 1989). It was originally conceived as a tiny volume of oxygen permeable polymer with luminescent PtP at the end of an optical fiber.

Porphyrins, such as other aromatic molecules, undergo dark and photo oxidation that causes degradation and changes to the spectral properties thus reducing its use life. Porphyrin reactivity with oxygen is influenced by the inductive effects of the functional group attached. To address this problem the photo oxidation process is reduced by the use of an electron withdrawing group such as fluorine. Perfluoro substitutions on porphyrins have been shown to reduce the electron density and increase the photostability (Khalil et al., 1989).

Table 16.1 lists pressure-sensitive dye examples from the porphyrins family as well as other known dyes. For each dye listed, the lifetime, relative quantum yield and wavelengths of operation are reported.

TABLE 16.1 List of Pressure-Sensitive Dyes

Pressure-Sensitive Dye	Lifetime ms (77 K)	Relative Yield (0% O ₂)	Wavelength (nm) λ_{ex} = Excitation λ_{em} = Emission
Platinum octaethylporphine (Kavandi et al., 1990; Gouterman, 1978; Kadish et al., 2000)	0.12	90	λ_{ex} 380, 500, 535 λ_{em} 650
Platinum tetra(pentafluorophenyl)porphine (Khalil et al., 1989; Khalil, 2002)	0.12	90	λ_{ex} 390, 506, 540 λ_{em} 650
Platinum tetra(pentafluorophenyl) porpholactone (Khalil, 2002)	0.072	60	λ_{ex} 396, 536, 574 λ_{em} 733
Platinum tetrabenzotetraphenylporphine (Borek et al., 2007)	0.073	70	λ_{ex} 430, 611 λ_{em} 765
Palladium octaethylporphine (Gouterman, 1978; Kadish et al., 2000)	1.93	50	λ_{ex} 390, 510, 545 λ_{em} 660
Palladium tetra(pentafluorophenyl)por- phine (Khalil et al., 1989; Khalil, 2002)	1.58	20	λ_{ex} 406, 519, 552 λ_{em} 660
Palladium tetra(pentafluorophenyl) porpholactone (Khalil et al., 1993; Gouterman et al., 1989)	1.1	20	λ_{ex} 412, 544, 584 λ_{em} 758
Galadonium octaethylporphine (Kavandi et al., 1990; Gamal and Khalil, 2007)	0.085	55	λ_{ex} 410, 540 λ_{em} 700, 786, 836
Galadonium tetra(pentafluorophenyl) porphine (Borek et al., 2007)	0.14	20	λ_{ex} 420, 550 λ_{em} 726, 810, 922
Tetra(pentafluorophenyl)porphine (Spellane et al., 1980; Wan, 1993; Baron et al., 1993)	0.00001	12	λ_{ex} 410, 505, 535, 580 λ_{em} 700
Thallium tetraphenylporphine (Khalil, 1973)	2.5	45	λ_{ex} 400, 527, 565 λ_{em} 712
Pyrene (Xu et al., 1995)	0.0005	80	λ_{ex} 350 λ_{em} 400
Ruthenium (Xu et al., 1994) tris(4,7- diphenyl-1,1-phenanthroline)Cl ₂	0.005	50	λ_{ex} 460 λ_{em} 610
Osmium (Carlson et al., 2009) tris (bathophenanthroline)dichloride	0.002	37	λ_{ex} 395 λ_{em} 620
Iridium (Fischer et al., 2009) tris(2-(beilzo [b]thiopliene-2-yl)pyridine)	0.0086	—	λ_{ex} 922, 366, 408 λ_{em} 596, 645

16.4 PSP POLYMER AND BINDER

PSP coatings consist of a luminophor dispersed in an oxygen-permeable polymer matrix or binder (see Figure 16.4). The choice of the polymer and matching it to the proper pressure-sensitive dye has been one of most challenging development for the PSP research community. PSP carriers can include polydimethylsiloxane, poly(vinyl chloride), poly(methyl methacrylate), polystyrene, poly(vinyl acetate), silica particles and anodized aluminum, as well as others (Gregory et al., 2008).

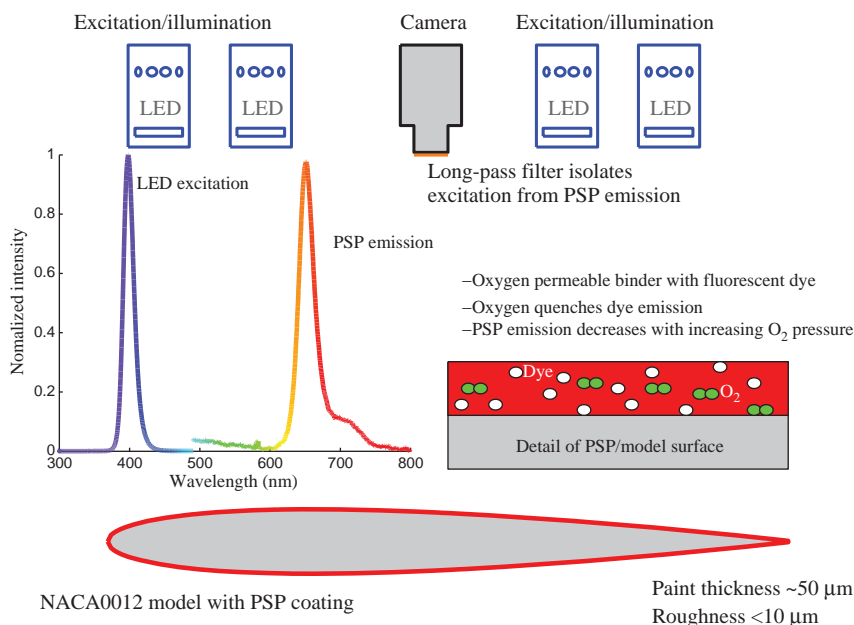

FIGURE 16.4 Basic PSP system showing dye/binder details. (See the color version of this figure in Color Plates Section.)

One of the most persistent problems of a luminescent oxygen sensing method, and hence for pressure-sensitive paint measurement, is the inherent temperature dependence. From the initial studies of PSP, it was clear that PSP accuracy requires temperature correction.

Temperature dependence is caused by several physical processes, such as temperature dependent oxygen permeability in the paint and thermal quenching of the luminescent probe. For most pressure-sensitive paints, the temperature sensitivity of the paint is a function of pressure, and the pressure sensitivity of the paint is a function of temperature. To solve this problem, a new polymer, FIB, was introduced (Carlson and Gouterman, 1997; Puklin et al., 2000), which is a random copolymer of heptafluoro-*n*-butyl methacrylate and hexafluoroisopropyl methacrylate. The FIB polymer has two important attributes: it consistently produces smaller temperature dependence values than other commonly used polymers; and most importantly, it has the same temperature dependence at vacuum and at atmospheric pressure. It was also shown that the small temperature dependence of FIB is due to its low activation energy of quenching and is relatively constant over the temperature range of interest (10–50°C) (Gouin and Gouterman, 2000). This allows for a simple temperature dependence correction.

The luminescence intensity $I(P, T)$ of Pt porphyrin in FIB polymer has been shown to have particularly simple temperature dependence:

$$I(P, T) = I_a(P)I_b(T) \quad (16.3)$$

This is shown by the superposition of the temperature dependence $I(T)$ taken at vacuum and at one atmosphere.

$$I(P_o, T)/I(P, T) = A + B(P/P_o) \quad (16.4)$$

TABLE 16.2 University of Washington PSP History of Pressure-Sensitive Paint

	1990	2000	2005
Sensor (Lakowicz, 1983; Jockusch et al., 2008)	Pt porphyrin	Fluorinated Pt porphyrin	Dual fluorinated Pt/Mg porphyrins
Matrix (Baron, 1996)	Silicone polymer	Fluorinated polymer (FIB)	Fluorinated polymer (FIB)
Pressure	1.0–0.3 Bar	1.0–0.05 Bar	1.0–0.001 Bar
Dynamic range			
90% Response time (ms)	2500	10	0.07
Temp. coeff. (Khan, 1985) (% int./deg.)	–2.5	–0.6	–0.05
Temp error (Baron, 1996) (mbar/deg.)	34	10	1
Applications (Mosharov et al., 1998)	High speed (airfoil) $M > 0.3$, $Re = 10^6$	Low speed (automobile) $M > 0.1$, $Re = 10^5$	Kinetic low speed (insect) $M \sim 0.02$, $Re = 10^3$

Over the past 15 years, the versatility and performance of pressure-sensitive paint has greatly increased. These improvements are described in Table 16.2.

16.5 MEASUREMENT METHODS

The relationship between surface illumination and paint luminescence is linear; therefore, any change in surface illumination will result in an equal change in paint luminescence. Errors in pressure measurements caused by variations in surface illumination can stem from several sources. Consider utilizing a point source for the illumination of a surface, as shown in Figure 16.5. The relationship between illumination intensity at a point on the surface and the distance between the source and the point of interest are an inverse function of the distance squared. Any movement of the painted surface or illumination source will result in a change in the distance between these two points, and thus a change in the illumination intensity at the surface. This movement can result from deformation of the model surface (bending or twisting of the wing due to aerodynamic loading), or physical displacement of the model (movement of the model on the sting due to aerodynamic loading). Even small deformations or displacements of the model can produce large errors in pressure measurements, as demonstrated in Figure 16.5. Another source of illumination errors is physical movement or temporal stability of the illumination source. Any variation of the intensity of the illumination source between the wind-off and the wind-on images will register as an error in illumination. Regardless of the source, illumination errors must be eliminated for the acquisition of quantitative PSP data, especially at low speeds.

For radiometric PSP, errors in pressure measurements due to temperature are largely the result of changes in the temperature of the model between the acquisition of the wind-off and the wind-on image. Any temperature gradient on the model surface, however, will result in a temperature-induced error in the pressure measurements. These temperature gradients can be the result of model construction, tunnel operation, or fluid dynamics. A rapid prototype model, for example, is constructed using an internal metal structure and a

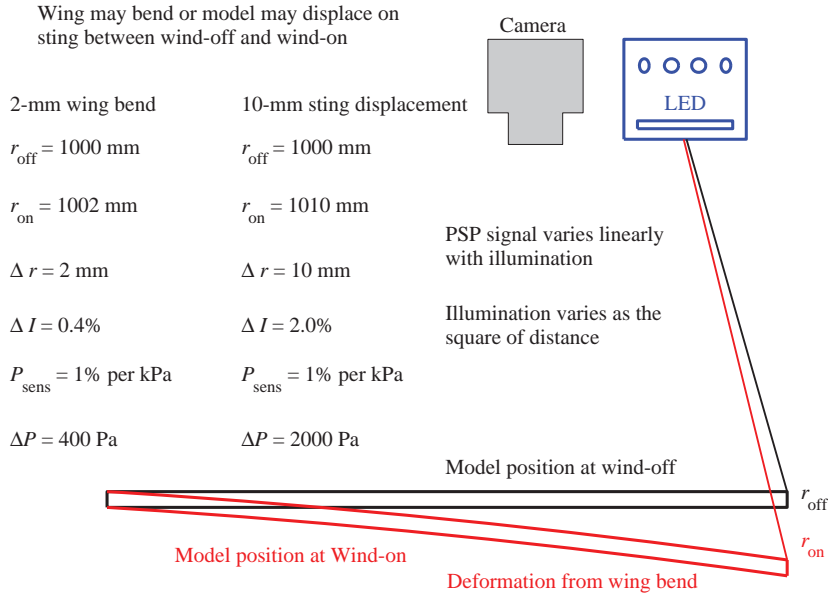

FIGURE 16.5 Illumination error. (See the color version of this figure in Color Plates Section.)

polymer resin. The thermal signature of the internal structure is apparent when the surface of the model is subjected to a heat flux. The model is exposed to a heat flux due to changes in tunnel Mach number, for example, this condition is most apparent during tunnel startup. Temperature errors can be minimized by using temperature-controlled tunnels and constructing the model from materials with high thermal conductivity. In fact, model construction and tunnel operation are key considerations for effective PSP measurements.

16.5.1 Intensity-Based Measurements

The intensity-based method commonly uses a CCD camera to directly measure the luminescent emission intensity, I , of the PSP while as it is being continuously excited by a light source of appropriate wavelength dictated by the choice of luminophor (Gouterman, 1997). For example, platinum octaethylporphyrin (PtOEP) features a strong absorption band at 390 nm, representing the $^1S_0 \rightarrow ^1S_x$ energy transition. This band is commonly known as the Soret band. Additionally, two weaker absorbing bands, known as the Q-bands, appear at 500 nm and 535 nm, and these represent transitions from the singlet ground state to different vibrational groups of the first singlet excited state, 1S_1 (Gouterman, 1997). Therefore, excitation at any of these wavelengths will be sufficient to result in an oxygen-sensitive emission centered at 650 nm.

The amount of phosphorescent emission will be directly related to the number of triplets produced in the intersystem crossing process. The triplet yield, Φ_T , is defined as the number of triplets produced divided by the total number of photons absorbed:

$$\Phi_T = \frac{k_2}{k_2 + k_1 + k_f} \quad (16.5)$$

For PtOEP, it has been shown that Φ_T is nearly 100%.

The triplet yield, in turn, dictates the phosphorescent quantum yield, Φ_P , which is the product of the triplet yield multiplied by the ratio of photons emitted as phosphorescence over the total number of photons absorbed:

$$\Phi_P = \Phi_T \frac{k_p}{k_p + k_{nr} + \kappa_q [O_2]} \quad (16.6)$$

Since (O_2) is directly proportional to pressure, Equation (16.4) becomes

$$\Phi_P = \Phi_T \frac{k_p}{k_p + k_{nr} + \kappa_q \sigma P_{O_2}} \quad (16.7)$$

Ultimately, the phosphorescence quantum yield is directly proportional to the emission intensity of PtOEP. Assuming that the temperature in the environment surrounding the PtOEP remains constant, the rates of phosphorescence (k_p) and collision quenching ($\kappa_q [O_2]$) will be the main parameters that determine the amount of intensity emitted. These processes are inversely proportional—that is, the higher the rate of collisional quenching by oxygen, the less energy remains for phosphorescent emission. In other words, higher oxygen concentrations results in less phosphorescence. Again, through Henry's Law, oxygen concentration can be directly related to pressure. Therefore, quantitatively measuring the phosphorescent emission of PtOEP in a PSP can be used to provide pressure measurements on aerodynamic surfaces.

A ratiometric calibration process is employed to obtain quantitative pressure measurements from emission intensities. First, an initial intensity measurement, I_o , is obtained at a reference pressure, P_o (usually 1 atm). The pressure surrounding the PSP is then changed, and its intensity response is measured. This response can then be quantitatively described by the Kavandi equation (Equation 16.8):

$$\frac{I_o}{I} = \frac{\Phi_o}{\Phi_p} = \frac{k_p + k_{nr} + \kappa_q \sigma P}{k_p + k_{nr} + \kappa_q \sigma P_o} = A + B \frac{P}{P_o} \quad (16.8)$$

$$A = \frac{k_p + k_{nr}}{k_p + k_{nr} + \kappa_q \sigma P_o} \quad (16.9a)$$

$$B = \frac{\kappa_q \sigma P}{k_p + k_{nr} + \kappa_q \sigma P_o} \quad (16.9b)$$

where A and B are known as the Kavandi parameters and are experimentally determined. These parameters are then used to directly equate measured intensities with pressure.

In practice, since PSP is a continuous layer that can cover large two-dimensional test surfaces, pressure distributions with high spatial resolutions over those surfaces can be obtained. This is accomplished by illuminating the PSP with a light source emitting the appropriate wavelength, such as a xenon lamp fitted with a 390 nm bandpass filter. PSP intensity measurements (I_o and I) can be obtained with a CCD fitted with a 650 nm bandpass filter to isolate only the photons resulting from the phosphorescent emission of the PSP. Postprocessing of the images yields I_o/I ratios over the entire imaged region. The Kavandi parameters obtained during calibration of the PSP can then be used to calculate the pressure distribution for the surface.

The intensity ratio serves a dual purpose. In addition to providing a linear relationship between intensity and pressure, intensity images that are compared with a reference image can correct for variations in excitation illumination, paint thickness, or luminophor concentration within the polymer matrix of the paint. However, the reference image requirement can be a significant limitation toward PSP applications, as it is necessary that the test surface remain static between the times that the reference image was obtained and the test images were captured. This approach cannot be used for moving objects, where it may be impossible to replicate the exact illumination conditions for both the reference and test images.

16.5.2 Reference Method Tool and Binary Pressure-Sensitive Paint

One means of dealing with sources of error such as illumination and temperature is to employ a reference probe, and thus, produce a binary pressure-sensitive paint. Several research teams (Bykov et al., 1997; Klein et al., 1999; Khalil et al., 2000) have successfully demonstrated this approach.

Several spectroscopic methods for measuring oxygen concentration or pressure are available that provide an internal referencing. These methodologies are designed to correct for many problems that exist with intensity measurement. Internal reference methods avoid several problems that arise with intensity measurement such as light source changes, index of refraction, optical geometry variations and fluctuations in film thickness, and dye concentration.

Advances in PSP technology have provided a solution to this limitation: a second, pressure-insensitive luminophor could be paired with a pressure-sensitive luminophor to result in self-referencing PSP (Khalil et al., 2004). Sometimes known as binary, or dual-luminophor PSP, the measurement relies on using the pressure-insensitive luminophor to provide reference emission intensity. Ideally, this reference luminophor can be excited at the same wavelength as the pressure-sensitive luminophor, and will have an emission that can be separately resolved.

An example of this is would be a binary-luminophor PSP using platinum tetra(pentafluorophenyl)porpholactone (PtTFPL) as a pressure sensor, and magnesium tetra(pentafluorophenyl)porphyrin (MgTFPP) as a reference. Both luminophors can be excited at 400 nm; PtTFPL provides the pressure-sensitive emission at 733 nm and MgTFPP provides the reference emission at 615 nm. Dual-luminophor PSP eliminates the need for a separate wind-off intensity measurement, as the reference intensity can be simultaneously imaged with the sensor intensity, usually through the use of a second CCD fitted with the appropriate bandpass filter. The binary luminophor PtTFPL and MgTFPP in the FIB polymer produced “ideal” PSP measurements with pressure sensitivity of 4.5% per psi and a temperature dependency of less than $-0.1\%/^{\circ}\text{C}$. The temperature dependency of the dual luminophor intensity ratio ($I_{\text{ref}}/I_{\text{sen}}$) is substantially reduced compared with the use of $I(\text{PtTFPP})$ alone which has a temperature dependence in FIB of $0.60\%/^{\circ}\text{C}$. The use and benefits of binary-luminophor PSP have been demonstrated numerous times, including a study performed by Youssef Mébarki of the NRC of Canada on low speed (20–40 m/s) automotive testing (Gouterman et al., 2004). In general, using a ratiometric method of the two intensities produces a more robust pressure measurement. Binary-luminophor PSP has since been commercialized by Innovative Scientific Solutions, Inc.

16.5.3 Lifetime-Based Measurements

Once illumination errors caused by model movement were identified as a significant source of error for Radiometric PSP systems, several teams began investigating lifetime techniques for wind tunnel applications. Approaches to measuring luminescent lifetimes for PSP have included phase-sensitive detection (Holmes, 1998) and multigate integration (Goss et al., 1999). Among the advantages of the lifetime approach is the elimination or minimization of illumination errors. Theoretically, all data are acquired at the wind-on condition and this minimizes or eliminates illumination as a source of error in the measurement. Errors due to temperature are still a source of uncertainty in lifetime-based PSP measurements as is shown by a calibration of UF-400 using the two-gate approach in Figure 16.6.

The practical implementation of the lifetime approach involves multigate integration using pulsed LEDs and frame transfer cameras with on-chip accumulation. A schematic of the two-gate lifetime approach is shown in Figure 16.7. The paint is excited to fluoresce using a short illumination pulse. Data are acquired in two distinct windows, in this case the first of these windows occurs during the illumination pulse and the second is centered on the decay of the fluorescence. The ratio of the integrated signal from the two gates is computed and the resulting signal is plotted versus pressure. The position and width of the gates is selected to maximize the systems sensitivity to pressure while maintaining a favorable signal to noise ratio.

A second technique measures the phosphorescent lifetime of the pressure-sensitive luminophor (Bell et al., 2001; Coyle, 1999). First, the PSP is excited with a quick burst of light at the appropriate wavelength from a pulsed light source, forcing the pressure-sensitive luminophor into its excited state. The luminophor will then lose its energy by emitting photons or transferring the energy to molecular oxygen. The loss of energy in the system ideally follows an exponential decay of the form:

$$I = I_0 e^{-t/\tau} \quad (16.10)$$

FIGURE 16.6 Lifetime calibration of UF-400 PSP using two-gate integration. (See the color version of this figure in Color Plates Section.)

FIGURE 16.7 Two-gate lifetime measurement approach. (See the color version of this figure in Color Plates Section.)

where I_0 represents the initial intensity of luminophor, t is time, and τ is the lifetime of the luminophor. As the lifetime is inversely proportional to the oxygen concentration of the environment, it can provide a measure of pressure. Traditionally, lifetimes of luminescent systems are measured using photodiodes or photomultiplier tubes designed to collect emission intensity in a time dependent manner. However, these detectors cannot provide spatially resolved lifetime data over two-dimensional surfaces.

Fortunately, it is possible to use a CCD to obtain such lifetime distributions. It can be shown that by dividing the phosphorescent decay curve into two regions (I and II) split at time t_d (Figure 16.8) and integrating each region, a lifetime value can be calculated using (Baron, 1996)

$$\tau = \frac{t_d}{\ln\left(\frac{I + II}{II}\right)} \quad (16.11)$$

where I and II are the integrated areas of regions I and II, respectively. Specially designed CCDs have the ability to obtain two images in rapid succession, separated by times as small as 200 ns. Known as the double image feature (DIF) (Terminology of Princeton Instruments MicroMAX CCD), it allows the user to set the exposure time of both windows, which can be as short as 1 μ s. As each image effectively integrates the emission intensity of their respective portions of the luminescence decay curve, it is possible to calculate the spatially resolved lifetime distributions, and thus the pressure distribution, over the test surface.

One of the attractive features of lifetime PSP is the potential for near real-time data presentation. Since there is no significant movement or deformation of the model between gate 1 and gate 2, conversion of the images to pressure requires only simple math. The background is subtracted from each gate, the ratio of gate 2 over gate 1 is computed, and this ratio is converted to pressure using a calibration. For the final data, the PSP data must be corrected using the pressure taps; however, the preliminary data are sufficiently accurate for real-time investigation and decision making.

FIGURE 16.8 A plot displaying the integrated regions of the phosphorescent decay curve utilized in modified rapid lifetime determination. (See the color version of this figure in Color Plates Section.)

Modern lifetime systems use pulsed LEDs for illumination and CCD cameras with signal accumulation for detection. The LED can be pulsed repetitively at several kHz and the camera can gate and integrate the fluorescent signal from the PSP. This combination of LEDs and signal accumulation is necessary as the number of photons from the PSP is limited. Generally, it is necessary to accumulate signal for several thousand pulses on each gate.

As lifetime determination of PSP is independent of lighting conditions, coating uniformity or concentration variations, it is often seen as being a more robust method of measuring pressure, as opposed to intensity-based measurements. However, lifetime-based measurements involve more complicated hardware setups and can be more difficult to obtain experimentally.

16.5.4 PSP by Singlet Oxygen Emission

PSP performance may be validated if it is compared to a direct oxygen concentration measurement method. We examined the possibility to measure oxygen concentration directly by looking at oxygen alone.

The ground state of molecular oxygen is a triplet, $^3\Sigma_g^-$. Its two lowest excited states are $^1\Delta_g$ and $^1\Sigma_g^+$, known as singlet molecular oxygen, which lie $7,882\text{ cm}^{-1}$ ($\sim 1,270\text{ nm}$) and $13,121\text{ cm}^{-1}$ ($\sim 760\text{ nm}$) above the ground state, respectively. In free molecular oxygen, $^3\Sigma_g^- \rightarrow ^1\Delta_g$ and $^3\Sigma_g^- \rightarrow ^1\Sigma_g^+$ transitions are very weak since these transitions are both electric dipole and spin forbidden. The production of singlet oxygen by direct stimulation is very inefficient, but the process of triplet quenching of PtP produces singlet oxygen very effectively (Jockusch et al., 2008). The radiative lifetimes of singlet oxygen are 45 min for $^1\Delta_g$ and 11 s for $^1\Sigma_g^+$. The observed lifetimes for $^1\Delta_g$ range from milliseconds in gaseous phase to microseconds in aqueous media (Khan, 1985; Wasserman and Murray, 1979; Schaap, 1976). The lifetime of $^1\Sigma_g^+$, on the other hand, is much shorter since $^1\Sigma_g^+$ is more reactive and quickly decays into $^1\Delta_g$ or $^3\Sigma_g^-$. With the availability of InGaAs NIR detectors, detection of $^1\Delta_g$ emission becomes much more feasible (Zebger et al., 2004). We have shown that the use

FIGURE 16.9 Images of 650 and 1270 nm emissions of UW logo. (See the color version of this figure in Color Plates Section.)

of $^1\Delta_g$ emission at 1270 nm can be a probe for direct oxygen concentration measurement (Khalil et al., 2005). For example, the emission collected from a PtTFPP film excited at 400 nm has a 650 nm phosphorescence band and a 1270 nm singlet oxygen emission band. Luminescence images at 650 nm and 1270 nm of a PtTFPP film shaped in the form of “UW” taken at two oxygen concentrations are given in Figure 16.9. Figure 16.9 shows the 1270 nm oxygen emission under air (21% oxygen) is bright and much weaker near 0% oxygen. On the other hand, images at 650 nm have little luminescence under air and brighter luminescence under vacuum. Thus, the two images would appear to be exchanged. This study shows qualitatively that the concentration of singlet oxygen over the surface of the film can be measured by the oxygen emission intensity as well as by the luminescence quenching of the PtTFPP.

16.5.5 Error Analysis

The sources of uncertainty for PSP measurements have been investigated and modeled by Liu and Sullivan (2004). These error sources include temperature, illumination, model displacement, model deformation, sedimentation, paint photo-degradation, stray light, and camera shot noise. While each of these error sources can be a significant problem in certain situations, those errors associated with model displacement and deformation as well as temperature are the major contributors in a large low-speed tunnel.

16.5.5.1 Stern–Volmer Equation The relationship between temperature, pressure, and intensity is given by the aerodynamic Stern–Volmer equation. In this equation T_{ref} is the reference temperature, P_{ref} is the reference pressure, and I_{ref} is the paint intensity at the reference condition

$$\frac{I_{\text{ref}}}{I} = A(T) + B(T) \frac{P}{P_{\text{ref}}} \quad (16.12)$$

The Stern–Volmer coefficients are temperature dependent because temperature affects both nonradiative deactivation and oxygen diffusion in a polymer. The Stern–Volmer

coefficients can be approximately expressed as a linear function of temperature as

$$\begin{aligned} A(T) &= A(T_{\text{ref}}) \left[1 + \frac{E_{\text{nr}}}{RT_{\text{ref}}} \left(\frac{T - T_{\text{ref}}}{T_{\text{ref}}} \right) \right] \text{thermal quenching} \\ B(T) &= B(T_{\text{ref}}) \left[1 + \frac{E_{\text{p}}}{RT_{\text{ref}}} \left(\frac{T - T_{\text{ref}}}{T_{\text{ref}}} \right) \right] \text{oxygen diffusivity} \end{aligned} \quad (16.13)$$

In this equation, E_{nr} is the Arrhenius activation energy for thermal quenching, E_{p} is the activation energy for oxygen diffusion, and R is the gas constant. These equations suggest that the temperature dependence of $A(T)$ is due to thermal quenching while the temperature dependence of $B(T)$ is related to the diffusivity of oxygen in the polymer binder. The Stern–Volmer coefficients are determined in the paint calibration process and these coefficients are necessary components in the error analysis process.

16.5.5.2 Uncertainty in Temperature and Pressure-Sensitive Paint Measurements

Sources of uncertainty for temperature- and pressure-sensitive paint measurements have been investigated and modeled by Liu and Sullivan. A functional relationship between the system components was developed by Liu and the elemental error sources and their sensitivity coefficients in the error propagation were evaluated. These error sources include temperature, illumination, model displacement and deformation, sedimentation, photo-degradation, and camera shot noise. To determine the overall variance in pressure for a single element the elemental error is computed and multiplied by its sensitivity coefficient. The total error is computed by summing each elemental error using

$$\frac{\text{var}(P)}{P^2} = \sum_{i=1}^M S_i^2 \frac{\text{var}(\zeta_i)}{\zeta_i^2} \quad (16.14)$$

To facilitate the error analysis of the data to be presented, a brief discussion of each error mechanism identified by Liu and the impact that each has on a given experiment is included. Finally, a table consisting of error sources, quantitative estimates of variances, and the final impact that these errors will have on the data are presented.

16.5.5.3 Temperature Sensitivity of Pressure-Sensitive Paint Errors in pressure measurements due to temperature are the result of changes in the temperature distribution on a test surface between the *wind-off* and the *wind-on* image acquisition. The physical process that causes the unsteady temperature on the jet impingement surface and the means for minimizing this error will be discussed later. Assuming one has minimized the thermal drift of the test surface, the remaining quantity of interest is the sensitivity of the system to temperature. Liu defines the sensitivity coefficient of the pressure-sensitive paint measurement to temperature using the Stern–Volmer coefficients that were defined in Equation (16.2). Differentiation of these equations and rearranging yields

$$\frac{-T}{B(T)} \left[B'(T) + A'(T) \frac{P_{\text{ref}}}{P} \right] \quad (16.15)$$

Again, $A(T)$ and $B(T)$ are defined using Equation (16.2), and the primes denote differentiation.

The elemental variance of the temperature can be estimated using both theoretical and experimental means. A theoretical estimate of the maximum temperature variation on a model can be obtained by computing the recovery temperature of the fluid on the model surface. This is accomplished using one-dimensional isentropic flow equations and the definition of the recovery temperature. An upper limit on the temperature variation is obtained by assuming the flow is laminar and the recovery factor (r) is 0.84. For an adiabatic model at Mach 0.2 $\text{var}(T)$ is about 0.4 K whereas at Mach 1.0 $\text{var}(T)$ is closer to 9 K.

An experimental measurement of the temperature variation can also be conducted using temperature-sensitive paint. The experimental variance for an isothermal model is generally about 10–20 times smaller than the theoretical prediction. The small temperature variation is the result of an experimental setup that seeks to minimize the temperature variation on the model surface. A temperature variation of 1 K will be used for the error analysis.

16.5.5.4 Illumination and Model Deformation/Displacement The relationship between surface illumination and paint luminescence is linear; therefore, any change in surface illumination will result in an equal change in paint luminescence. Errors in pressure measurements caused by variations in surface illumination can stem from several sources. Consider utilizing a point source for the illumination of a surface. The relationship between illumination intensity at a point on the surface and the distance between the source and the point of interest is an inverse function of the distance squared. Any movement of the painted surface or illumination source will result in a change in the distance between these two points, and thus a change in the illumination intensity at the surface. This movement can result from deformation of the model surface, or physical displacement of the model or illumination source. Another source of illumination errors is the temporal stability of the illumination source. Any variation of the intensity of the illumination source between the *wind-off* and the *wind-on* images will register as an error in illumination. The sensitivity coefficient for the illumination errors as defined by Liu is

$$\varphi = 1 + \frac{A(T)}{B(T)} \frac{P}{P_{\text{ref}}} \quad (16.16)$$

In this equation, $A(T)$ and $B(T)$ are defined in Equation (16.2), P is the experimental pressure, and P_{ref} is the reference pressure. The quantity in Equation (16.6) is a very common sensitivity coefficient and is therefore defined as φ .

In general, illumination errors are a major contributor to the overall error in pressure-sensitive paint measurements. The use of lifetime and binary paints has been developed specifically to mitigate this error source. If a tradition PSP is used, it is essential that the model surface, illumination source, and camera are all mounted rigidly so as to eliminate relative movement. The rigid nature of the experiment setup results in experimental system where errors due to displacement or deformation are negligible.

The remaining source of illumination error is the temporal stability of the illumination source. LED arrays have been developed that provide very stable illumination and are recommended for high quality PSP testing.

16.5.5.5 Detector Noise One significant source of noise for radiometric pressure-sensitive paint measurements using CCD cameras identified by Liu is noise from the detector. For a CCD camera this includes both read noise and shot noise. The read noise for most scientific grade CCD cameras is well below the shot noise. If this is not the case, the camera is not suitable for PSP measurements. The remaining discussion of detector noise will focus on shot noise of the detector. For a CCD array, the quantity of interest is the number of photoelectrons collected. In the absence of other sources of detector noise (e.g., read noise), the uncertainty in the intensity measurement is an inverse function of the square root of the number of photoelectrons that the measurement is based on. It is worth noting that, theoretically, the detector can be eliminated as a source of error; simply acquiring multiple frames and summing the images will drive the noise to zero. The shot noise will decrease with the square root of the number of shots acquired, or the total number of photons the measurements is based on.

$$\text{Shot noise} \propto \frac{1}{\sqrt{Nn_{\text{pe}}}} \quad (16.17)$$

In this equation, n_{pe} is the average number of photoelectrons collected by a camera pixel during each exposure, and N is the number of images acquired.

Unfortunately, acquiring an infinite number of images is not practical in an experimental environment. Test parameters such as fluid or surface temperature, photo-degradation and sedimentation of the painted surface, and illumination stability are difficult, or impossible to control in practical situations. As these parameters change during the data acquisition process, they begin to introduce more noise than is being eliminated by the additional images. There is a tradeoff between the time required to acquiring multiple images, and thus drive down shot noise, and the stability of the test parameters. For this reason, a limited number of images must be acquired at each test condition. Data sets consisting of 1–128 images are generally used for PSP experiments. This number is usually set by a limit on the time on condition allowed for data acquisition. The full-well capacity of the CPO.1600 camera is about 40,000 photoelectrons. Assuming the average pixel reached 80% of the full-well capacity, a set of 128 images will yield a shot noise of about 0.05%. Combining this shot noise with the sensitivity coefficient for detector noise

$$S = \left[1 + \frac{A(T)}{B(T)} \frac{P}{P_{\text{ref}}} \right] \left[\sqrt{1 + A(T) + B(T) \frac{P}{P_{\text{ref}}}} \right] \quad (16.18)$$

the noise level for pressure-sensitive paint measurements using FIB is about 70 Pa. This represents a best-case noise level for a data set with no low pass filtering.

16.5.5.6 Photo-Degradation and Sedimentation Photo-degradation of the luminescent probe and sedimentation of the painted surface introduce bias errors into the pressure measurements. Photo-degradation is an optical reaction that is a function of the illumination intensity, spectral content of the illumination, and time. Sedimentation is caused by dirt and oils in the flow that accumulate on the painted surface. Over time the sediments screen the paint from the illumination light and mask the paint luminescence from the detector. If sedimentation and photo-degradation occurred uniformly over the test surface, this error could be corrected using an *in situ* pressure tap. Unfortunately, these effects are a function of the local conditions. To minimize errors due to sedimentation and

photo-degradation it is necessary to minimize the time interval between the *wind-off* and the *wind-on* images.

It is noted that photo-degradation and sedimentation are not eliminated by the use of a binary PSP. The photo-degradation rate of the two dyes in a binary paint is rarely equal, and therefore, the difference in the photo-degradation rates is effectively the photo-degradation rate of the paint. In the case of a lifetime-based measurement, photo-degradation has almost no effect, other than to lower the PSP signal, and therefore, the shot noise. The impact of sedimentation is mitigated substantially by the use of either a binary or lifetime-based PSP system. It is possible that the optical density of the sediment is not identical for each channel of a binary PSP. It is also possible that sedimentation could occur rapidly, thus having an impact between the acquisition of individual images; however, these effects are generally negligible.

A worst case estimate of the impact of photo-degradation and sedimentation for a traditional PSP is based on the test facility and experimental hardware. The data acquisition time is generally several minutes and the photo-degradation rate is about 1% per hour at the exposure levels seen in most wind tunnels. Generally, the photo-degradation rate is about 1% per hour at the exposure levels seen in most wind tunnels. Sedimentation varies widely with wind tunnels, and therefore, a very rough estimate of 1% per hour is applied here as well. Assuming data is acquired at five to ten test conditions between *wind-off* data sets, the time required to complete data acquisition is about 5 min. This results in photo-degradation and sedimentation of about 0.09%. The sensitivity coefficient for sedimentation and photo-degradation is again, φ , defined in Equation (16.6).

16.5.5.7 Spectral Variability and Filter Leakage The output of some illumination sources, such as flash-lamps, experience spectral variations over time. Variations in the spectra of the illumination source can result in variations of the paint luminescence. The variation in the paint luminescence is due to variations in the absorption characteristics of the luminescent molecule. The spectral output of the LED array is, however, very stable over the life of the array, but there is a warm-up period lasting several minutes during which the spectral output of the LED array will shift by less than 0.1 nm. Following this warm-up period, the output is stable. Spectral variations of the illumination source of this magnitude are of no significant consequence. It is noted that spectral variation can be a significant problem for other illumination sources. Care must be taken to filter the source and ensure a stable illumination spectrum.

The purpose of the filter on the detector is to eliminate the blue/UV excitation from the red-shifted emission of the paint. Errors due to filter leakage can result if the illumination source includes spectral content at the wavelength of paint luminescence. Generally, this spectral content is minimized by using a short pass filter on the illumination source. Most LEDs, for example, do have some spectral content at wavelengths beyond 600 nm; this contribution is minimized by adding an appropriate short-pass filter to the LED array. The variance for spectral variability is assumed negligible for the LED lamp, while the filter leakage is estimated to be 0.01%. This is combined with the sensitivity coefficient for spectral variability and filter leakage φ , defined in Equation (16.6) to determine the uncertainty in the final pressure measurement.

16.5.5.8 Reference Pressure and Paint Calibration Parameters The quantity P_{ref}/P appears directly in the Stern–Volmer equation. Any error in measuring the reference pressure, the pressure that the *wind-off* images are acquired at, will result in an error in the

final pressure measurement. The sensitivity coefficient for this error is unity. This error is based on the accuracy of the pressure transducer available in the laboratory during the experiments and is less than one-tenth of a percent.

The uncertainty in determining the Stern–Volmer coefficients $A(T)$ and $B(T)$ are calibration errors. These errors can be estimated by performing repeated calibrations and computing the variance of the quantities $A(T)$ and $B(T)$. The variance computed from such tests in the controlled calibration chamber is generally less than 1%. The use of a priori calibrations often results in bias errors in field tests. If these errors are the result of variations in the Stern–Volmer coefficients, then the a priori calibrations are not valid. A more likely explanation is that other errors, such as temperature, illumination, and model movement are responsible for the inaccuracies. The respective sensitivity coefficient for $A(T)$ and $B(T)$ are $1 - \varphi$ and 1.

16.5.5.9 Sensitivity Coefficients A summary of the physical source of the each error and the corresponding sensitivity coefficient for that error is given in Table 16.3. Some means of estimating the variance of each error source is also necessary. The physical

TABLE 16.3 Estimation of Elemental Errors for Pressure-Sensitive Paint Measurements

Variable	Physical Origin	Sensitivity Coefficient	Elemental Variance	Estimated Error
		S_i	$\frac{\text{var}(\zeta_i)}{\zeta_i^2}$	
T	Temp. sens. of PSP	$\frac{-T}{B(T)} \left[B'(T) + A'(T) \frac{P_{\text{ref}}}{P} \right]$	$\left(\frac{\Delta T}{T} \right)^2$	$\Delta T \approx 1K$
$D_x(\Delta x)$	Deformation/ displacement	$\varphi = 1 + \frac{A(T) P_{\text{ref}}}{B(T) P}$	$\left(\frac{\Delta x}{x} \right)^2$	$\Delta x \approx 0$
$D_{q0}(\Delta t)$	Temporal variation in illumination	φ	$\left(\frac{\Delta I}{I} \right)^2$	$\frac{\Delta I}{I} \approx 0.1\%$
V_{ref}	Photo-detector noise ref. image	$\varphi \left(\sqrt{1 + A(T) + B(T) \frac{P}{P_{\text{ref}}}} \right)$	$\frac{1}{n_{\text{pe}}}$	$n_{\text{pe}} \approx 3.6 \times 10^6$
V	Photo-detector noise signal image	$-\varphi \left(\sqrt{1 + A(T) + B(T) \frac{P}{P_{\text{ref}}}} \right)$	$\frac{1}{n_{\text{pe}}}$	$n_{\text{pe}} \approx 3.6 \times 10^6$
$D_t(\Delta t)$	Photo-degradation and sedimentation	φ	$\left(\frac{\Delta D_t}{D_t} \right)^2$	$\frac{\Delta D_t}{D_t} \approx 0.1\%$
Π_t/Π_{fref}	Illum. spectral varia- bility and filter leakage	φ	$\left(\frac{\Delta \Pi}{\Pi} \right)^2$	$\frac{\Delta \Pi}{\Pi} \approx 0.05\%$
P_{ref}	Error in reference pressure	1	$\left(\frac{\Delta P}{P} \right)^2$	$\frac{\Delta P}{P} \approx 0.1\%$
A	Paint calibration	$1 - \varphi$	$\left(\frac{\Delta A}{A} \right)^2$	$\frac{\Delta A}{A} \approx 1\%$
B	Paint calibration	-1	$\left(\frac{\Delta B}{B} \right)^2$	$\frac{\Delta B}{B} \approx 1\%$

parameter used to estimate the variance of each source is also listed in Table 16.3. The sensitivity coefficients are a function of the paint calibration coefficients, the temperature, and the pressure. To demonstrate the advantages of a PSP with low-temperature sensitivity, a theoretical experiment is performed using several common paint formulations, Ruthenium in RTV and PtTFPP in FIB are included.

$$\begin{aligned} A(T) &= 0.56 \left[1 + 2.72 \left(\frac{T - 298}{298} \right) \right] \\ B(T) &= 0.43 \left[1 + 4.75 \left(\frac{T - 298}{298} \right) \right] \text{ Ruthenium in RTV} \end{aligned} \quad (16.19)$$

$$\begin{aligned} A(T) &= 0.25 \left[1 + 0.96 \left(\frac{T - 298}{298} \right) \right] \\ B(T) &= 0.75 \left[1 + 1.52 \left(\frac{T - 298}{298} \right) \right] \text{ PtTFPP in FIB} \end{aligned} \quad (16.20)$$

The relative importance of each error source can be evaluated by comparing the elemental errors. The error in pressure that would result from the estimated elemental variance listed in Table 16.3 was computed at a P_{ref}/P of unity for PtTFPP in FIB, Ruthenium in RTV with Silica Gel, and Ruthenium in RTV. The pressure errors, plotted in Figure 16.10, indicate that temperature and paint calibrations are the major sources of error for these measurements. The temperature error is minimized using PtTFPP in FIB. The errors associated with the Ruthenium in RTV paint compare poorly to both PtTFPP in FIB and Ruthenium in RTV with Silica Gel in each category. This poor performance is related to the inferior pressure sensitivity of Ruthenium in RTV.

Temperature variation has been identified as a major source of error for many PSP measurements. Further insight into the susceptibility to temperature errors for the paint is

FIGURE 16.10 Elemental errors for pressure-sensitive paint measurement. (See the color version of this figure in Color Plates Section.)

FIGURE 16.11 Sensitivity coefficient for temperature for three paint formulations. (See the color version of this figure in Color Plates Section.)

provided by plotting the sensitivity coefficient for temperature as a function of P_{ref}/P ; the result is shown in Figure 16.11. Again, PtTFPP in FIB provides the smallest sensitivity coefficient for temperature. It is also evident that the sensitivity coefficient for temperature of PtTFPP in FIB is a very weak function of temperature. The overall low-temperature sensitivity is the result of the low activation energy for the FIB polymer. In contrast, Ruthenium in RTV has a very high-sensitivity coefficient for temperature.

The goal of the preceding discussion is to introduce the tools for error analysis of pressure-sensitive paint measurements. Insight into the data acquisition procedure that will yield the best possible data is obtained by considering each error and the experimental mechanisms available to minimize each error. A good experimental setup will provide a very rigid framework for mounting the test surface, illumination source, and detectors to eliminate model movement and deformation. This can also be accomplished by using a lifetime or binary PSP system. Data acquisition should be performed quickly to minimize photo-degradation and sedimentation of the test surface. The detector should acquire multiple images quickly to minimize shot noise. Finally, the temperature of the test surface should be uniform throughout the test. In this case, a temperature compensating binary PSP can minimize the impact of both temperature and model movement.

16.6 PRESSURE-SENSITIVE PAINT MEASUREMENTS

16.6.1 Research Facilities

The use of pressure-sensitive paint for measurements in research-based experiments is well developed. The use of PSP is quite common in transonic tunnels, with measurements conducted at a variety of academic, government, and even commercial production facilities. Today, these measurements are conducted using both binary and lifetime-based PSP

FIGURE 16.12 Pressure measurements on a supersonic flameholding pylon at Mach 2. (See the color version of this figure in Color Plates Section.)

systems. A few examples of the application of PSP systems in these facilities are included here. The goal is to demonstrate the application of PSP in different wind tunnel settings; this is by no means a comprehensive list of the users of PSP.

16.6.1.1 Supersonic Flameholding Pylons An example of binary PSP data acquired in a supersonic tunnel is an experimental study of a flameholder pylon in a direct-connect supersonic facility located at WPAFB/AFRL. Symmetric facility nozzles were used to produce supersonic flow at nominal Mach numbers of 2 and 3. Windows are located on both side walls and top wall for optical access and two sets of illumination source and CCD camera were aligned to obtain the side view and top view for PSP measurements. Each system was composed of a PCO.1600 CCD camera with a filter wheel, a 55-mm Nikon lens, and a laptop PC running OMS Acquire.

Surface pressure distributions on one pylon at Mach 2 are illustrated in Figure 16.12 (Crafton et al., 2009). A high-pressure zone at the thin leading edge of the strut due to the flow impingement and a low-pressure region behind the expansion are clearly observed. As these pylons are under investigation for super-sonic flame holders, there are several fuel injection ports evident on the surface. An interesting use of PSP is as a flow visualization tool. Nitrogen (N_2) was injected through the injection ports and the resulting pressure field is indicative of both pressure and mass fraction of injected gas. A pair of bow shocks are formed in front of the injection ports as would be expected. The trace of the injected N_2 near the pylon surface is identified by the low-pressure region behind the injection ports. These regions are not really low pressure, but the result of the replacement of oxygen by the injected N_2 . The presence of the gas on the surface would indicate that some of the injected gas should enter the stagnant subsonic zone behind the strut, and therefore, possibly be available for combustion and flame holding.

16.6.1.2 Transverse Jet Injection in a Supersonic Flow The jet-in-crossflow is a simple configuration and as such is often considered a canonical problem for both low- and high-speed flows. For high-speed flows, it has many interesting features that make it challenging to simulate, including flow separation (both upstream and downstream of the jet axis) and unsteadiness; furthermore, the degree of separation and unsteadiness appear to depend strongly on injection angle and pressure. PSP offers a means of studying the features on this flow with high spatial resolution.

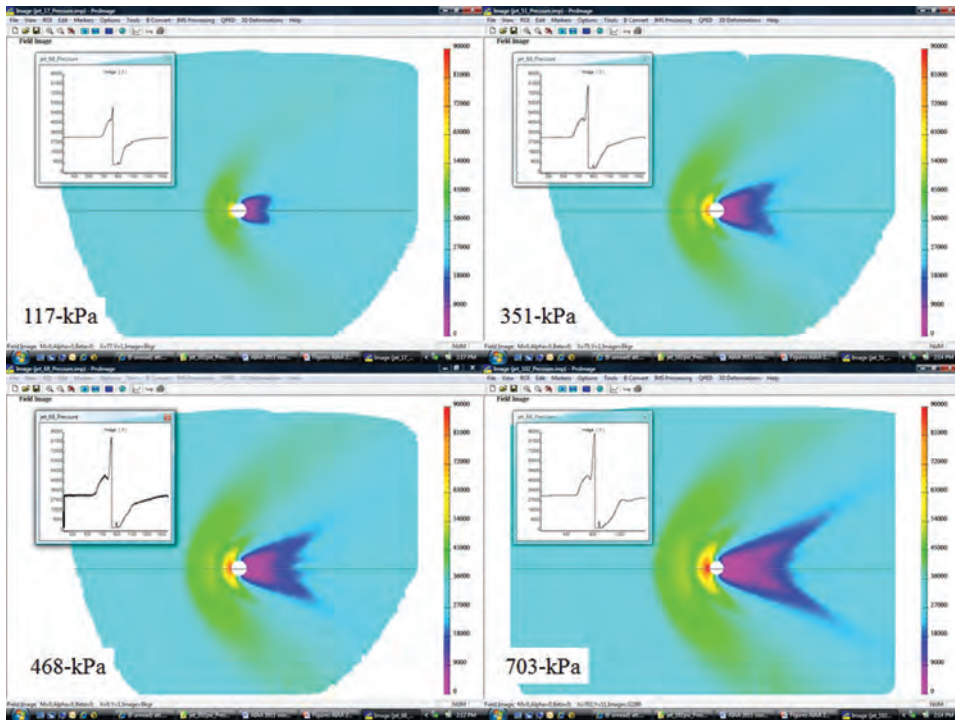

FIGURE 16.13 Mean pressure distribution for 3/16-in. injector block operating at several injection pressures. (See the color version of this figure in Color Plates Section.)

The experimental study was conducted in a supersonic flow facility operated within the Aerospace Propulsion Division, of the Propulsion Directorate, Wright-Patterson AFB (AFRL/RZA). Four injection blocks were tested in a Mach 2 flow at a series of injection pressures. Data were acquired with a binary PSP system composed of a PCO-1600 CCD camera with a 55-mm focal length lens, a filter wheel, two LM2X-400 LEDs, and a laptop PC running OMS Acquire. This particular experiment is part of an ongoing effort to build a database for high-fidelity CFD model validation and development.

A single pressure tap (in the field of view) was used for an *in situ* correction of the PSP data. Past experience in this facility indicates that the final binary PSP data should be accurate to within 200 Pa after the *in situ* bias correction. Examples of the pressure distribution using the 3/16 in. injector block at a series of injection pressures is shown in Figure 16.13 (Crafton et al., 2011). The flow features, such as the stagnation zone with high pressure just upstream of the jet, the bow shock upstream of the stagnation zone, and the low-pressure region behind the injector are expected. The flow is very symmetric about the injector. The pressure increases slowly from the bow shock toward the injector. There is a small pressure decrease, associated with a horseshoe vortex, followed by a stagnation zone just upstream of the jet. The low-pressure zone behind the injector is again symmetric, with the flow expanding to return to a flat pressure distribution downstream of the injector. Behind the jet, there are expansion fans emanating from the low-pressure zone. As the injection pressure is changed, the overall structure of the flow is unchanged. The bow shock, horseshoe vortex, and stagnation zone are still present in

front of the jet, and there is still a low-pressure zone behind the jet. The horseshoe vortex is not evident in the pressure distribution at the lowest injector pressure. As the injector pressure increases, the bow shock moves upstream and the stagnation pressure in front of the jet increases. The low-pressure zone and expansion fans behind the jet are also expanding and extending downstream.

16.6.2 Production Wind Tunnels

The use of PSP is becoming more common in large transonic tunnels, with production systems in use in several facilities such as AEDC (Ruyten and Sellers, 2004), ARA (Mosharov et al., 1998), and DLR (Engler et al., 2005). These measurements have been conducted using both binary and lifetime-based PSP systems. A demonstration of a lifetime and binary PSP system was conducted in the 9×8 ft transonic tunnel at ARA to compare these approaches to PSP. A binary PSP and data acquisition system was utilized on one wing and a lifetime PSP and data acquisition system was utilized on the other wing. The binary paint system was composed of BF-400 PSP, 3 LM2XDM-400 LEDs, and a PCO.1600 with a filter wheel. The lifetime system was composed of UF-400 PSP, 3 LM2XDMHP-400 LEDs, and a PCO.1600 with a pulse generator. Data were acquired at identical test conditions, and pressure tap data were collected at 48 stations along two span locations of the wing. Several of the pressure taps were used to anchor the absolute pressure of the PSP measurements and the remaining taps were used to estimate the accuracy of the PSP data by computing the deviation between the tap and PSP data.

Data were acquired at Mach 0.7 and 5° , the resulting pressure distribution, along with a comparison of the PSP and pressure tap data is shown in Figure 16.14 (Lifetime System) and Figure 16.15 (Binary System) (Lee et al., 2010). The pressure tap data were compared with the PSP data for each system, and the deviation between the taps and the PSP was about 400 Pa ($\sim 0.03 C_p$) for the data acquired at this test condition. It is noted that the hardware used for each system is quite similar, PCO.1600 CCD cameras, LED

FIGURE 16.14 Pressure distribution using lifetime PSP on an airfoil in the ARA 9×8 ft transonic wind tunnel. (See the color version of this figure in Color Plates Section.)

FIGURE 16.15 Pressure distribution using Binary PSP on an airfoil in the ARA 9×8 ft transonic wind tunnel. (See the color version of this figure in Color Plates Section.)

illumination, and PtTFPP-FIB-based paints, and therefore, it is not surprising that similar results were obtained. One of the advantages of PSP is the detailed surface pressure distribution that it can provide when the system is used to acquire full field images of the model. In this case, the data were analyzed and presented on a bitmap, and therefore, no loads calculations were conducted. Data from a later entry in 2009 with a 10-camera system and a full view of the model were presented by Vardaki et al. (2010). In this case, the deviation between the taps and PSP was about 500 Pa, and the integrated C_L and C_M data agreed with the balance to within 5%.

One of the first tunnels to deploy a PSP system integrated into the tunnel data acquisition system was the lifetime-based PSP system at Arnold Engineering Development Center (AEDC). The 16T PSP data acquisition operates in two-gate lifetime mode using PtTFPP FIB paint, 8 CoolSnap K4 Cameras, and 40 LM4X-400 LEDs to provide full coverage of the model. The system is tightly integrated into the tunnel to provide productive testing and near real-time data presentation of the results on the model mesh. In 2008, AEDC demonstrated their PSP system using the Facility Aerodynamics Validation and Operations Research (FAVOR) model. This model is for use as a standard check model for propulsion wind tunnel (PWT) 16T. The test article is a 5% scale model of the F-111 with new wings having a NACA 64-210 profile, a fixed sweep angle of 35° , and a span of 1.22 m. PSP data were acquired for demonstration of the techniques' capability to measure surface pressure and determine total vehicle loads and for use in CFD validation. The PSP data were compared and validated by conventional pressure data measured on the model and with total vehicle loads measured by the internal balance.

Testing was conducted from Mach 0.4 to 1.1 and from -3° to 24° angle of attack. The data at several Mach numbers and 10° are presented in Figures 16.16–16.18. These data illustrate excellent agreement with the conventional pressure data as well as having excellent symmetry between the left and the right wings. Similar to the ARA data, the PSP data were anchored by the conventional pressure measurements using an average offset. There still remains a residual error between the paint and each individual orifice

FIGURE 16.16 Pressure distribution at Mach 0.8 and 10° on the FAVOR model at 16T, AEDC. (See the color version of this figure in Color Plates Section.)

and the PSP measurement error can be estimated by computing the difference between the PSP and the conventional pressure measurements on the two wings and the limited fuselage locations. The average pressure error of all data points at each Mach number and for each pressure tap was computed. The average error for Mach 0.8, 0.95, and 1.1 was about 550, 440, and 400 Pa, respectively. Replicate runs were performed with similar results; these measurement errors are very good for PSP.

As full field data were acquired, a comparison of measured balance loads with the PSP integrated loads for the total vehicle were also computed. The PSP normal force and pitching moment agree very well with the balance measurements at all Mach numbers with the exception of the PSP pitching moment at Mach 0.4 for angles of attack less than 14° . The most likely reason is the very small and strong low-pressure region along the

FIGURE 16.17 Pressure distribution at Mach 0.95 and 10° on the FAVOR model at 16T, AEDC. (See the color version of this figure in Color Plates Section.)

FIGURE 16.18 Pressure distribution at Mach 1.1 and 10° on the FAVOR model at 16T, AEDC. (See the color version of this figure in Color Plates Section.)

leading edge of the wings. A small error in the mapping of this gradient can significantly affect the integrated pitching moment. The side force and yawing moment should be near zero since the model is supposedly symmetric. While the balance side force is near zero, a significant yawing moment was measured, especially when asymmetric separation occurred over the wing. This separation is evident in the large rolling moment generated and coincided with a spike in the yawing moment. This must be a coupling yaw moment because the side force did not have a corresponding change. The PSP yaw and roll plane data typically tracked the balance data but with some offset. It is difficult to pinpoint the source of the error in the PSP data because small forces at large distances (i.e., wing tips) from the moment reference center can introduce large moment errors. The PSP axial force tracked the balance measurement for all conditions but was always low. This was as expected because the PSP does not measure skin friction force, which is measured by the balance. Generally, the integrated C_L and C_M data agreed with the balance to better than 10%.

16.6.3 Low-Speed Applications of Pressure-Sensitive Paint

Low-speed wind tunnel measurements have been a target for deployment of pressure-sensitive paint systems for over 15 years; however, quantitative pressure measurements in flows below Mach 0.3 have proven challenging. Over the past 7 years, core PSP hardware such as CCD cameras, LEDs, image processing software, and temperature compensating binary paints have been improved. Integration of this improved hardware into pressure-sensitive paint systems has resulted in several successful demonstrations of pressure-sensitive paint in low-speed wind tunnels. These demonstrations include several small tunnel tests where the deviation between the pressure taps and pressure-sensitive paint data is as low as 50 Pa. In larger production style tunnels, deviation between the pressure taps and pressure-sensitive paint data of close to 100 Pa has been demonstrated. This section includes an overview of the challenges associated with utilizing pressure-sensitive paint in low-speed wind tunnels and gives an outline of the equipment and experimental procedures that have produced high quality pressure data in low-speed tunnels.

16.6.3.1 Background Early investigations into the use of PSP in low-speed wind tunnels were conducted by Brown (2000) and Bell (2004). Brown focused on applying careful experimental procedures to mitigate sources of error such as temperature and model movement. While Brown demonstrated very accurate PSP measurement, the experimental procedures are not practical in a large production wind tunnel. Bell (2001) investigated the sensitivity of the lifetime and binary measurements (Bell, 2004). Bell investigated the sensitivity of the lifetime and binary⁵⁷ PSP techniques to the common sources of errors in PSP measurements. Bell offers an excellent overview of the experimental procedures necessary to acquire high quality PSP data, concluding that binary systems offer the best option for deploying a productive PSP system. This, along with the demonstrations of production-style binary PSP systems from DLR14 and TsAGI13 indicate that a binary approach may yield accurate, productive PSP measurements in large low-speed wind tunnels.

16.6.3.2 Automotive Mirror in the AFIT Wind Tunnel One of the target applications of a low-speed PSP system is automotive research. Of particular interest is the generation of acoustic noise by the interaction of the automobile with the surrounding fluid, for example, vortex shedding from mirrors or cross-flow. An experiment to demonstrate the use of PSP for automotive testing was conducted in July 2004 in the Air Force Institute of Technology (AFIT) low-speed wind tunnel. The AFIT tunnel is an open circuit wind tunnel with a 3 ft by 4 ft test section and a maximum speed of Mach 0.2. A full-sized automotive mirror was outfitted with six pressure taps and painted with PSP. Testing was conducted at 30, 45, and 60 m/s.

A second automotive experiment was conducted using a side mirror. In this case, six pressure taps were placed on the mirror, and the mirror was mounted in the tunnel. The mirror was painted with binary FIB and tests were conducted at speeds of 30, 45, and 60 m/s. In this case, data acquisition involved averaging 10 signal and reference images at wind-off and wind-on conditions. The data were processed by aligning the images using the registration markers, computing the ratio as described in Equation (16.3), applying a 16 pixel Gaussian low pass filter, and then converting to pressure using an a priori calibration. The processed data were then corrected using the pressure tap data. A simple bias correction was computed by minimizing the mean squared deviation between the pressure taps and the PSP data, and a bias correction of 479 Pa was applied to the data. With the correction applied, the mean squared deviation between the taps and the PSP data was just under 200 Pa.

The corrected data acquired from the system at 60 m/s is shown in Figure 16.19 (Crafton et al., 2006). The flow is from the right to the left in Figure 16.19 and the upstream face of the mirror is oriented such that the side of the mirror is approximately parallel to the flow. The pressure increases as the flow stagnates on the upstream surface of the mirror, then the pressure drops as the flow accelerates around the curved corner near the middle of the mirror. The pressure drop is most noticeable at the lower rounded corner of the mirror. On the downstream surface, the pressure is relatively flat, and close to tunnel static. At 60 m/s, the tunnel dynamic pressure is about 2200 Pa and the range of pressures between the downstream and upstream surfaces of the mirror is about 2200 Pa, a C_p of about 1. The C_p drops to about -1 on the long curved corner, and to about -1.7 on the rounded corner. The PSP and pressure tap data compare to within about 200 Pa. In this case, this is about 10% of the tunnel dynamic pressure and better than 4% of the dynamic range on the mirror surface.

FIGURE 16.19 Pressure measurements on an automotive mirror. (See the color version of this figure in Color Plates Section.)

Several issues and system improvements were identified during this set of low-speed wind tunnel tests. Both tests were conducted using four LM2-400 LEDs. This illumination source produces about 200 mW of 400 nm light, for a total of 800 mW. Exposure times on these tests were over 1 s per image, and therefore, the on condition time was well about 30 s. A brighter illumination source would facilitate shorter exposures, and therefore, more images could be averaged during a given time on condition. More signal averaging in a shorter time would produce better signal-to-noise and therefore, more accurate data. It is also noted that long data acquisition times are prohibitive in large wind tunnels due to the cost of tunnel time. A stronger illumination source was developed for future tests.

16.6.3.3 MicroX in SARL Measurements of pressure using the PSP system were conducted on an 8% scale model of the Micro-X model in the Subsonic Aerodynamics Research Laboratory (SARL) in November 2005. The SARL is an open circuit tunnel at Wright Patterson Air Force Base with a 7 ft by 10 ft test section. Past PSP campaigns in the SARL have been compromised by errors from model movement, background lighting, sedimentation of the model, and temperature variations of the test surface (Crafton et al., 2005). In these tests, the mean squared deviation between the taps and PSP has never been better than 1000 Pa. The impact of these errors should be minimized by the use of the upgraded binary PSP system, careful design of the model, and careful experimental procedures.

The model was constructed of aluminum to minimize temperature gradients and a temperature compensating binary FIB paint was applied to compensate for errors due to model movement as well as any remaining thermal errors. Both wind-off and wind-on images were acquired while interlacing background shots to compensate for the dynamic background lighting encountered in this tunnel. The experimental setup included two views of the model, one concentrated on the top surface of the wings and canards and the other on the side body of the model. Each subsystem was composed of four LM2X-400

FIGURE 16.20 PSP versus taps in large tunnel. (See the color version of this figure in Color Plates Section.)

LEDs and a PCO.1600 with a filter switch as described in Figure 16.7. The exposure time for each system was approximately 1.5 s per image. The two-component system was armed to acquire data and then controlled using a single quantum composer to trigger the cameras and lamps from each system. Data acquisition consisted of collecting eight signal and reference images along with the interlaced backgrounds at each test condition. Data were acquired at Mach 0.3 and from 0° to 35° angle of attack in 5° increments. Finally, the model included pressure taps for anchoring and validating the PSP data and resection markers so that the final data could be mapped onto a surface mesh.

The data were processed by aligning the images using the registration markers, computing the ratio as described in Equation (16.3), applying a 16 pixel Gaussian low pass filter, and then converting to pressure using an a priori calibration. The processed data were then corrected using the pressure tap data and minimizing the mean squared deviation between the pressure taps and PSP data. Since this test program included a CFD mesh of the model and physical locations of the pressure taps, the pressure tap correction process is accomplished on the mesh upon completion of the resection process.

The PSP and pressure tap data for one test condition are presented in Figure 16.20. For this test condition, the bias error indicated by the taps was 675 Pa. After correcting the PSP data for the bias the residual root mean squared deviation between the taps and PSP serves as an indicator of the noise level in the PSP measurement for that condition. Features with amplitude lower than the mean squared deviation cannot be considered relevant. The residual deviation between the PSP and the taps was 270 Pa for this test condition, about 5% of the dynamic pressure. This level of uncertainty represented a significant improvement over past entries into this facility; however, the targeted error budget for the system is closer to 100 Pa. Further, system refinements are needed.

One of the more interesting data points in this test campaign that demonstrates the utility of PSP for measurements in large low-speed tunnels involves the development

FIGURE 16.21 MicroX in SARL PSP data. (See the color version of this figure in Color Plates Section.)

of a multivortex system on the tail wings. This configuration includes a large tail at 70° dihedral. The pressure distribution on the top surface of the tail at six angles of attack, from 0° to 35° , is shown in Figure 16.21. At 5° angle of attack, the presence of three distinct vortices on the leading edge of the tail is evident. These vortices sweep along the leading edge of the tail from the root to the tip. The first vortex, located near the root of the tail, is expected as it seems to originate near the junction of the swept tail and the main body of the model. The second and third vortices are somewhat smaller and were not anticipated by the aerodynamics team. These three vortex structures persist through the 10 and 15° angles of attack; however, the second and third vortices seem to be weakening at 15° . By 35° only the expected junction vortex is present. This multivortex system, which was later determined to be caused by a slight defect in the model, would be very difficult to detect using traditional pressure taps.

16.6.3.4 Four Camera Binary PSP System in the ADD 3-m Tunnel (Lee et al., 2010)

In the summer of 2009, ISSI and the team at the Agency for Defense Development (ADD) installed the system in the ADD low-speed wind tunnel in Taejeon, Korea. The ADD low-speed wind tunnel is a closed circuit, temperature controlled tunnel with a 3 m by 2.25 m test section. The test section is created using Plexiglas, and therefore, provides excellent optical access. The tunnel operates from 10 m/s to 120 m/s and has an axial turbulence level of less than 0.05%. The model angle of attack can be set using a pitch sector and the yaw angle is set using ceiling/floor turntables. The pitch sector is mounted to the floor turntable and ceiling turntable is linked using a mechanical linkage. Optical access to the upper and lower surfaces of the model is obtained through windows in the turntables. The cameras and lamps for PSP are mounted onto the turntables above the windows, and therefore, the cameras and lamps move with the model as the yaw angle is changed. Four

camera/filter wheel sets were installed for this test: two on the ceiling turntable and the two under the floor.

The model for this test is a wing body type aircraft that has a 2 m span and a 1 m length. Testing focused on the upper and lower wing surfaces. The model was constructed of aluminum and included 26 pressure taps that were monitored and recorded during the test using a PSI8400 system with a ± 1 psid ESP module. Resection markers were placed on the model periphery for alignment of wind-off and wind-on images, and for mapping 2D images onto the 3D mesh describing model geometry. The binary PSP data acquisition system is comprised of a four subsystems controlled by a master computer using a local network. Each of the four subsystems includes a PCO.2000 camera, a filter switch, and two LM2XX-400 LEDs. The model is illuminated using a total of eight LM2XX-400 LED lamps. The LM2XX-400 is a water cooled LED lamp that provides 12 W of optical power at 400 nm from a 75 mm diameter head. Each camera images the model through a 24 mm Nikon lens and each filter switch includes a 645 nm long-pass filter for the signal channel and a 550 nm ± 40 nm band-pass filter for the reference channel.

The master PC arms each of the subsystems and controls triggering of subsystem components using a pulse generator that is connected to the PSP network. The master PC may be connected to the tunnel network and collect run conditions and model data, or it may run in a stand-alone mode. The subsystem PC controls the camera and filter switch and stores all data locally using a master file name sent from the master PC. Other information collected by the master PC such as tunnel conditions, model attitude, or pressure tap data can be organized and stored for use in post processing on the subsystem PC.

The wing/body model was painted with binary FIB PSP and installed in the tunnel. Two cameras were focused on the upper surface of the wing and two cameras on the lower surface. Data were acquired on the ADD model using the four channel system at tunnel speeds of 46, 60, and 80 m/s. Wind-off images were acquired at each wind-on model position to minimize image alignment errors. As the tunnel speed was low, signal averaging was used to drive down the shot noise and improve the overall signal-to-noise of the measurements. Exposure time was approximately 1 s, and 64 images of the signal and reference channels were averaged at each wind-off and wind-on condition. The data were processed by aligning the images using the registration markers, computing the ratio, applying a 16 pixel Gaussian low pass filter, and then converting to pressure using an *a priori* calibration. The processed data were then mapped to the mesh and the *in situ* correction using the pressure tap data were applied by minimizing the mean squared deviation between the pressure taps and the PSP data.

An example of the data from a Mach number sweep at 5° angle of attack is shown in Figure 16.22. The pressure distribution on the wing is clearly visualized at the 60 and 80 m/s conditions. Note that between 46 and 80 m/s the dynamic pressure, and therefore, the pressure variation on the wing, increases by a factor of over 3. It is difficult to see the pressure distribution on the wing at 46 m/s using the stretched scale necessary to display the Mach number sweep.

To demonstrate the PSP system capability at the 46 m/s speed, data from two beta conditions at this speed are displayed in Figure 16.23. In this case, the pressure map is stretched over a smaller range and the pressure distribution on the upper surfaced of the wing is clearly visualized. In fact, slight variations in the pressure distribution on the wing can be detected at the different test conditions, even at this low speed. The data in Figure 16.23 demonstrate that the binary PSP system can be used to obtain data in a larger tunnel at this low speed.

FIGURE 16.22 Binary PSP data at three Mach numbers. (See the color version of this figure in Color Plates Section.)

FIGURE 16.23 Binary PSP data at 46 m/s. (See the color version of this figure in Color Plates Section.)

FIGURE 16.24 Comparison of PSP and pressure tap data. (See the color version of this figure in Color Plates Section.)

A linear curve fit to a plot of the corrected PSP data versus the pressure tap data at several test conditions is shown in Figure 16.24. Note that the slope is very close to 1, indicating that the *a priori* and *in situ* calibrations are in very good agreement. In this test campaign, the root mean squared deviation between the taps and the PSP was 148 Pa. While this may not serve as a formal means of evaluating the absolute accuracy and resolution of the PSP data, it yields some insight into the uncertainty level in the data. This noise level corresponds to 3.8% of the tunnel dynamic pressure at the 80 m/s test condition. This is approaching the target error budget of 3% for the low-speed system. It is noted that this error level is still about 11% of the dynamic pressure at the 46 m/s test condition. In any case, the data in Figures 16.22 and 16.23 represent very promising results for a low-speed PSP test in a larger wind tunnel.

16.6.3.5 Demonstration of the Color Camera System in the ADD Low-Speed Tunnel (Lee et al., 2010) The data presented in the previous sections were acquired using a single camera and a filter switch. While this has proven effective for low-speed PSP systems, further improvements to the system are under investigation. One such improvement involves the use of a color camera to replace the filter switch. The most significant advantage of the color camera system is that it acquires both the signal and the reference data simultaneously through a single optical system, and therefore, image alignment between the signal and reference channels is excellent. Other potential errors such as vibration of the model, variations in the model temperature, or variations in illumination that could occur between signal and reference images will be eliminated.

A preliminary demonstration of the color camera concept in a larger low-speed wind tunnel was conducted in the ADD low-speed tunnel test described in Section 16.6.3.4. During this test, a single Apogee 2000 color camera was installed in the wind tunnel, and data were acquired at a limited number of test conditions. Data were acquired using the same binary FIB PSP and illumination was provided by the LM2XX-400 LEDs. An

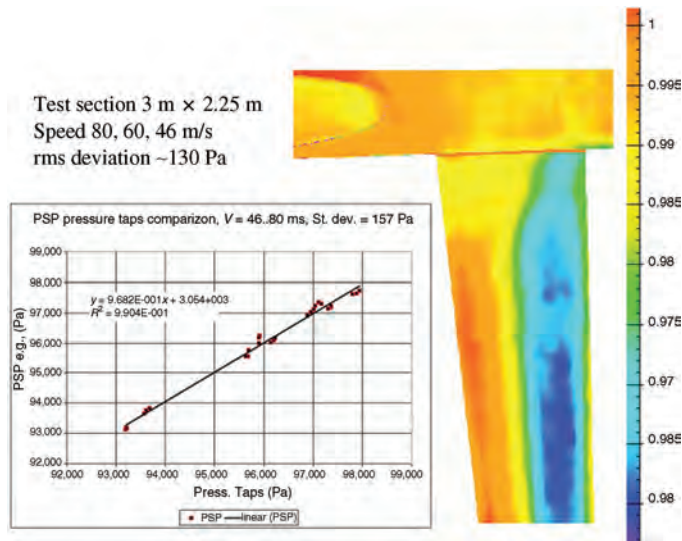

FIGURE 16.25 Binary PSP data using a color camera. (See the color version of this figure in Color Plates Section.)

example of data acquired using a color camera system is shown in Figure 16.25. The data produced by the color camera system compares favorably with the filter switch system. The root mean squared deviation between the PSP data and the pressure taps was 157 Pa for the color camera data. This is very close to the result obtained with the more mature filter switch system. As described earlier, the major limitation of the color camera system is related to the limited number of pixels available on this camera. The effective size of this camera is 600 pixels by 800 pixels and this limits either the field of view or the spatial resolution of the system. As cameras with higher pixel density are released onto the market, this type of color camera system should be investigated further.

16.6.4 Pressure-Sensitive Paint on Rotating Machinery (Juliano et al., 2011)

Experimental measurements of the mean and unsteady pressure distribution on rotating machinery such as compressors, propellers, and rotorcraft blades have proven difficult. These measurements are difficult due to the cost and complexity of installing a significant number of pressure transducers that operate in the rotating frame. Furthermore, pressure data from experimental measurements are available only at discrete points, and therefore, are unlikely to capture the distribution of spatial frequencies or peak pressures on the rotating surface. A means of acquiring measurements of the mean and unsteady pressure with high spatial resolution on the rotating surface would be of significant value. A demonstration of PSP measurements on a rotating surface has recently been performed; the experimental procedure and results are described here.

Lifetime-based PSP measurements have proven to be effective for minimizing model deformation errors in production PSP systems. These systems employ pulsed LED arrays and gated integration cameras with accumulation to acquire data from two gates in the decay curve of an excited pressure-sensitive molecule (Figure 16.7). Pulsed LED arrays produce about 100 μJ per pulse, and therefore, the use of the accumulation option on the

FIGURE 16.26 Experimental setup for PSP measurements on a model airplane propeller. (See the color version of this figure in Color Plates Section.)

cameras allows multiple pulses to be averaged on chip to improve the signal to noise of the measurement. This type of averaging requires that the flow be stable for several seconds as the signal is accumulated for each gate. The flow on a rotating surface, such as a helicopter rotor or aeroelastic surface is subject to unsteady fluid-structure interactions, and therefore, signal averaging is not an option. It is essential that all data from both gates be acquired on a single illumination pulse.

To accomplish this goal of single-shot PSP data acquisition, a single-shot lifetime-based PSP system has been developed and demonstrated. Excitation for the PSP is provided by a NewWave Solo 532 nm PIV laser. This laser produces 120 mJ per pulse, an increase in power of over 100 compared to an LED array. A PCO.1600 CCD camera operating in Frame Transfer mode is used for data acquisition. In this mode, the camera acquires data for a specific time using an electronic shutter. The frame is then shifted to the storage portion of the array and the CCD reexposes. These two frames are then read out and two-gate lifetime data, as described in Figure 16.7, are stored and processed. Timing may be controlled by externally triggering the camera to synchronize it with the laser and propeller. The camera and laser timing are controlled using a pulse generator.

A bench top experimental setup (Figure 16.26) was constructed using a model airplane propeller and electric motor (Electrify V-Pitch GPMG4501) to demonstrate single-shot PSP measurements on a propeller. The blade radius was 12.6 cm and the chord was 2.5 cm. At a rotation rate of 70 Hz, the tip speed of this blade is about 55 m/s; therefore, the theoretical maximum pressure differential to be expected on the blade is around 3600 Pa (assuming $\Delta C_p = 2$). This experiment is a very aggressive demonstration as it combines two of the most challenging aspects of PSP, low-speed flows and rotating machinery. One blade was painted with a Ruthenium in RTV with Silica Gel PSP. While this is not a fast-responding PSP, the goal of this experiment was to demonstrate the single-shot data acquisition system on a rotating airfoil. Unsteady measurements could be conducted using the same system with a fast-responding PSP.

The laser was positioned approximately 6 m from the rotor hub while the camera was at a distance of about 3.5 m. A 75-mm lens was used to expand the beam which then passed through a piece of ground glass to diffuse the beam. PSP systems using lasers as light sources can suffer from pulse-to-pulse variations in intensity and mode shape, and high frequency intensity variations caused by speckle. Both issues are negated here by acquiring both images from the same laser pulse, with the same camera, using the same optical elements. Each image contains the same illumination intensity pattern so a ratio of these images removes the intensity variations.

FIGURE 16.27 Binary PSP data using a color camera. (See the color version of this figure in Color Plates Section.)

The rotor was set to a low RPM to simulate a wind-off condition and a series of image pairs were acquired and averaged to minimize the wind-off shot noise. The rotor was then set to its highest operating RPM (55 m/s tip speed) and a series of single shot image pairs were acquired. The signal level in these single shot images is about 65% of the dynamic range of the camera, or about 25,000 photoelectrons. A quick calculation combining the shot noise ($\sim 0.6\%$ per image) and pressure sensitivity ($\sim 3\%$ per psi) suggest a best case noise level of about 1700 Pa for these data. Note that the dynamic pressure at the tip is only 1800 Pa, and therefore, the resulting data would have a noise level in C_p of about 1. The noise level can be improved with some low pass filtering (e.g., 16 pixel filter) to about 150 Pa ($C_p \sim 0.08$) with the sacrifice of some spatial resolution. The final wind-off ratio to wind-on ratio data are presented in Figure 16.27. Note the low-pressure region on the leading edge of the blade. The chord-wise variation in pressure across the blade would suggest a ΔC_p of about 2 for this propeller blade.

The data presented in Figure 16.27 are a significant accomplishment in that this data was acquired in single-shot mode, at low speed, on a rotating blade, and from a tunnel-scale operating distance. This data represent only the first phase of development for the proposed system. The system must integrate a fast-responding PSP and then it could be used to study a variety of unsteady flows such as aeroelasticity, flutter, supersonic inlets, or generation of acoustic noise.

16.6.5 Fast-Responding Pressure-Sensitive Paint

Typical paint formulations are comprised of an oxygen-sensitive fluorescent dye and a binder for physically attaching the dye to the model surface. Conventional formulations

typically use a polymer as a binder material. The disadvantage of the binder, however, is that it inhibits the interaction of the atmospheric oxygen and the embedded dye molecules. The response time of the paint to pressure is largely governed by the rate of diffusion of gas within the binder. Conventional, polymer-based paint formulations have response times on the order of 1 s, making them unsuitable for evaluating unsteady aerodynamic phenomena such as unsteady flows or aeroelastic phenomena.

The temporal-response characteristics of PSP are primarily governed by the thickness of the paint formulation and the diffusion coefficient of the binder material, according to the relation

$$\tau_{\text{diff}} \propto \frac{h^2}{D_m} \quad (16.21)$$

where the response time due to diffusion (τ_{diff}) increases with the paint thickness (h) squared and decreases with increasing diffusion coefficient (D_m). Some investigators have focused on decreasing the thickness of the paint in order to improve the response characteristics. This approach, however, has the disadvantage of sacrificing luminescent output from the paint and, thus, the signal-to-noise ratio (SNR). The paint formulation to be used in the proposed work has been developed based on the strategy of increasing the diffusivity of gas within the paint binder, as described by Gregory et al. (2008). Porous binders have been developed with the goal of enhancing the oxygen diffusion within the paint layer and, thus, improving the temporal response.

The difference between a conventional polymer-based PSP and a porous PSP is described schematically in Figure 16.28. For conventional PSP, oxygen molecules in a test gas must permeate into the binder layer for oxygen quenching. The process of oxygen permeation in a polymer binder layer produces slow response for a conventional PSP. On the other hand, the dye in a porous PSP is open to the test gas so that the oxygen

FIGURE 16.28 Comparison of the composition of porous PSP and conventional PSP. (See the color version of this figure in Color Plates Section.)

molecules are free to interact with the dye. The open binder creates a PSP that responds very quickly to changes in oxygen concentration and, therefore, pressure. A large effective surface area due to the porous surface improves luminescence intensity; thus, a higher SNR can be achieved. The drawback of the porous PSP approach is that the dye is too accessible to the oxygen. This results in near-complete quenching of all of the dye molecules at very low pressures. These formulations are effective for supersonic tunnels where the static pressure is below 15 kPa. For flows with higher pressures, the SNR ratio suffers.

Polymer/ceramic PSP (Scroggin et al., 1999) has been developed as a hybrid paint formulation that incorporates the advantages of both traditional and porous PSP. The polymer/ceramic formulation incorporates a high percentage of ceramic particles that provide the porous structure for rapid oxygen quenching, with a small amount of polymer to bind the paint to the surface. A dye is deposited onto the polymer/ceramic surface to complete the paint formulation. The resulting system is a fast-time-response paint layer with favorable SNR at higher pressure. Unlike anodized aluminum the polymer-based paint can be airbrushed onto a model; thus, paint application to complex surfaces is possible.

Experimental demonstrations of fast PSP have been conducted by several research teams. Gregory et al. (2007) have used these polymer/ceramic PSP formulations to measure oscillating pressure fluctuations with frequencies up to 20 kHz on a fluidic oscillator. Oscillating airfoils have been investigated by Fonov et al. (1999) using a thin coating of a binary PSP. In this experiment, the pressure distribution on a NACA-0012 oscillated at 20 Hz was investigated, thus demonstrating the capability of fast PSP on periodic flows. Nonperiodic PSP data were acquired by Kameda et al. (2005) on a delta wing in a Mach-0.6 flow. Here, Kameda detected the oscillation frequency of shocks on the delta wing at up to 170 Hz using frequency analysis of the PSP images. Nakakita (2007) demonstrated point-by-point frequency analysis of a fast PSP signal acquired on a cylinder in cross-flow.

These experiments demonstrate the potential of fast PSP as a tool for experimental studies and the evolution of the tool for wind tunnel settings. It is noted that the experiments included here incorporate many of the concepts previously demonstrated such as high-speed data acquisition and frequency analysis of the signal. The contribution of this work is in demonstrating the use of newer cameras and illumination sources to improve SNR of the PSP system. The improved cameras and LEDs are allowing fast PSP to be used as a tool in a study of fluids rather than focusing on the development of PSP capability.

16.6.5.1 Demonstration of Pressure-Sensitive Paint Measurements in a Short Duration Facility Another demonstration of the fast response PSP system involved the detection of the pressure distribution on an airfoil in a shock tube. The experimental setup (Figure 16.29) is composed of a small NACA-0012 airfoil at 2° angle of attack mounted near the end of a shock tube. The shock tube is fired with the endplate removed so there is no reflected shock, and therefore, the shock tube operates as a short duration transonic wind tunnel. After the shock passes by the airfoil, the flow is transonic with the actual velocity dependent on the pressure ratio of the diaphragm rupture. The flow is generally about 200 m/s in this facility and the duration of the flow, which is based on the arrival of the reflected expansion fan, lasts about 3 ms. This run time is sufficient to acquire a single PSP image on the airfoil using the fast response PSP.

The shock tube has a 1 m driver section mated to a 2 m driven section. The driven section has a 5 in. by 3 in. square cross-section with 5 in. by 5 in. windows on both sides at the 1 m and 1.5 m location. The NACA-0012 airfoil mounts onto a blank window in the

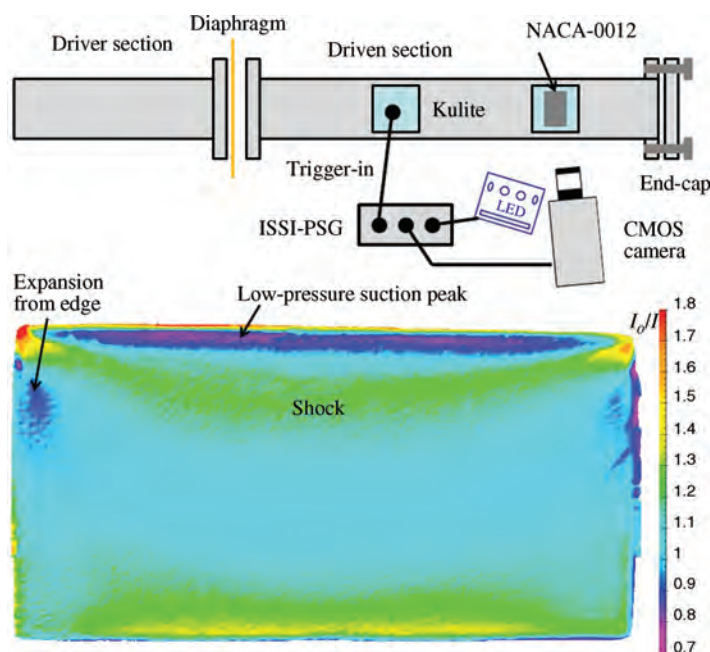

FIGURE 16.29 PSP measurements on an airfoil in the ISSI shock tube. (See the color version of this figure in Color Plates Section.)

downstream location and optical access is provided from the opposite window. A Kulite is mounted in a blank window in the upstream location to provide a trigger signal to the pulse generator. The pulse generator is programmed with a short delay (~ 1 ms) to allow the shock to pass and the transonic flow to establish itself on the airfoil and then the camera and LED are fired.

An example of the flow on the suction side airfoil with the flow at about 200 m/s is shown in Figure 16.29. The flow accelerates to a supersonic speed around the leading edge of the airfoil, and a shock forms at about 15% chord. Weak expansions can be seen on the sides of the airfoil as well. It is noted that this simple setup does not produce high quality flow, repeatable operation, or meaningful Reynolds numbers. The point of this setup is to demonstrate the use of PSP in a short duration facility such as a shock tunnel or Ludwig tube.

16.6.5.2 Unsteady Pressure Measurements (Crafton *et al.*, 2011) Recently, a demonstration of unsteady PSP measurements in a transverse jet injected into a supersonic flow was conducted at Wright-Patterson AFB (AFRL/RZA). Four injection blocks tested were tested in a Mach 2 flow at a series of injection pressures. This test included both fast PSP and traditional binary PSP for mean pressure measurements, presented in Figure 16.13; here, we present data from a fast-responding PSP. The fast PSP system utilized a Photron SA5 CMOS camera with an LM2XX-400 LED for illumination and a PtTFPP-PP fast PSP.

The fast PSP data from the 3/16 in. normal injector block were processed and an example of a sequence of images is shown in Figure 16.30. Here, the pressure distribution from the porous polymer is shown at three time steps along with the mean pressure distribution. In

FIGURE 16.30 Mean and unsteady pressure distribution on the 3/16 in. normal injection block operating at 703 kPa. (See the color version of this figure in Color Plates Section.)

the first time step, the stagnation zone is compressed and asymmetric and the ridge of higher pressure associated with the front of the horseshoe vortex upstream of the stagnation zone is disrupted. It is possible that a feature in the flow, for example, a turbulent structure in the boundary layer, has moved through the flow and impacted the jet. As the system recovers, the stagnation zone expands and the pressure in the stagnation zone is lower than the average condition. The secondary pressure ridge is reforming as well. Finally, the flow returns to near its average position. This entire process occurs in less than 1 ms.

The data presented in Figure 16.30 represent only a fraction of the potential of the current fast PSP system. Using the fast PSP system, over 5000 samples similar to those in Figure 16.30 were acquired. Furthermore, the data were acquired in a continuous stream at 7 kHz, and therefore, can be presented and analyzed in a manner similar to traditional fast pressure tap data. The pressure data at a particular pixel can be plotted frame by frame, as shown in Figure 16.31, to produce a pressure-versus-time plot. In this case, the data from four specific locations are presented. The pressure in the freestream region, upstream of the bow shock, is nearly constant. Near the bow shock, the pressure fluctuates with an amplitude of several kPa. In the stagnation zone, the pressure fluctuations are similar to those near the bow shock but the amplitude of the fluctuations is up to 10 kPa. Behind the jet, the pressure drops, as does the amplitude of the fluctuations. It appears from the time trace that some of the larger scale pressure fluctuations are correlated in the bow shock, stagnation zone, and expansion zone regions.

The power spectrum of data presented in Figure 16.31 can be computed to investigate the frequency content of the flow. The amplitude of the power spectrum for each data set presented in Figure 16.31 was computed, and the resulting data are presented in Figure 16.32. From the data presented in Figure 16.32, it appears that the majority of

FIGURE 16.31 Fast PSP data as a function of time at four locations. (See the color version of this figure in Color Plates Section.)

the frequency content of the flow is below 500 Hz. There are no clear peaks in any of the spectra, suggesting that there is no fundamental frequency content to this flow. The freestream data contain no significant pressure fluctuations, and therefore, there is no significant information in the amplitude of the power spectrum. It is possible that this data set represents a noise floor of the detection scheme, or of the flow. The power

FIGURE 16.32 Amplitude of the power spectrum from the fast PSP pressure data presented in Figure 16.31. (See the color version of this figure in Color Plates Section.)

spectrum of the data near the bow shock and behind the jet both decay to a value near this noise floor by about 2 kHz. This would suggest that the 7 kHz data acquisition rate is fully resolving the frequency content in these regions of the flow. The power spectrum of the data near the stagnation point, by contrast, is indicating significant pressure fluctuations out to the 3.5 kHz limit of this data set. A data acquisition system with higher bandwidth would be of value for interrogation of this flow. In fact, several data sets were acquired at 25 kHz with a lower spatial resolution.

It is recognized that the data and analysis presented in Figures 16.31 and 16.32 is identical to the data and analysis that can be obtained with a few traditional fast pressure transducers. The major advantage of the current system is that there are approximately 1 million transducers available for the analysis. This data can be extracted at each pixel location and analyzed as shown in Figure 16.31. Quantities such as the mean pressure and deviation of the pressure from the mean at each spatial location can be computed. The original data set included over 1 million data points at 5,000 time steps. To mitigate the size of the data set, a 10-pixel binning filter was applied to the data. The resulting data set represents an array of 10,000 fast pressure transducers that have been sampled 5,000 times at a 7 kHz rate. While some spatial resolution has been sacrificed, the binning filter does improve the shot noise of the measurement by a factor of 10, and the size of the data set is manageable. The mean and standard deviation of the pressure was computed. Not surprisingly, the pressure fluctuations are largest in the stagnation zone where the amplitude is about 5 kPa. There is a second region of large pressure fluctuations associated with the bow shock. These may be related to fluctuation in the strength or the location of the bow shock. It is noted that these pressure fluctuations showed a strong correlation with the pressure fluctuations in the expansion region behind the jet (Figure 16.32). A final set of large pressure fluctuations are present near the location of the horseshoe vortex and just upstream of the stagnation zone. These fluctuations have a magnitude of about 2 kPa, similar to those in the bow shock. It is likely that there is some correlation between these pressure fluctuations given the similar structure and amplitude.

A final demonstration of the fast PSP system capability is the ability to analyze the frequency content of the flow with high spatial resolution. The data collected by the fast PSP system can be processed spectrally, as shown in Figure 16.32, at each pixel to produce a map of the amplitude of the power spectra at each frequency. An example of these maps at six frequency bins is shown in Figure 16.33. It is interesting to compare these maps, which represent the amplitude of the pressure fluctuations within a specific frequency range, with the overall pressure fluctuations presented in Figure 16.33. In the lowest frequency bin (~ 14 Hz), the flow shows a slight asymmetry in the stagnation zone, the bow shock, and the horseshoe vortex. There is no asymmetry present in the pressure fluctuation data in Figure 16.33. At the next frequency bin (~ 27 Hz); the flow is again symmetric at all locations. As the frequency increases, the amplitude of the pressure fluctuations is dropping in most locations. Around 287 Hz, a set of expansion fans begin exhibit fluctuations in the flow. By 438 Hz, the fluctuations of the expansion fans are effectively gone, but the flow now exhibits a bifurcated node structure at several locations. Interestingly, these node structures are only present at this frequency bin. At frequencies above about 2 kHz the only significant pressure fluctuations are associated with the stagnation zone in front of the jet. A sequence of several hundred of these maps can be combined into a movie, thus allowing the frequency content of the flow to be visualized spatially.

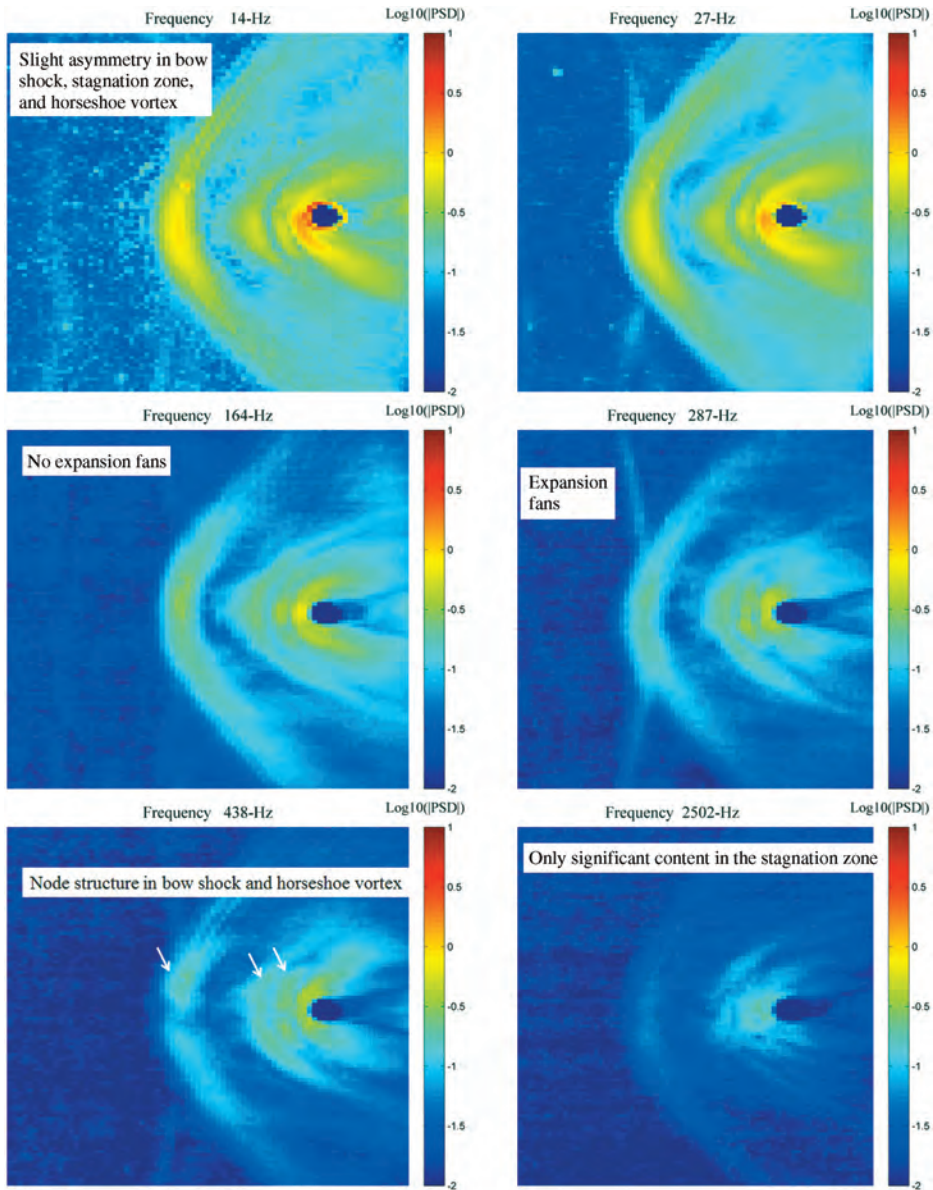

FIGURE 16.33 Map of the power spectrum amplitude at several frequencies. (See the color version of this figure in Color Plates Section.)

17.2 Trends in flow measurement

Further readings

Flow is one of the most important variables measured in industrial and commercial environments. Whether the fluid is oil, gas, steam, air, or water, there are many occasions when it is vitally important to know how much flow is traveling through a pipe. Measurement of petroleum liquids such as oil has become especially important, as the price of oil has increased to nearly \$100 per barrel. And measuring natural gas at multiple points along the distribution chain for natural gas is also critical for custody transfer, where ownership of the natural gas changes hands. In addition, some flow is measured in rivers and streams, rather than in closed conduits, and this is called open-channel flow measurement.

17.1 NEW-TECHNOLOGY AND TRADITIONAL TECHNOLOGY FLOWMETERS

Flow is measured by flowmeters that either measure the volume of flow or its mass. A flowmeter is a device designed to measure the quantity of fluid flow in an open channel or closed pipe. Flowmeters are often divided into two broad categories

- New-technology flowmeters
- Traditional technology flowmeters.

The difference between new and traditional technology flowmeters has to do with when they were introduced, their accuracy and reliability, and the methods they use to measure flow.

New-technology flowmeters are distinguished by the following characteristics

1. They were introduced into the commercial market in 1950 or after.
2. They incorporate technical advantages that avoid some problems with earlier flowmeters.
3. They are the focus of more product development by suppliers than are traditional technology flowmeters.
4. Their level of performance, including reliability and accuracy, is better than that of the pre-1950 flowmeters.
5. They typically have been quick to adopt modern communication protocols such as highway addressable remote transducer (HART), Foundation Fieldbus, and Profibus.

Traditional technology flowmeters, by contrast, have been around for many years, in some cases as long as several 100 years. They have the following characteristics

1. They were introduced into commercial and industrial environments before 1950.
2. They typically require more maintenance than new-technology flowmeters.
3. Suppliers generally do less product development on traditional technology flowmeters than on new-technology flowmeters.
4. They typically are not as accurate or reliable as new-technology flowmeters.
5. They have been relatively slow to adopt modern communication protocols such as HART, Foundation Fieldbus, and Profibus.

17.1.1 New-Technology Flowmeters

New-technology flowmeters are so-called because they represent new methods of flow measurement that postdate the traditional methods of turbine, positive displacement, and differential pressure. Most new-technology flowmeters were introduced in the 1960s and 1970s, although magnetic flowmeters came onto the market even earlier than that. The following are the five types of new-technology flowmeters

- Coriolis
- Magnetic
- Ultrasonic

- Vortex
- Thermal

17.1.2 Coriolis Flowmeters

Coriolis flowmeters get their name from the French mathematician Gustave Coriolis. Coriolis showed in 1835 that it is necessary to take an inertial force into account when describing the motion of an object in a rotating frame of reference. This effect is often illustrated by using the rotating Earth as an example. An object hypothetically thrown from the North Pole toward a target on the equator will miss its mark because, by the time it arrives, the target will have rotated from its previous position with the rotation of the Earth. This same example is sometimes illustrated using a merry-go-round instead of the rotating Earth. Someone at the center of a merry-go-round who aims a ball at a target at the edge of the spinning object will miss the target if the merry-go-round is spinning fast enough because by the time the ball reaches the location of the target, the target will have moved on, along with the spinning merry-go-round.

The Coriolis effect as described in terms of the rotating Earth and a spinning merry-go-round is actually a perceptual effect rather than a force. A ball thrown from the North Pole or the center of a merry-go-round will appear to curve when viewed from the position the ball is thrown from. However, there is no actual force being exerted on the ball causing it to curve, apart from the force exerted on the ball when it is thrown. The ball only appears to curve because of the rotating frame of reference beneath it. Hence, this example describes only a Coriolis effect, not a Coriolis force (Figure 17.1).

FIGURE 17.1 A Coriolis flowmeter being calibrated at Colorado Engineering Experiment Station, Inc. (CEESI); photo by Flow Research.

The force that is involved with the motion of Coriolis flowmeters is less easy to understand, but it has to do with the fact that the meter is oscillating. Coriolis flowmeters are made up of one or more vibrating tubes, which are usually bent. The fluid accelerates as it moves through the tube toward the point of maximum vibration, and decelerates in the tube as it leaves this point. This motion causes the tubes to twist. Mass flow is directly proportional to the amount of twist in the tubes. Tube positions are sensed by position sensors.

Although the majority of Coriolis flowmeters have bent tubes, some have both single and dual straight tubes. KROHNE introduced the first commercially successful straight tube Coriolis flowmeter in 1994. Since that time, other vendors have begun offering straight-tube flowmeters. Straight-tube meters cause less pressure loss than bent-tube meters and also are less susceptible to clogging and easier to clean. This is especially important for food and other sanitary applications. While straight-tube meters are quite effective for liquid applications, suppliers have had very limited success in applying them to gas applications.

Suppliers have differentiated themselves by various tube designs. Most of the bent tube designs for Coriolis meters are proprietary to the manufacturers. In 1977, Micro Motion was the first company to introduce a commercially successful Coriolis meter, a bent-tube meter. Since that time, a number of other companies have entered the market, including Endress+Hauser, KROHNE, and Foxboro (Invensys). While most Coriolis meters have either single or dual tubes, whether bent or straight in design, in 2011 Endress+Hauser introduced a four-tube bent tube Coriolis meter.

For many years, between 85 and 90% of all Coriolis flowmeters line sizes were of 2 in. or less. Rheonik was the only company that manufactured Coriolis meters with line sizes above 6 in. In the past several years, three new suppliers, Micro Motion, Endress+Hauser, and KROHNE, have begun manufacturing Coriolis meters in large line sizes above 6 in. These large line size meters typically cost over \$50,000 and are mainly designed for custody transfer applications, especially in the oil and gas industry. Most of these large line size meters are 8, 10, or 12 in. However, Endress+Hauser's new four-tube Coriolis meter is designed for 14-in. line sizes.

17.1.3 Magnetic Flowmeters

Magnetic flowmeters were first introduced in 1952 in the Netherlands by a company called TOBI. Since 1952, they have come to dominate the water flow measurement market. They are used to measure the flow of conductive liquids and slurries, including black liquor and paper pulp slurries. Their main limitation is that they can only measure conductive liquids. As a result, they are not widely used in the petroleum industry, since hydrocarbons are nonconductive. Magnetic flowmeters do not create pressure drop and are highly accurate. Their purchase price can be relatively high, depending on line size. While some magnetic flowmeters are less than 1/4 in. in size, some can range up to 110 in. in size. The large size meters are typically used for water and wastewater applications.

Magnetic flowmeters, or magmeters as they are sometimes called, use Faraday's Law of Electromagnetic Induction. This principle states that a voltage is generated in a conductive medium when it passes through a magnetic field. The amount of this voltage is proportional to the length of the conductor, the magnetic field density, and the velocity of the conductive medium. Using Faraday's Law, these three variables are multiplied together to yield the magnitude of the voltage.

Magnetic flowmeters have wire coils mounted inside or outside the body of the flowmeter. Either alternating current (AC) or direct current (DC) is applied to these coils,

FIGURE 17.2 KROHNE magnetic flowmeters in Dordrecht, the Netherlands; photo by Flow Research.

which generates a magnetic field inside the meter body. As conductive liquid passes through the meter body, a voltage is generated due to the presence of the magnetic field. Electrodes on either side of the meter body detect this voltage. The flowmeter uses this voltage value to compute the flowrate.

Although magmeters can measure the flow of almost any type of liquid, they cannot be used to measure the flow of steam or gas. Almost 30% of magmeters are used in the water and wastewater industry, and many of these are relatively large in size. Because they can measure dirty liquids, they are widely used in the pulp and paper and metals and mining industries. They are also used in the chemical and food and beverage industries to measure the flow of liquids in manufacturing and food processing operations. Filling machines are another major application for magnetic flowmeters (Figure 17.2).

Because magnetic flowmeters are used to measure the flow of so many different types of liquids, different types of linings are used, depending on the type of application involved. Both hard and soft rubbers are used to measure dirty liquids, as they are very durable. Other liners include polytetrafluoroethylene, polyurethane, and Teflon. Sanitary liners are widely used in the chemical; food and beverage; and pharmaceutical industries to measure the flow of food, beverages, and chemicals.

17.1.4 Ultrasonic Flowmeters

Ultrasonic flowmeters were first commercially introduced in 1963 in Japan by Tokyo Keiki. Since 1963, ultrasonic flowmeters have come to be a dominant force in the flow measurement industry. Their advantages are many: they create very little pressure drop in the line, they are highly accurate, and they are very reliable over time. Suppliers have

advanced the technology of ultrasonic flowmeters over the years and have developed multipath ultrasonic meters that are highly accurate and are used for custody transfer applications. Ultrasonic flowmeters are mainly used for liquid and gas applications, although some are now being used to measure steam flow.

The dominant technology used in ultrasonic flowmeters is called transit time. Transit time meters have one or more ultrasonic transducers that send an ultrasonic pulse across the flowstream at an angle and back. A transducer on the other side of the pipe acts as a receiver. The flowmeter measures the “transit time” of the pulse from one side of the pipe to the other. When the signal travels with the flow, it travels faster than when it travels against the flow. The difference between these two transit times is proportional to flowrate.

When liquids contain a large number of impurities, Doppler ultrasonic meters are used. Doppler meters work like transit time meters except that instead of bouncing a signal off the other side of the pipe, they bounce a signal off the particles in the flowstream. These particles are traveling at the same velocity as the liquid flow. As the ultrasonic pulse bounces off the particles, a frequency shift in the signal occurs that is proportional to the velocity of the flow. A receiver detects this shift in frequency and uses it to compute flowrate.

Doppler ultrasonic meters are used to measure the flow of dirty liquids and slurries. Transit time meters are used mainly to measure the flow of clean liquids. However, in recent years, suppliers have made progress in enabling transit time meters to measure liquids with some impurities in them. Doppler meters are not as accurate as transit time meters, but measuring the flow of dirty liquids and slurries is a difficult measurement. Many end-users are now using transit time technology where formerly they would have used Doppler because of the improvements in the ability of transit time meters to handle somewhat dirty liquids (Figure 17.3).

Mounting type is an important consideration for ultrasonic flowmeters. Some ultrasonic meters use clamp-on technology, meaning that the transducers are clamped onto the pipe and the internal flow velocity is read by an external transmitter that sits somewhere on the outside of the pipe. Clamp-on flowmeters have a great advantage in that they are completely nonintrusive and have no impact on the flowstream. They are sometimes used as check meters to monitor the performance of another flowmeter and where it is desirable to

FIGURE 17.3 An ultrasonic flowmeter being tested at CEESI; photo by Flow Research.

measure flow at different locations. The chief disadvantage of clamp-on ultrasonic meters is that they are less accurate than inline ultrasonic meters. The ultrasonic signal has to pass through the pipe wall, and its thickness and material of construction can have an impact on the signal. Also, if there is any buildup on the side of the pipe, this can affect the internal diameter of the pipe and the accuracy of clamp-on ultrasonic meters. For these reasons, inline ultrasonic flowmeters are generally used where high accuracy is required.

Multipath ultrasonic flowmeters have been developed to increase the accuracy of ultrasonic flowmeters, and are some of the most accurate flowmeters made. Multipath meters contain three or more paths, with each path containing a pair of ultrasonic transducers. A path is simply the trail of an ultrasonic pulse as it travels across the pipe. Multipath meters have the advantage of measuring the transit time signal at multiple locations in the pipe, thereby increasing measurement accuracy. Most multipath ultrasonic meters have 4, 5, or 6 paths, but some meters have been developed with as many as 8 or 18 paths.

Multipath ultrasonic meters have received the approval of the American Gas Association (AGA) for use in custody transfer of natural gas. Because of their high accuracy and reliability, they are displacing turbine and differential pressure (DP) flowmeters that are also used for this purpose. Multipath ultrasonic flowmeters, which are always inline, are used for to measure the flow of natural gas in large pipelines at custody transfer points. Many of these pipelines are 24–42 in., or even larger. Until ultrasonic meters received AGA approval in 1998, turbine and DP flowmeters were mainly used for custody transfer.

17.1.5 Vortex Flowmeters

Vortex flowmeters are the most versatile type of flowmeter because they can reliably measure liquid, steam, and gas flows with relative ease. They are also able to withstand the high temperatures and pressures associated with steam flow, and hence are uniquely qualified to measure steam. More recently, vortex flowmeters have received approvals from the American Petroleum Institute (API) for use in custody transfer applications. This draft standard was first approved in 2007, and then revisited in 2010.

Vortex flowmeters make use of what is called the von Karman effect. According to this principle, fluid passing by a bluff body will alternately generate vortices that are used to measure flow. The vortex flowmeter counts the number of vortices generated by the bluff body, which is a broad object with a flat front that is inserted into the flowstream. Flow velocity is proportional to the frequency of the vortices. Flowrate is calculated by multiplying flow velocity times the area of the pipe.

Vortex flowmeters are widely used for steam flow measurement. Due to its high pressure and temperature, steam is the most difficult fluid to measure. How steam flow is measured also depends on the type of steam: whether it is wet, saturated, or superheated. Steam is measured for power generation purposes, and it is also often measured in process plants. Vortex meters can handle the high pressures and temperatures associated with steam. The other type of flowmeter widely used for steam flow measurement is differential pressure.

Vortex flowmeters offer reliable and accurate flow measurement at a reasonable price. However, they do not have the same compelling features that some other new-technology flowmeters have. They do not have the high accuracy of multipath ultrasonic or Coriolis flowmeters, for example. Neither do they have the ability of magnetic flowmeters to measure the flow of almost any type of water, dirty, or clean. Instead, vortex flowmeters offer reliable and accurate measurement of flow in a wide range of conditions.

17.1.6 Thermal Flowmeters

Thermal flowmeters are used almost entirely for gas flow measurement. They were developed in the 1970s by a group of researchers who had previously worked on hot-wire anemometers used to measure airflow in a laboratory environment. The laboratory research, conducted by Dr. John Olin and Dr. Jerry Kurz, was intended to investigate airflow turbulence and air velocity profiles. The group wanted to adapt the hot-wire anemometers to an industrial environment, but they were too fragile for that purpose. Drs. Olin and Kurz developed a thermal flowmeter that was more rugged and hardened than the hot-wire anemometers that worked well in laboratory environments.

Somewhat before the research done by Drs. Olin and Kurz, Fluid Components International (FCI) took a different approach to the development of thermal flowmeters. FCI developed thermal flow switches to detect oil flow through pipes in the oil patch. While FCI's thermal flow switches preceded the thermal flowmeters developed by Olin and Kurz, FCI did not actually create thermal flowmeters until 1981, when they put more sophisticated electronics on their switches, creating thermal flowmeters.

Thermal flowmeters work differently from other new-technology types. They actually introduce heat into the flowstream and measure how quickly this heat dissipates. Heat dissipation is measured using one of the two methods

- Constant temperature differential
- Constant current

The constant temperature differential method involves the use of two temperature sensors. One sensor is heated and the other measures the gas temperature. Mass flowrate is calculated based on how much electrical power is necessary to keep a constant difference in temperature between the two temperature sensors.

The constant current method also requires the use of two sensors. One sensor is heated and the other sensor measures the temperature of the flowstream. Electrical power is kept constant to the heated sensor. Mass flow is measured based on the difference between the flowstream temperature and the temperature of the heated sensors. Both methods use the principle that greater cooling results from higher velocity flows.

In the early 1990s, there was an environmental push to measure the amount of sulfur dioxide (SO_2) and nitrous oxide (NO_x). Thermal flowmeters found a niche in this market, which is referred to as continuous emissions monitoring (CEM). At this time, thermal flowmeter suppliers developed multipoint thermal flowmeters to more accurately measure the flow through large exhaust pipes and smokestacks. Single point thermal meters were not sufficiently accurate because they only measure flow at a point, while the multipoint meters measured flow at multiple points. Some multipoint meters measure flow at as many as 16 points.

Since 2008, the Obama administration has placed a renewed emphasis on monitoring greenhouse gas emissions. This has opened up new opportunities for thermal flowmeters in areas such as biomass gasification, measuring flue gas, monitoring flare gas flow, methane recovery from coal mines, and measuring landfill gases. These opportunities have given a substantial boost to sales of thermal flowmeters in the past several years. While there is still a need for CEM, these new applications are well suited to thermal flowmeters, which are almost exclusively used to measure gas flow.

17.1.7 Traditional Technology Flowmeters

Traditional technology flowmeters incorporate more traditional technologies than new-technology flowmeters. As a group, these flowmeters have been on the market longer than new-technology meters. Their maintenance requirements are typically higher than new-technology meters. And while some suppliers are bringing out new features and new products into the traditional technology flowmeter market, suppliers are less active in researching and developing traditional technology flowmeters than they are in bringing enhanced and upgraded new-technology flowmeters to market.

The following are the flowmeter types that fall into the traditional technology category:

- Differential pressure
- Positive displacement
- Turbine
- Open channel
- Variable area

17.1.8 Differential Pressure (DP) Flowmeters

Differential pressure flowmeters operate by placing a constriction in the flowstream that creates a difference in pressure upstream and downstream from the constriction. The constriction is called a primary element. DP flowmeters use the difference in pressure to generate a flow measurement. There are many types of primary elements, including the following

- Orifice plates
- Venturi tubes
- Flow nozzles
- Pitot tubes
- Other

DP flowmeters differ from other flowmeters in that the primary elements used with DP transmitters to measure flow are often sold separately from the DP transmitter itself. Some companies are in the business of manufacturing primary elements. They may leave it up to the customer to specify whose DP transmitter they prefer to use with the primary element.

An *orifice plate* is a round plate, usually made of steel, with a hole in it. The hole may be located at various places on the plate; not all are located in the center. Orifice plates are relatively inexpensive, but are generally good at handling dirty fluids. One chief disadvantage of orifice plates is that they create significant pressure loss because the part of the plate that does not have a hole, or “orifice,” in it blocks the flow. They are also subject to wear over time, which can degrade the accuracy of the flow measurement.

Primary elements include the following devices

A *Venturi tube* is an elongated tube that narrows at one end. Venturis can be used with clean liquids, gases, and steam, although they also can handle slurries and dirty liquids. They cause less pressure loss than orifice plates because of their relatively wide opening. Venturis are the best suited for high-speed flows. They tend to be relatively expensive, and can also be difficult to install.

A *Pitot tube* is a vertical flow element that has pressure ports both in the front and also in the back of the tube. Pitot tubes are designed for use with clean liquids, gases, and steam. They are subject to clogging when used with dirty fluids or fluids with particles. Pitot tubes cause relatively little pressure drop. Averaging Pitot tubes are quite common; these measure the flow at multiple ports and average the result, giving a more accurate measurement than single port Pitot tubes.

A *flow nozzle* is a shortened tube that curves inward to form a narrower opening than the internal diameter of the pipe. Flow nozzles can handle both clean and dirty liquids, as well as clean gases and saturated steam. Like Venturi tubes, they work best with high-speed flows, and they also do well in high temperature applications. Flow nozzles have less pressure loss than orifice plates.

Other primary elements include wedge elements, laminar flow elements, Dall tubes, and proprietary flow elements such as the V-Cone. Each type has its own advantages and disadvantages. Laminar flow elements are often used to measure low flows. The V-Cone is designed to minimize the need for upstream and downstream piping. It used to be manufactured exclusively by McCrometer, but now other companies such as Cameron have begun manufacturing their own version of the V-Cone.

Some companies have brought out products that integrate a DP flow transmitter with a primary element. Examples include Emerson Process Management's ProBar and ProPlate. The ProBar integrates a DP transmitter with an Annubar primary element, which is an averaging Pitot tube. The ProPlate integrates a DP transmitter with an orifice plate. One advantage of these products is that they can be factory calibrated with the DP transmitter already attached to and working with the primary element.

The roots of DP flow measurement go back several centuries. The groundwork was laid by Benedetto Castelli and Evangelista Toricelli with their idea that flowrate equals velocity times the area of the pipe, and with their work on pressure. Toricelli is best known for developing the barometer. In 1738, Daniel Bernoulli developed the hydraulic equation for flowrate that forms the basis of DP flow measurement. This has come to be known as Bernoulli's theorem, and it still forms the basis of DP flow measurement today.

DP flowmeters were the first type of meter to receive approval from the AGA for use in custody transfer applications. The first AGA report was published in 1930, and it was followed by a second report in 1935. These reports were updated in 1955 and issued as AGA-3. AGA-3 was accepted by the API as a standard in 1975. It was adopted as an ANSI/API standard in 1977 and updated in 1992 and 2000. For many years, these approvals gave DP flowmeters a significant edge over other flowmeters, including turbine and ultrasonic, in custody transfer applications.

17.1.9 Positive Displacement Flowmeters

The first positive displacement flowmeter was invented by Thomas Glover in 1843. Glover had some problems with liquid-sealed drum meters, which date back to the early 1800s. As a result, he created a positive displacement flowmeter with sheet metal enclosures and sheepskin diaphragms. Today positive displacement flowmeters have cloth or synthetic rubber diaphragms and are made from cast aluminum.

Positive displacement flowmeters work by capturing the flow in compartments of known quantity, emptying those compartments, and then counting how many times this is done. This need for counting explains the register that appears on positive displacement flowmeters; this register serves as a counter for determining how often the compartments

are filled and emptied. Positive displacement flowmeters are used to measure the flow of liquids and gases, but they cannot be used to measure steam.

There are a number of different types of positive displacement flowmeters that are classified by their design. The main types are as follows

- *Diaphragm*: a diaphragm to capture the flow.
- *Rotary*: one or more rotors to trap the flow.
- *Oval Gear*: two oval gears or rotors mounted inside a cylinder.
- *Helical Gear*: a rotor resembling the shape of a helix.
- *Nutating Disc*: a round disc located inside a cylindrical chamber; as the fluid enters the chamber, the disc wobbles or “nutates.”
- *Oscillating Piston*: a piston that rotates inside a cylindrical chamber.

Positive displacement flowmeters are important for measuring the following types of fluids:

- Water
- Oil
- Industrial liquids
- Gas

Positive displacement meters are used to measure commercial and industrial water, but they are also widely used to measure flow in residential applications. Positive displacement flowmeters are used to measure viscous fluids including fuel oil, hydraulic fluids, and lubricating oils. They are used for in-plant measurement of industrial liquids. And diaphragm meters in particular are widely used for billing applications involving gas used as fuel for businesses and industrial plants.

17.1.10 Turbine Flowmeters

The first inventor of the turbine flowmeter is generally believed to be Richard Woltman, who created this flowmeter in 1790. Woltman was a German engineer who wrote several books about hydraulic engineering. His life was dedicated to the Department of Ports and Navigable Waters of Hanover, Germany.

The word “turbine” comes from a Latin word meaning “spinning thing.” Turbine meters have a rotor with propeller-like blades that spins as fluid passes over it. The rotor has bearings and is mounted in a housing. The rotor spins in proportion to flowrate. Different methods are used to detect the speed of the rotor, including an electronic sensor and a mechanical shaft.

There are at least seven different types of turbine meters that vary according to the design of the spinning rotor:

- *Axial*: a rotor that revolves around the axis of flow.
- *Jet*: mainly used for water measurement, jet meters have an orifice that water is forced through, forming a “jet”; the two types are single jet and multi-jet.
- *Paddlewheel*: a lightweight paddlewheel spins in proportion to flowrate.

- *Pelton Wheel*: like paddlewheel meters but with a single size rotor with straight blades.
- *Propeller*: mainly used for dirty liquids, with helical-shaped blades that are longer than the blades of most other turbine meters.
- *Woltman*: also called “bulk” meters, are water meters for large volume applications. They have a gear train to convert the motion of the rotor into the rotation of a vertical shaft.
- *Compound*: because they incorporate 2 meter technologies; typically they have turbine technology for high flowrates and positive displacement technology for low flowrates.

Similar to positive displacement meters, turbine meters are used for water, oil, gas, and industrial liquid applications.

17.1.11 Open-Channel Flowmeters

Most flow measurement occurs in closed pipes. However, there is one type of flowmeter that is designed to measure flow in rivers, streams, and open conduits. Called an open-channel flowmeter, these meters are used for agriculture, irrigation, and wherever flow has to be measured outside of a closed pipe. Another way to draw the distinction is between flow that occurs under pressure and gravitational flow. Flow in closed pipes typically occurs under pressure, whereas flow in rivers, streams, and open conduits typically relies on the force of gravity to generate the flow.

Weirs and Flumes: There are several different methods of open-channel measurement. One common method involves the use of weirs and flumes. Weirs and flumes are hydraulic structures placed in an open channel that have a known depth-to-flow relationship. Water depth is then measured upstream of the weir or flume, and flow is determined in this way.

A weir is like a dam placed across an open channel. It is placed in the open channel in such a way that the water can flow over it. An equation is associated with each weir to determine flowrate based on the depth of the flow that is measured upstream of the weir.

A flume has an area or slope that is different from that of the open channel. It is a specially shaped portion of the open channel. Liquid depth is measured at different specific points in the flume. An equation is associated with each flume that takes flume size into account. This equation is used in calculating flowrate.

Area Velocity Method: Another common method for measuring flow in open channels does not involve the use of weirs or flumes. Instead, flow is measured by calculating the mean velocity of the flow at a cross-section. This value is then multiplied by the flow area. Normally, this method requires making two measurements: one to measure velocity and another to determine depth of flow. Flowrate Q is computed by multiplying velocity with area:

$$Q = V \times A$$

The area velocity method is used when using a weir or flume is impractical, and for temporary flow measurements. Examples where this method is used include sewer flow monitoring and influx and infiltration studies.

In addition to being used to measure flow in rivers and streams, open-channel flow is also used to measure flow in large water and wastewater pipes that are part of a water or

sewer system. Even though the flow may be occurring in pipes, the pipes are large and are open at either end. In open-channel flow, the pipes are often only partially filled. The liquid flowing through the pipes is not flowing under pressure, and this is classified as open-channel flow.

17.1.12 Variable Area Flowmeters

Variable area flowmeters play a unique role in the world of flow. Most of them are read manually, and they are sometimes used to indicate a flow/no-flow situation. Because they are manually read, their accuracy is typically low. Flowrate is read by comparing the position of a float in a tube in the meter to a dial on the outside of the tube that indicates flowrate.

The first variable area flowmeter was invented by Karl Kueppers in Aachen, Germany in 1908. Felix Meyer founded the company Deutsche Rotawerke GmbH in Aachen the following year. This company was the predecessor of the company known today as Rota Yokogawa. In 1921, KROHNE started manufacturing variable area flowmeters in Duisburg, Germany, where they are still manufactured today.

Most variable area flowmeters consist of a tapered tube containing a float. Typically, these meters are mounted vertically, and the fluid's upward force is counterbalanced by the force of gravity. At some point, the float remains constant and the flowrate can usually be read from a scale on the meter tube. The variable area meter tubes consist of glass, metal, and plastic. Plastic tubes are the lowest in cost, whereas metal tubes are used to handle high pressure applications. Some meters called purgemeters have been developed to handle low flow applications.

Although variable area meters have traditionally been manually read, some are now being produced with a transmitter output. Some even have the HART protocol available. This makes it possible to do control and recording with variable area meters, and turns the meter into something more than a visual indicator. Despite this added feature, the use of variable area flowmeters is still limited by their relatively low accuracy. Variable area meters can be used to measure liquids and gases, but they are not used to measure steam flow.

17.2 TRENDS IN FLOW MEASUREMENT

One important trend in flow measurement is the move from traditional technology to new-technology flowmeters. Many end-users are selecting new-technology flowmeters for their accuracy, reliability, lack of pressure drop, and reduced need for maintenance. Positive displacement and turbine flowmeters in particular have moving parts that are subject to wear. This wear can degrade measurement accuracy over time. Orifice plates, which are used with DP transmitters to measure flow, are subject to wear. They also cause substantial pressure loss in the line, because all the flow is forced to pass through one or more "orifices" or holes in the plate that are substantially smaller than the line size.

In custody transfer of natural gas, DP and turbine flowmeters are losing ground to ultrasonic meters. In 1998, ultrasonic flowmeters gained the approval of the AGA for use in custody transfer of natural gas. DP and turbine meters had gained this approval much earlier. The first approval of DP flowmeters for use in gas flow measurement came in 1930, whereas turbine meters first received AGA approval in 1981. So these meters had a substantial head start on ultrasonic meters. Despite this, multipath ultrasonic meters have been gaining in popularity for custody transfer of natural gas because they have high

accuracy, cause virtually no pressure drop, do not have moving parts, and are highly reliable over time.

In the area of petroleum liquid distribution, positive displacement flowmeters are losing ground to Coriolis meters. Petroleum liquids are often delivered on trucks to businesses, and also to trains, ships, and airplanes. This is typically a custody transfer measurement that has been done by positive displacement meters. Coriolis meters are taking their place in many applications because of their high accuracy and reliability. Also, the price of crude oil has risen substantially in the past year, and companies are willing to pay more to measure it. Although the initial purchase price of Coriolis meters is higher than that of positive displacement meters, their total cost of ownership is often less because they require little maintenance. For these reasons, many end-users are choosing Coriolis meters over positive displacement meters for delivery of petroleum liquids.

Traditional technology flowmeters are holding their own in some applications. Diaphragm and rotary positive displacement flowmeters are holding their own in utility and billing applications for the use of gas in commercial and industrial buildings. Turbine meters are still widely used as reference meters for calibration facilities and laboratories, due to their high accuracy. Both positive displacement and turbine meters have a hold on the residential water meter market, although magnetic flowmeters are beginning to be used for this purpose. And variable area meters are still used when a low-cost meter is wanted for a flow/no-flow indication.

The primary attributes that end-users look for in flowmeters include accuracy, reliability, and lack of required maintenance. This trend primarily benefits ultrasonic, Coriolis, and magnetic flowmeters. The use of vortex meters is also growing, especially for steam applications. And thermal flowmeters are not so much displacing other meters as they are being increasingly used for a wide range of new environmental applications involving the measurement of greenhouse gases. For all these reasons, the new-technology flowmeter market is growing at a faster rate than that of the traditional technology flowmeter market. And even though the traditional technology flowmeter market as a whole is still showing modest growth, the markets for positive displacement and turbine flowmeters appear to be declining slowly.

18.1 INTRODUCTION

As the cost of energy increases, the importance of predicting and controlling its movement is of increasing concern. For many years, the calculation of heat transfer has been considered a fundamental part of the engineering design of any thermal system. Whether for building environments, power production, or manufacturing processes, temperature control is often of paramount concern for physical comfort and the production of industrial materials and products. To effectively control temperature requires that energy be transferred in a known, and controlled manner. It is understood that good temperature measurements are essential and many companies offer extensive lines of temperature sensors for almost any environment. But it is equally important to know the details of the energy transfer itself.

Temperature is a fundamental property of a material and accurate measurement and calibration standards are readily available. The measurement of heat transfer, however, is a very different situation. First, it is much more challenging because heat transfer is the movement of thermal energy through a material and is not a property. Consequently, establishing measurement standards and calibration methods is much more challenging. Second, the whole concept of heat flux or thermal energy transfer per area is not as well understood by the general population. Even many engineers do not have a good physical understanding of a watt per square meter or a British thermal unit per square foot hour. Heat flux gage sales are a miniscule fraction of the thermal measurement market. Hopefully this article will encourage researchers and practitioners to use this important technology. Part of an engineer's education should be the experience of using heat flux gages, and measuring heat transfer.

Previous reviews have covered the history of heat flux instrumentation. The most comprehensive was done in 1993 (Diller, 1993). Combustion applications were covered by Arai et al. (1996), focusing on radiation heat transfer measurement. An emphasis on electronic cooling was given by Keltner (1997). Heat transfer measurements in buildings was presented by Flanders (1994). Childs et al. (1999) covered the broad range of sensors used for convection measurements, while Han et al. (2001) focused more specifically on gas turbine applications. A compilation of heat flux gage manufacturers with details of the available gages is also available (Diller, 1999).

The focus of the present review is the most useful current heat flux instrumentation, particularly heat flux gages. Although some heat flux gages are available commercially and may even be standard stock items, others are currently limited to research laboratories. The latter may be the commercial gages of the future. Optical methods are discussed briefly, but these are generally research methods that require sophisticated equipment and data processing techniques. General principles for the proper use of heat flux gages are discussed first, followed by the details of specific gages along with some of their typical applications. Three classifications of gages are considered based on measured temperature difference over space, the temperature change with time, and the power dissipated at a maintained temperature. In all of these cases it is important to understand the pathways of heat in and around the sensor, which means that how gages are mounted on or in materials can consequently be crucial. The measurement methods are also categorized according to the type of temperature measurement. The three common techniques are thermocouples (either individually or differentially), resistance temperature devices (RTDs), and optical (liquid crystals, infra-red, or thermographic phosphors). Calibration of heat flux gages is then discussed along with error analysis. Obtaining a signal from a heat flux gage is easy; properly interpreting the measurements is the challenge.

18.2 IMPORTANT ISSUES

There are a number of styles of gages commercially available, made by several companies in the United States and Europe. While many of these gages are easy to install and read the output, it is often crucial that a gage with the correct style and range is selected to give meaningful results for a specific application. For example, it is desirable to use different types of gages to measure the low heat fluxes typical of buildings and natural convection, the moderate heat fluxes of radiation from fires and forced convection in fluids, and the high heat fluxes of high speed combustion, and hypersonic flow.

As explained in this section, there are a number of problems and complications that should be taken into account while planning for any heat flux measurements. The most important issue is maintaining the proper heat flow and corresponding temperature distributions while making the measurements. The presence of a heat flux gage on or in a surface will necessarily alter the temperature field and heat flux to some extent. For considering this effect the gages can be categorized as either surface mounted or insert. The surface-mounted gages are flat and are attached to the surface with some type of glue or paste. The insert gages are usually cylindrical and are pressed into a hole flush with the surface. An additional issue, which is sometimes neglected, is where the heat goes, or the heat sink. This will be considered first, followed by the potential heat flow disruption. If these issues are not properly considered, even the most accurate heat flux gage will give erroneous results.

18.2.1 Heat Sink

For the transfer of thermal energy to occur there must be a heat source and a heat sink. Heat flux gages are designed to measure the net heat transfer between the heat source and the heat sink, usually normal to a surface between them. For example, if a heat flux gage is mounted to a surface that does not provide a good heat source or sink, it will usually measure no heat flux at steady-state conditions, irregardless of the surrounding temperatures.

Figure 18.1 illustrates the usual condition at the surface of a material. Conduction occurs through the material to the heat sink or source with convection and/or radiation exchange at the surface. If the material is low thermal conductivity, the heat flux at steady-state conditions will be very small. Therefore, high conductivity metals are usually desired for the material. Also, it is usually difficult to arrange conditions at the surface

FIGURE 18.1 Surface heat balance.

which provide only convection or radiation. There is usually always some of both at least to some extent. The surface heat balance is then expressed as

$$q_{\text{conduction}} = q_{\text{convection}} + q_{\text{radiation}} \quad (18.1)$$

Alternatively, another material may be placed against the surface to provide conduction in place of convection and radiation.

18.2.2 Potential Disruption of Surface-Mounted Gages

The measured heat flux at the surface of the material on which the gage is mounted is assumed to be one-dimensional. Because of the thermal disruption caused by the placement of the gage on the surface, this may not be true, however. Wesley (1979) and Baba et al. (1985) have analyzed the thermal effects of a flat gage mounted on the surface of the material. They determined that the one-dimensional assumption is valid when

$$\left(\frac{k}{k_s}\right)\left(\frac{\delta}{R}\right) \gg 1 \quad (18.2)$$

where k_s is the thermal conductivity of the substrate, R is the radius of the gage, and δ and k are the effective thickness and thermal conductivity of the gage and adhesive. In addition, the gage should be mounted on the surface with a uniform layer of adhesive or thermal grease to minimize thermal contact resistance and keep the conditions one dimensional.

Measurements of convective heat flux are particularly sensitive to disturbances of the temperature of the surface. Convection is often expressed in terms of a heat transfer coefficient (h) and the fluid and surface temperatures.

$$q''_{\text{convection}} = h(T_{\text{fluid}} - T_{\text{surface}}) \quad (18.3)$$

Because the heat transfer coefficient in a boundary layer is increased locally by any surface temperature change, the effect of a small temperature change with location is further amplified at the gage location, as explained by Diller (1993). Therefore, any surface temperature disruptions caused by the gage should be kept much smaller than the surface to environment temperature difference causing the heat flux. For gages with one-dimensional heat transfer according to Equation (18.2), the corresponding criterion for surface disruption of temperature (5% of the fluid-to-surface temperature difference) is

$$h \frac{\delta}{k} \leq 0.05 \quad (18.4)$$

where h is the heat transfer coefficient between the fluid and surface. The important parameter is the ratio of the gage thickness (δ) to the gage thermal conductivity (k). As this ratio increases, the sensitivity of the gage increases, but the disruption caused by the gage also increases according to Equation (18.4). An optimum value for the particular application must be determined. If the gage material uniformly covers the entire surface, however, the value of $h\delta/k$ can be up to an order of magnitude larger because there are no local disruptions of the surface temperature. Independent measures of the substrate surface temperature and the gage surface temperature are advantageous in defining a value

of the heat transfer coefficient and insuring that the sensor does indeed provide a small thermal disruption.

Measurements of radiation heat transfer *from* the surface have similar sensitivities to surface temperature disturbances as convection. This is not true for radiation *to* the surface, however. This asymmetry of disturbance effects is due to the radiation heat flux being proportional to the fourth power of the absolute temperature. Consequently, a high-temperature heat source dominates the transfer exchange over the low-temperature heat sink. The surface coating properties of the gage (absorptivity, transmissivity, reflectivity, and emissivity), however, should be matched with those of the surrounding surface for either case with radiation present. If the coating is nearly black, a match of emissivity is usually sufficient.

18.2.3 Potential Disruption of Insert Gages

Insert heat flux gages appear to cause less disruption of the surface because they can be mounted flush with the surface. This does not insure a good temperature match with the surrounding surface, however. The local temperature and heat flux in the vicinity of the sensor is disturbed whenever the thermal properties, and heat sink of the gage are different than those of the surrounding surface. Gifford et al. (2010) have modeled the two effects as

$$\frac{q_g''}{q_p''} = \frac{1}{\frac{h_p}{h_g} + h_p R''} \quad (18.5)$$

where the heat flux measured by the gage (q_g'') is compared to that of the surrounding undisturbed surface (q_p''). The thermal resistance of the gage is represented by R'' , which causes a lower apparent heat flux from the gage. The resulting temperature disruption decreases the apparent heat transfer coefficient over the gage h_g relative to the surrounding undisturbed surface h_p . The effect has been demonstrated for laminar flow (Diller, 1993) and calculated for turbulent boundary layer flow (Kandular and Haddad, 2007). Moffat et al. (2000) have shown experimentally that this effect is larger than originally anticipated for turbulent boundary layers because of the laminar sublayer. It is counter-intuitive that this effect actually becomes larger as the gage size becomes smaller. Therefore, surface temperature disruptions caused by the gage should be kept much smaller than the surface to environment temperature difference causing the heat flux.

If the gage is not water cooled, it relies on the surrounding material to conduct away the heat it receives. Therefore, it must have a good thermal path to the surface into which it is mounted. It should also have good physical contact insured by a tight fit in the hole or threads with a method to tighten the gage into the surface. For steady-state measurements the gage should have an effective thermal conductivity as high or higher than the surrounding material because all of the heat must be dissipated into the surrounding surface. For unsteady heat transfer conditions, however, the gage properties should match those of the surrounding material to insure the same thermal transients. If the gage is water-cooled, the surrounding substrate can still affect the readings whenever forced or natural convection is present (Robertson and Ohlemiller, 1995). In either case, independent measures of the substrate and the gage surface temperatures are advantageous in defining a value of the heat transfer coefficient and for insuring that the gage does indeed match the surface temperature.

18.3 GAGES BASED ON SPATIAL TEMPERATURE DIFFERENCE

These heat flux gages operate by measuring a temperature difference over a spatial distance. There are several different geometries and temperature measurement methods. Because these gages measure continuously, the heat flux through the gage can be measured as long as the signal is monitored. They can be attached on the surface or inserted into the material. The different styles are discussed in separate subsections.

18.3.1 One-Dimensional Planar Gages

The simplest concept for heat flux measurement is the layered gage as illustrated in Figure 18.2. The temperature is measured on either side of a thermal resistance layer in the direction normal to the surface. The two most common methods of measuring the temperature difference are resistance temperature devices (RTD's) and thermocouples. A new ASTM standard is devoted to these heat flux gages (ASTM E2684–09, 2009).

The voltage output of the heat flux gage illustrated in Figure 18.2 is not only a function of the temperature difference, but also the thickness and thermal conductivity of the thermal resistance material, δ and k . At steady state the one-dimensional conduction equation reduces to

$$q'' = \frac{k}{\delta} (T_1 - T_2) \quad (18.6)$$

The transient response of the gage is a function of the thermal resistance layer thickness and the thermal diffusivity of the material. Hager (1965) has analyzed the one-dimensional transient response when mounted on a perfect heat sink and gives the time required for 98% response as

$$t = \frac{1.5 \delta^2}{\alpha} \quad (18.7)$$

where α is the gage thermal diffusivity. It should be noted that the sensitivity increases linearly with the thermal resistance layer thickness, but the response time increases as the square of the thickness. Consequently, sensitivity versus time response is one of the major tradeoffs in design of these gages.

FIGURE 18.2 Layered heat flux gage.

18.3.1.1 Surface Mounted Gages Using RTD Sensors Any material that is an electrical conductor and changes electrical resistance with temperature can in theory be used as an RTD (resistance–temperature device). The temperature sensitivity for most metals is nearly constant over a wide temperature range, but is small (a fraction of a percent change in resistance per degrees Celsius). The advantage of an RTD is that it usually has a higher precision in measuring temperature than a thermocouple and it gives absolute temperature. It must be supplied with a small constant current, however, for measurements. Another disadvantage is that its resistance is also sensitive to strain and other factors, such as aging.

Epstein et al. (1986) produced a heat flux gage for turbomachinery research using a 25 μm thick sheet of polyimide (Kapton) with nickel RTD's deposited on either side. The nickel resistance element (1.0 mm by 1.3 mm) is immediately contacted to gold leads to isolate the voltage drop of the measurement at the sensor location. The leads from the bottom element are brought through the polyimide sheet so that all four leads can be taken to the edge of the sheet together. The nickel elements are either vacuum deposited with dc sputtering or electroless plated. Up to frequencies of about 20 Hz the gage responds directly to the heat flux, as indicated in Equation (18.6). For frequencies above 1 kHz the polyimide resistance layer appears infinitely thick, and the top resistance element (T_1) responds like a transient heat flux gage described in Section 18.4.1. To cover the entire range from dc to 100 kHz a numerical data reduction technique is used to reconstruct the heat flux signal. One of the advantages of these gages is that they can be wrapped onto curved surfaces, although the temperature calibrations change during this process, which may necessitate *in situ* calibration.

The heat flux gage developed by Piccini et al. (2000) is made by sputtering platinum RTD's onto one side of a 50 μm thick sheet of Upilex to measure T_1 . A thermocouple is mounted into the metal substrate onto which the sheet is glued for the second temperature measurement, T_2 . The heat flux at steady state is calculated from the temperature difference between the RTD and the thermocouple as shown in Equation (18.6). The thickness and thermal conductivity of the Upilex and the glue layer are determined from direct calibration. Analytical solutions of the unsteady heat transfer equations are used to determine the unsteady heat flux up to frequencies of 100 kHz, similar to the method used by Epstein et al. (1986).

For higher temperature applications, Talib et al. (2005) painted platinum films onto an enameled piece of 2 mm thick Inconel. This was mounted onto a surface with embedded thermocouples to create a heat flux gage of the same functionality as Piccini et al. (2000). This was used in a propane burner for fire testing. Fralick and Wrbanek (2002) have demonstrated a heat flux gage with platinum RTD's printed on both sides of a 1 mm thick slice of alumina for high temperature applications. This double-sided arrangement keeps both temperature measurements on the gage itself, which avoids the required *in situ* calibration of the previous two methods.

18.3.1.2 Surface Mounted Gages Using Thermocouple Sensors The temperature sensitivity of different combinations of materials for thermocouples is indicated by the Seebeck coefficient, S_T . Excluding the semi-conductor materials, the maximum sensitivity for any of the possible pairs is 50–100 $\mu\text{V}/^\circ\text{C}$. Kinzie (1973) lists details of many non-standard thermocouple pairs. Although a reference temperature is required for measuring absolute temperature, thermocouples generate an electrical output without the excitation current required of RTD's. For measuring temperature difference, however, a reference

FIGURE 18.3 Thermocouple measurement of temperature difference.

temperature is not needed. This is illustrated in Figure 18.3 where the output voltage E is

$$E = S_T(T_1 - T_2) \quad (18.8)$$

If a number of these units are connected together in series, the result is a thermopile which increases the voltage output for a given temperature difference. An example of such a thermopile heat flux gage is illustrated in Figure 18.4. Here five pairs of thermocouples are shown combined in series across the thermal resistance layer. Each produces an output voltage that is proportional to the temperature difference, $T_1 - T_2$. The total output voltage is then proportional to the number of thermocouple pairs, N , and the Seebeck coefficient for the thermocouple pair, S_T .

$$E = NS_T(T_1 - T_2) \quad (18.9)$$

Using a thermopile, therefore, can easily overcome the greater sensitivity of individual RTD's. Thermocouples are also insensitive to strain and most other factors besides

FIGURE 18.4 Thermopile heat flux gage.

temperature. Moreover, only two leads are required for a heat flux measurement, versus four for two RTD's. The corresponding heat flux sensitivity of the ideal layered gage is therefore

$$S_q = \frac{E}{q''} = \frac{NS_T\delta}{k} \quad (18.10)$$

To minimize the temperature disruption of the gage the thickness, δ , should be kept as small as possible, particularly if there is a large convection coefficient on the surface, as shown in Equation (18.4).

The values of δ used in different gages vary widely depending on the range of heat fluxes to be measured. Thermal resistance layers with thicknesses of 1 mm or more have generally been used for heat fluxes less than 1 kW/m². The time response is on the order of a second or more. Applications are typically conduction heat flux in building structures or insulation and natural convection. Bales et al. (1985) have published a book of articles discussing the design, calibration, and use of heat flux gages for building applications. One design uses welded wire to form the thermopile across a sensor about 1 mm thick with an upper temperature limit of 300°C. These are manufactured in a range of sizes by International Thermal Instrument Co. Applications include heat transfer in buildings and physiology. Sensors with higher sensitivity are made with semiconductor thermocouple materials for geothermal applications. One type of sensor is designed for operation at gage temperatures of up to 1000°C.

For heat fluxes of up to 100 kW/m² thermal resistance thicknesses of 25–100 μ m have been used. The corresponding time response is as low as 50 ms. Some improvement in the frequency response is possible with appropriate signal conditioning (Bauer and Heywood, 1997). To measure the temperature difference, $T_1 - T_2$, Ortolano and Hines (1983) used a thermopile constructed of thin metal foils built around a Mylar or Kapton sheet. It is very versatile because it easily conforms to most surface shapes. Applications have included many types of conduction, convection, and radiation. These gages (named HFS) are manufactured by the RdF Corp. and sold by several distributors. The same approach has been used by Hubble and Diller (2010) to produce an array of heat flux sensors on a Kapton sheet. Instead of connecting the differential thermocouples in series, however, they were isolated individually as single pairs that gave 10 heat flux readings on each sheet. With appropriate data processing a 95% time response of 36 ms was obtained.

Thick film technology was used by Van Dorth et al. (1983) to put over 500 thermocouple pairs on a heat flux sensor that was 15 by 30 mm in size. Platinum and platinum–gold conductors were printed over and under a thermal resistance layer of glass-like material. This gave good sensitivity for demonstrated heat fluxes up to 200 kW/m² and temperatures up to 500°C.

A smaller, but similar sensor design has been made with screen printing techniques of conductive inks (Langley et al., 1999). A copper/nickel thermocouple pair was used with a dielectric ink for the thermal resistance layer. The inks were printed onto anodized aluminum sheets for the substrate. Although the entire package is 350 μ m thick, the thermal resistance is low because of the high thermal conductivity of all of the materials. Sensitivities are sufficient to measure heat fluxes as low as 0.1 kW/m². The thermal time constant is about 1 s, and the upper temperature limit is approximately 150°C. The aluminum base provides some limited conformance to a surface.

Printed circuit techniques were previously used by Vatel Corp. to produce a heat flux gage by plating two thermocouple materials on either side of a 0.2 mm thick printed

FIGURE 18.5 HTHFS, schematic of the measuring element (a) and, complete sensor (b).

circuit board. The thermocouples were connected in series by holes drilled and plated through the board forming many thermocouple pairs to give good sensitivity. The time constant for transient response was approximately one second.

An array of heat flux sensors was made with thermal vapor deposition by Ewing et al. (2010). Thermocouple pairs were formed on both sides of a $50\text{ }\mu\text{m}$ thick sheet of Kapton individually wired to give a separate heat flux and temperature output for each pair. There are a number of fabrication tricks to make a reliable sensor, including fluxless soldering of lead wires, vacuum depositing through holes in the sheet, and sealing the entire sensor to prevent oxidation with time.

A robust high temperature heat flux gage (HTHFS) was designed and fabricated by Gifford et al. (2010) by welding Chromel and Alumel strips as illustrated in Figure 18.5. The thermal resistance between the top and bottom thermocouples is formed by the elements themselves. The ceramic (ZTA) strips are included to provide electrical insulation between elements. An additional thermocouple wire welded to the top of the gage provides the surface temperature, which is useful for interpreting the heat flux signal. Long time operation and cycling to 1000°C was demonstrated. The time constant was less than one second. The measurement chip can also be mounted in an insert type housing which can be air or water cooled for gage temperature control.

Hubble and Diller (2010) developed a simple data processing method to extend the operation of the HTHFS so that it could be used on any substrate material. All of the sensors in this section are designed for the heat to go through the sensor into the material on which they are mounted as described in Section 18.2. The calorimeters described in Section 18.4 actually absorb the heat into the sensor itself, using the rate of temperature rise as the measure of heat transfer. The HTHFS can operate in both modes simultaneously—as a differential sensor and a calorimeter. Combining the heat transfer at the surface gives what is termed the “hybrid heat flux”

$$q'' = q''_{\text{differential}} + \frac{1}{2} q''_{\text{calorimeter}} \quad (18.11)$$

This gives the correct heat flux whether the gage is mounted on a good heat sink (high conductivity material) or a good insulator (low conductivity material). It also increases the time response of the gage by about an order of magnitude. The differential heat flux is proportional to the usual temperature difference measured across the gage and the calorimeter heat flux is proportional to the time rate of temperature change of the gage.

A thin-film version of a high temperature heat flux gage has been developed by MesoScribe Technologies, Inc. that can be deposited directly onto test surfaces using a

Direct Write Thermal Spray process (Theophilos et al., 2010). Up to eighty thermocouple pairs (Type K or N) are scribed around a layer of dielectric serving as the thermal resistance for the heat flux signal and a separate thermocouple gives the surface temperature. A layer of yttria-stabilized zirconia is first deposited on a metal surface to provide electrical isolation. It can also be deposited over the gage to encapsulate it for better durability. All of the layers are on the order of 0.1 mm thick, which gives a good output signal and good survivability at high gage temperatures.

An anisotropic thermoelement has been used by Mityakov et al. (2002) to produce a heat flux gage with ten to one hundred times the voltage output of the usual thermopile gages. This is attributed to the transverse Seebeck effect which is experienced in single crystal bismuth strips. The strips are wired in series and mounted on a mica base. The output voltage is generated at the surface of the material, which can be as thin as 0.1 mm.

18.3.1.3 Surface Mounted Wire-Wound Gages The wire-wound gage is similar to the thermopile layered gages except for the method of producing the thermocouple junctions around the thermal resistance layer. A fine wire of one of the thermocouple materials, for example constantan, is wrapped around the thermal resistance layer N number of turns. One-half of the wire is then electroplated with the other thermocouple material, for example copper. The result is a set of thermocouple junctions where the electroplating stops on the top and bottom of the thermal resistance layer. It is different from the thermopile gages of Section 18.3.1.2, however, because one of the wires is continuous all around the sensor. This forms a thermopile with the wire on one side and the wire and plating in series on the other side. There are N pairs of thermocouple junctions corresponding to the N windings. The theoretical output is therefore less than a true thermopile gage and is a function of the plating thickness in addition to the overall geometry and thermoelectric output of the materials.

A major use of these gages is low heat flux measurements on the surface of equipment to measure heat losses and insulation effectiveness. A summary of the theory is given by Hauser (1985) and a review of the applications by van der Graaf (1989). Thicknesses of the thermal resistance layer vary from 0.5 to 3.0 mm, with time constants from 1 to 30 s. Some of the sensors are flexible for wrapping around pipes and curved surfaces. Applications include building structures, insulation, geothermal and medicine, with heat fluxes generally less than 1 kW/m^2 . Concept Engineering offers this type of gage commercially.

18.3.2 Insert Heat Flux Gages

These heat flux gages are mounted through a hole in the material flush with the surface. The heat sink is provided either by the material in which it is mounted or by water cooling through channels in the gage. A new ASTM standard is devoted to these heat flux gages (ASTM E2683-09, 2009).

18.3.2.1 Insert Gages Using Thin-Film Thermocouple Sensors A differential thermopile as illustrated in Figure 18.4 can be deposited directly onto a substrate to give design and manufacturing flexibility. Such a thin-film device has been described in detail by Diller and Onishi (1988) and was first produced by Hager et al. (1991, 1993) using sputtering techniques. Microfabrication methods are used to deposit hundreds of thermocouple pairs around a silicon monoxide layer to create the differential thermopile.

FIGURE 18.6 Heat flux microsensor pattern (Holmberg and Diller, 1995).

Either photolithography or stencil masks can be used to define the patterns. The resulting physical and thermal disruption of the surface due to the presence of the sensor is extremely small.

While the original version of this heat flux microsensor (HFM) placed the temperature sensors almost directly over top of each other across a single thermal resistance layer as illustrated in Figure 18.4, it is not a requirement. The bottom temperature sensors simply need to be at a uniform temperature and the top temperature sensors need to be at a temperature dictated by the heat flux perpendicular to the surface. This can be accomplished on a high conductivity substrate (aluminum nitride) by separate thermal resistance pads ($1\text{ }\mu\text{m}$ layer of silicon monoxide) underneath the top thermocouples. The pattern is illustrated in Figure 18.6 (Holmberg and Diller, 1995). The bottom temperature sensors can then be placed directly on the substrate with or without thermal resistance pads on top. Leads are taken down the side and attached to wires on the side or behind the sensor substrate. The substrate is then press fit into a high conductivity metal housing with an outside diameter of about 6 mm. A thin-film RTD or thermocouple is also deposited on the surface for independent temperature measurement of the sensor surface. The applicable range for heat flux measurement is from 1 kW/m^2 to 10 MW/m^2 . Because the sensor is so thin, the thermal response time is less than $10\text{ }\mu\text{s}$ (Holmberg and Diller, 1995), giving a good frequency response well above 10 kHz .

18.3.2.2 Insert Wire-Wound Gages The Schmidt–Boelter version of the wire wound gage is illustrated in Figure 18.7. The thermal resistance layer (wafer) is usually made of a high thermal conductivity material, for example anodized aluminum ($\sim 0.5\text{ mm}$ thick). The nonconductive coating is necessary to provide electrical insulation with the bare wire of the thermopile. The wire is usually constantan with copper plating on one side of the wires top and bottom. This forms a type of differential thermopile, but the segmented plating on the wire gives an output less than for a true thermopile (Kidd and Nelson, 1995). The entire wafer is placed in contact with a heat sink and surrounded by potting material to give a smooth surface to the top of the gage.

Schmidt–Boelter gages are manufactured by Medtherm Corp. in a range of sizes down to 1.5 mm diameter. They are designed to measure moderate to high heat fluxes

FIGURE 18.7 Schematic of an insert wire-wound heat flux gage.

(10–1000 kW/m²). One advantage of the Schmidt–Boelter gage is that it can be contoured to a curved surface. One of the drawbacks is that one-dimensional heat transfer is not really maintained. Two-dimensional effects can be significant and the potting material affects the gage sensitivity. The transient response is typically 25–50 ms, but is usually not first-order. Techniques for improving and correcting the time-response are presented by Kidd and Adams (2001) for making time-resolved measurements. A Schmidt–Boelter design having a first-order response has been patented (Hevey and Langley, 2001).

An alternative design was produced by Long et al. (2004) by winding constantan wire onto an annular disc of Macor. Copper plating of the outer radius of the wire produced a circular thermopile for use in turbomachinery research. Epoxy resin was used to cover the wires and appeared to substantially increase the thermal resistance of the gage.

18.3.2.3 Circular Foil Gage (Gardon) The circular foil gage was originated by Robert Gardon (1953) and consequently is often called a Gardon gage. A sketch of the circular foil gage is shown in Figure 18.8. Constantan is usually used for the disk material and is attached to a hollow copper body. A copper wire is attached to the center of the foil to

FIGURE 18.8 Schematic of a circular foil gage.

create a differential thermocouple between the center and edge of the disk. Unlike the previous gages discussed, however, the heat transfer in the gage is not in the direction that it enters the surface. The thermal energy is collected by the disk and transported laterally to the heat sink connected to the edge of the disk. The recorded temperature difference is, therefore, a function of the total heat transfer to the disk, but also is a function of the distribution of heat flux over the disk surface (Diller, 1993; Kuo and Kulkarni, 1991; Liechty et al., 2007; Agnone, 2009).

The usual application for Gardon gages is radiation to a water-cooled gage. Because there is negligible radiation from the gage, the heat flux is uniform and the temperature distribution across the foil is parabolic

$$T - T_w = \frac{q''}{4k\delta}(R^2 - r^2) \quad (18.12)$$

where R is the foil outer radius, r is the radial coordinate, and T_w is the temperature of the wall, which is assumed equal to the temperature at the outer edge of the foil. When convection is present, however, the convective heat transfer is proportional to the difference in temperature between the fluid and the gage. Because of the temperature distribution radially across the gage, the heat flux is no longer uniform. For the same total heat transfer, therefore, the gage will give less output than for radiation. If the convection heat transfer coefficient is uniform over the gage, the analytical correction of the heat flux for convection is approximately (Borell and Diller, 1987)

$$\frac{q''_{\text{corrected}}}{q''_{\text{uncorrected}}} = \frac{1}{1 - \frac{3S_q h}{4S_T}} \quad (18.13)$$

where S_q is the sensitivity of the gage as calibrated by radiation, h is the convection heat transfer coefficient, and S_T is the thermoelectric constant for the thermocouple pair. The correction is proportional to the gage sensitivity and the heat transfer coefficient. Consequently, the sensitivity of the gage should be kept low to limit the size of the correction and associated uncertainties. A general rule for specifying copper constantan gages is

$$\frac{q''_{\text{convection}}}{q''_{\text{fullscale}}} \leq \frac{T_{\text{fluid}} - T_w}{3200^\circ\text{C}} \quad (18.14)$$

where the full-scale heat flux is that corresponding to an output of 10 mV. The measurement error becomes even larger if the heat transfer coefficient is nonuniform over the gage surface, as can occur in strong shear flows. In addition, the surface temperature disruption caused by the presence of a circular foil gage affects the local thermal boundary layer and changes the local heat transfer coefficient, as discussed in Section 18.2.3.

These corrections are all based on the assumption that the gage makes perfect contact with the wall. Because the gage is normally slip fit into place, there may be an additional temperature drop between the heat sink of the gage and the wall. This would cause an additional drop in gage output and would require an additional correction of the results.

Most Gardon gages are made with a water cooling jacket as part of the sensor to keep it from overheating when in high heat flux environments. Water cooling should never be used when convection is being measured. The problem is that this causes a local

“cold spot” and results in an erroneously high heat flux measurement, the opposite of the foil temperature disruption effect just discussed.

Circular foil gages are manufactured and sold by Medtherm Corp. and Vatell Corp. Most are used for radiation measurements and are water cooled. The ASTM standard (ASTME511-07, 2009) for these gages provides a good summary of the best practice for their use.

18.3.3 Radiometers

With the proper surface coating any heat flux gage can be used to measure radiation, although specialized radiometers have been developed to increase the accuracy of radiation heat flux measurements (Murthy et al., 2003). One example is the Kendall radiometer (Kendall and Berdahl, 1970), which is a blackbody cavity with a thermopile and an installed electric heater. This allows the electric power measurement to serve as the standard to provide a self-calibrated device for total irradiance. Consequently, these instruments can be used as the primary standard for heat flux calibration of other gages. Several models are available from Medtherm Corp.

To eliminate the effects of convection a transparent window or lens can be placed over the end of a heat flux gage to transmit only the desired radiation transfer. The reduced angular view of the gage with a window must be included in the calibration, along with the transmissivity of the window. Without a window the effects of natural convection are particularly a problem at low heat flux levels (less than 15 kW/m^2) (Robertson and Ohlemiller, 1995). An additional problem in dirty environments is deposits on the window that reduce the transmissivity. One solution is to blow air past the window. A different approach without a window is the transpiration radiometer which blows air through a porous plug which composes the exposed surface of the gage. This not only blows off the fluid boundary layer with any contaminants, but the air is heated as it passes through the plug. The measured radiation is then related to the temperature change of the air as it passes through the plug (Martins et al., 2000, 2006).

Brajuskovic et al. (1991) have developed a slightly different version to operate in boilers. Instead of going through the plug, the air is directed through slots around a solid plug. The air-flow keeps particles from reaching the heat flux element and it takes away the thermal energy. The path of the heat transfer is radial through the plug, however, as in a circular foil gage. The heat flux is proportional to the temperature difference between the center and edge of the plug.

18.4 GAGES BASED ON TEMPERATURE CHANGE WITH TIME

The time–temperature history of a material can be used to infer the corresponding heat flux. This involves solving the conduction heat transfer problem of the temperature gage and the adjoining material. Because the solution starts with the measured temperature as a function of time and calculates backward to find the needed heat flux boundary condition, it is in the form of an inverse heat transfer problem.

18.4.1 Thin-Film Methods

Transient thin-film gages are designed to measure the surface temperature of a semi-infinite material (substrate) in response to the applied surface heat flux. The requisite

transient conduction solutions for the one-dimensional semi-infinite model are given in numerous references. The starting point (Schultz and Jones, 1973) is the solution of the one-dimensional heat diffusion equation for a step change in surface temperature from a uniform initial temperature

$$q'' = \frac{\sqrt{k\rho C}}{\sqrt{\pi t}}(T_w - T_0) \quad (18.15)$$

The material properties of the substrate enter as the square root of the product of $k\rho C$ (thermal conductivity, density, and specific heat). A number of data reduction schemes have been developed based on variations of this solution to determine the heat flux from the surface temperature history, represented by measured temperatures at specified times. One common method is given by

$$q''(t_n) = \frac{2\sqrt{k\rho C}}{\sqrt{\pi}} \sum_{i=1}^n \frac{T_i - T_{i-1}}{\sqrt{t_n - t_i} + \sqrt{t_n - t_{i-1}}} \quad (18.16)$$

The summation for the heat flux at each given time is based on the current and all previous temperatures. One limitation of this equation is that constant thermal properties have been assumed for the substrate. A more serious problem, however, is the inherent instability of using a temperature record to infer the heat flux. This is akin to taking the derivative of the temperature signal, which greatly amplifies any noise present in the signal and is particularly important when making detailed measurements of time-resolved heat flux. To increase sensitivity and solution stability a variety of inverse heat conduction techniques have been developed (Walker and Scott, 1998; Oldfield, 2008).

The advancement of thin-film deposition techniques has made the fabrication of large numbers of resistance elements for temperature measurement on the surface of models much simpler. All that is required is the application of a thin temperature measuring layer (usually an RTD) on the model with appropriate lead connections. The most popular methods have been to apply a thin layer of platinum paint or to directly sputter onto an electrically insulated substrate. With a typical thickness of $0.1 \mu\text{m}$ the response of the RTD's is of the order of $0.01 \mu\text{s}$. This causes negligible effect on the heat flux measurements for times greater than a few microseconds. Therefore, results that are properly processed are essentially instantaneous even for high-speed flows. There is a limit on the length of the useful test data, however, due to the semi-infinite substrate assumption used in the modeling. The upper time limit for a 1% error in the heat flux at the surface is

$$t = 0.3 \frac{\delta^2}{\alpha} \quad (18.17)$$

For a typical insulating substrate (MACOR) of $\delta = 1 \text{ mm}$ thickness the corresponding maximum time is nearly 400 ms. This makes the technique useful for many types of short-duration flows, such as shock tubes or high-speed blow-down facilities.

To measure the resistance of the RTD to determine the transient temperature history a small current is used to drive a bridge circuit. The constant current source must be large enough to provide a measurable output voltage, but small enough to keep the self-heating effects negligible. This optimization is made easier if the sensor resistance is a high value.

For a resistance of at least 100 ohms, a current of 1–2 mA provides good results. One of the advantages of vacuum deposited resistance films is that the value of resistance is easier to control during fabrication.

Calibration of the sensors for heat flux measurements requires two steps. First, the resistance versus temperature relationship must be determined for each sensor. This can simply be done by putting the model in an oven and monitoring the resistance of each gage over a set temperature range. The second part of the calibration is to determine the thermal properties of the substrate. The most popular method is to measure the response of the sensor to a pulse of energy provided by an electrical discharge through the resistance film or a pulsed radiation source to the surface. It is important to measure the value of $k\rho C$ for each model because properties can vary significantly for many of the substrate materials between batches.

A group at Oxford has developed a technique to apply the thin-film gages to metal substrates using a vitreous enamel coating to provide electrical insulation (Doorly and Oldfield, 1986). Although this gives much greater flexibility for experimental application of the method, it also complicates the data analysis. One method is to use an analog circuit plus digital processing of the signals, including filters and a frequency boosting circuit (Ainsworth et al., 1989). The calibration is also more complicated because of the multiple layers making up the substrate. A further refinement has been to place multiple RTD's on a single polyimide sheet which is then glued to the metal surface (Guo et al., 1998).

Another group has developed round Pyrex inserts that are placed in metal surfaces for measuring time-resolved heat flux in short duration turbine research test facilities. The data reduction includes both analog circuits and digital data processing, including Fourier transforms to optimize the frequency response and accuracy of the time-resolved results (Dunn et al., 1986). Concern over the thermal disruption caused by the Pyrex inserts was investigated and reported to be insignificant for the short 20–25 ms test times of the experiments (Dunn et al., 1997). Moffat et al. (2000) have investigated the more general case of longer times when the temperature rise of the insert becomes substantially more than the surrounding metal material.

18.4.2 Transient Optical Methods

A number of optical methods have been developed to measure the transient surface temperature for determination of heat flux. These include liquid crystals, infrared radiation measurement, temperature-sensitive paints and thermographic phosphors. The advantage is that cameras can be used to give full coverage of the surface, although the results are usually limited to steady-state convection. The usual method involves a flow facility where either the model is injected into the flow at a different temperature or the flow is suddenly initiated with the model at a different initial temperature.

Infrared cameras offer the most potential measurement capability. Once the surface emissivity is calibrated, the data processing is relatively easy (Ekkad et al., 2004). High speed versions are currently available that allow time-dependent measurements of heat flux from the transient temperature signals (Ahn et al., 2010). Proper surface coatings should be used. Viewing angles are important along with reflections from other surfaces.

Thermographic phosphors emit radiation in the visible spectrum when illuminated with ultraviolet light, which can be related to temperature at specific wavelengths (Khalid and Kontis, 2008). Their main advantage is that they offer the possibility to operate in

elevated temperature environments (Bizzak and Chyu, 1995). A CCD camera is required to record the optical images and the data processing and calibration are challenging (Walker, 2005).

The temperature-sensitive paint method uses a Europium complex as the luminophore with a mercury–xenon arc lamp for illumination (Kurits and Lewis, 2009). A CCD camera is used to collect the images as a function of time. Because the paint layer has a low thermal conductivity, a two-layer model to relate the measured surface temperature to the heat flux is usually required.

Liquid crystals are chiral-nematic molecules that reversibly change color as a function of temperature. They are limited to a temperature range of about 25–40°C and are available commercially from Hallcrest in a convenient micro-encapsulated form. A hue capturing technique is used with a temperature calibration to reduce the data to temperatures as a function of time (Ireland and Jones, 2000). The liquid crystal method is used almost exclusively with convection testing in air to obtain the distribution of heat transfer coefficients as defined in Equation (18.3) (Wagner et al., 2005; Das et al., 2005). Multiple step changes of the air temperature can even be used to obtain additional information, such as adiabatic wall temperatures (Talib et al., 2004).

18.4.3 Coaxial Thermocouple

Coaxial thermocouples are rugged sensors designed to be insert through a material to measure the surface temperature of the model wall as a function of time, the same as thin-film gages. Consequently, the same equations can be used to determine the corresponding heat flux. The physical concept is simple (Kidd, 1990), as illustrated in Figure 18.9. One thermocouple material forms the center wire, which is surrounded by an electrical insulator. The second thermocouple material forms a sheath around these two layers. The final assembly is often then drawn down to a smaller diameter. A second insulating material is sometimes placed around the assembly to isolate the thermocouple electrically from a metal substrate. The completed unit is press fit into the model. The actual thermocouple junction is formed at the very end by plating a thin layer of one of the materials, vacuum deposition, or by simply lightly sanding to mix the two materials together and bridge the thin insulating layer. Because the thickness of the top junction layer can be on the order of 10 μm , the initial response time can be much less than 1 ms. Smith et al. (2002) include a

FIGURE 18.9 Schematic of a coaxial thermocouple.

FIGURE 18.10 Null-point calorimeter schematic.

second thermocouple with the use of a parameter estimation method to reduce the temperature data to heat flux.

The most important parameter in specifying the coaxial thermocouple gages is to match the material thermal properties with those of the wall. As seen from Equation (18.16), the property of importance is the product $k\rho C$, which for the coaxial thermocouple is taken as the average of all the layers. Usually this can be matched quite well by judicious choice of the thermocouple pair and the thickness ratios.

18.4.4 Null-Point Calorimeter

In very high heat flux environments gages that measure surface temperature cannot physically survive for long. One solution is to make the gage body from high conductivity copper and move the thermocouple back away from the surface, as illustrated in Figure 18.10. The goal of the design is to produce the same temperature history at the null point (thermocouple location) as would occur on the surface of a semi-infinite slab of the model if the gage were not present. Consequently, the gage is called a null-point calorimeter. The proper placement of the thermocouple relative to the surface and the size and depth of the hole in the gage behind it are based on analytical modeling. An ASTM Standard (ASTM E598-08, 2009) gives the design details and guidelines on its proper use. The typical value for the useful measurement time for a copper body is between 1 and 300 ms. The usual thermocouple pair is chromel/alumel. Its attachment to the gage is one of the major fabrication difficulties. To accomplish a test within the recommended test time, the model is often swept through the flow. This also minimizes the time that the model and gages are exposed in high heat flux environments and extends their useful life. Because the null-point temperature on the back of the gage is designed to match the undisturbed wall temperature, the front side of the gage is necessarily hotter. Although this creates a “hot spot” effect, these gages are often used at the stagnation point of models where the effect is small (Kidd, 1992).

18.4.5 Slug Calorimeter

A calorimeter is a device used for measuring the quantity of absorbed thermal energy as a function of time. In all of the other sensors in this section the temperature distribution as a function of time is used for a specific solid shape and size. A slug calorimeter uses one

temperature measurement on the back surface to represent the entire mass of the slug, which is assumed to change temperature at a uniform rate. If a control volume is taken around the slug, application of energy conservation yields

$$q = mC \frac{dT}{dt} + q_{\text{losses}} \quad (18.18)$$

where q is the heat transfer at the gage surface and mC is the thermal mass of the slug. The losses are minimized by insulating all of the surfaces other than the front surface. If the losses can be neglected and the heat flux is constant with time, the gage temperature increases linearly with time.

$$T = T_0 + \frac{q''A}{mC} t \quad (18.19)$$

The result is a straight line on a temperature versus time plot, with the slope of the line giving the desired heat flux. The ASTM Standard (ASTM E547-08, 2009) also recommends calculating the slope for the cooling process after the heat source is removed as an indication of the losses during heating. To neglect losses, the rate of cooling should be less than 5% of the rate of heating. A method for accounting for losses, however, has been demonstrated (Hightower and Olivares, 2008), which allows for accurate measurements when larger losses are present.

There are several inherent problems in using slug calorimeters. Because the thermocouple is mounted on the back of the slug, the temperature measurement is not the average temperature of the slug. The material of the gage should be the same as the wall to minimize nonuniform temperature effects. The heat losses are usually hard to control in models with high heat flux conditions. Although slug calorimeters are rarely used currently, they can provide an important standard in the calibration process.

18.4.6 Differential Flame Thermometer

The differential flame thermometer (Keltner et al., 2010) consists of two inconel plates separated by a layer of insulation with a thermocouple mounted on each plate. The plates are 120 mm square and the insulation is 19 mm thick. The resulting time constant for the system is about 90 s. The application is in a radiation dominated furnace or combustor to measure the heat flux and steady-state temperature. Inverse heat transfer methods are used to convert the two temperature records into heat flux. It should be noted that this device is different from a standard heat flux gage because it is suspended in the furnace or environment and does not have a heat sink.

18.5 GAGES BASED ON ACTIVE HEATING METHODS

Because electric power dissipation can be easily and accurately measured, it is attractive to incorporate electric resistance heating into the measurement of heat transfer. At steady-state conditions the electric power supplied to the system must equal the heat transfer from the surface plus the heat losses. One drawback is that the transfer is always *from* the surface. Consequently, this method is most useful in well-controlled laboratory

experiments. Because of the time constraints and power limitations, it is not used in high heat flux or high temperature situations. This eliminates most high-speed flows. In addition, it is difficult to maintain truly steady-state conditions. Because the thermal capacitance of the surface material is usually large, very small time rates of temperature change may cause large errors in the measured heat transfer and it may take a long time to achieve steady-state conditions under which the temperature is no longer changing.

The techniques used can be grouped according to the two boundary conditions that normally result, constant heat flux, and constant wall temperature. In constant heat flux cases the experiment usually runs until a steady-state temperature distribution is achieved. For constant wall temperature manual or active control of the power is required to stabilize the system at the prescribed constant temperature.

18.5.1 Constant Heat Flux

Measurements of convective heat transfer coefficients with electrically heated constant heat flux surfaces have been done for many years. The most common method is to use a heater with uniform resistance, insulate the back surface, and minimize lateral conduction by the design. A thin metal sheet is often used as the heater to provide uniformity of resistance (and heat flux) and to minimize the lateral conduction. Several centimeters of good insulation as the backing material usually insures acceptable heat loss from the back surface. Unfortunately, the response time for this arrangement is typically very long, depending on the surface convection and substrate properties. With a surface heat transfer coefficient of $100 \text{ W/m}^2 \text{ K}$ and a good substrate insulator the time from a cold start to reach steady-state conditions (within 2%) is typically over 1 h. The time limitation is the result of transient heat transfer into the insulation backing layer.

Surface temperature measurements are not needed to determine the heat flux, but they are required to quantify the conditions under which the heat flux occurs. Temperature is particularly necessary for the determination of the heat transfer coefficient. Although any of the methods for measuring temperature are possible candidates, only thermocouples, resistance temperature devices, infrared cameras, and liquid crystals are commonly used. Their use is discussed in that order.

When thermocouples are used to measure the surface temperature their attachment and layout is important because of the potential problems caused by heat transfer through the wires. Because the wires have a much larger thermal conductivity than the insulation, the measured temperature can be significantly lowered. Running the wires parallel to the surface for a distance and using small diameter wire can minimize the effect.

If the temperature is measured with an RTD, it may also be used for supplying the electrical power. A thin-film resistance element sputtered onto quartz was used by Samant et al. (1984) for boiling studies of refrigerant 113. Because the surface of the heated film was only 0.25 mm by 2.0 mm, significant heat was transferred laterally through the quartz substrate, giving the heater a larger effective surface area by an estimated 12–15%. Normally the edge effect is much larger, but the high heat fluxes in boiling kept it to a minimum.

Infra-red optical techniques have been used extensively with large heater foils to measure the temperature distributions on constant heat flux surfaces to infer the convective heat transfer coefficients (Buchlin, 2010). Images are taken with an infrared camera, which is calibrated for the surface emissivity using surface thermocouples (Colban et al., 2006).

Praisner and Smith (2006) used liquid crystals to record the instantaneous heat transfer distributions for water flow over a surface. A stainless steel foil was painted black and heated electrically. The liquid crystals were applied to the underside of the test plate where the temperature distributions were read with a thermal imaging system. The frequency response of the system for determining the surface heat transfer coefficients was greater than 100 Hz. Heating can also be supplied by an infrared source on the opposite side from the liquid crystals (Ochoa et al., 2005).

18.5.2 Constant Surface Temperature

The design and operation of constant surface temperature experiments are substantially different than those for constant heat flux. Instead of measuring the temperature that results from an imposed heat flux, the electrical power is measured that is required to maintain a set temperature. This typically requires a control system to maintain the temperature constant spatially and/or temporally, depending if steady or unsteady measurements are desired. Although electric resistance heating is almost exclusively used, providing heat transfer *from* the surface, a device capable of providing a measured heat transfer in either direction has been constructed using Peltier devices (Shewen et al., 1989).

Many time-averaged measurements of spatial distributions of convection heat transfer have been made using segmented plates and heaters. If the plates are made of a thick, high-conductivity material, the surface will be nearly isothermal, even if the heat transfer coefficient has large spatial variations. Some thermal isolation is required between segments, often provided by insulation strips. Usually the individual heaters are adjusted manually to achieve a uniform temperature, although a good set of PID automatic temperature controllers can speed the stabilization process by an order of magnitude. On-off type controllers are generally not adequate to maintain a steady-state condition.

Figure 18.11 illustrates the typical geometry for segmented plate heaters. The measured heat flux occurs from the top surface of the plates that have a thickness of d . The bottom side of the plate is well insulated. The heat loss from the edges usually causes the major errors. The two modes of heat loss (VandenBerghe and Diller, 1989) are shown as q'_1 , the loss per unit width through the insulation by convection from the insulation surface, and q'_2 , the loss per unit width by conduction through the insulation to the adjoining plates. The reason for having the insulation is to thermally isolate the plates to allow

FIGURE 18.11 Segmented-plate constant wall temperature system.

individual heat transfer measurements from each. The potential error represented by q'_2 arises from conduction between the plates when the temperatures are not perfectly matched. It was demonstrated that the one-dimensional conduction solution

$$q'_2 = \Delta T \frac{kd}{w} \quad (18.20)$$

is almost always sufficient to represent this measurement uncertainty. The thermal conductivity of the insulation is k , the thickness of the insulation is w , and the temperature offset between any two plates is represented by ΔT . As expected, the conduction error decreases as the insulation width w increases. Conversely, the correction for the convection loss q'_1 increases with increasing w , and the centerline temperature of the insulation is further depressed below the wall temperature of the plates. The optimal design is where these competing effects are minimized.

Most experiments are designed with an insulation thickness much larger than needed for negligible conduction effects. The convection loss through the insulation and temperature disruption of the surface over the insulation, therefore, are much larger than necessary. In addition, there is a limit to how small the errors can be made for heater plates of any given size. As the measurement plate becomes smaller, the area of the edges increases relative to the surface area of the plate. Consequently, the errors become larger relative to the measured heat transfer as the plate area decreases, which limits the theoretical resolution of the method. Furthermore, if guard plates are not used on all edges, the measurement accuracy is even more limited. Only if the measurement plate is large and the heat transfer coefficient high is the relative convection loss through the insulation on the sides small.

One of the most detailed descriptions of the use of the segmented constant temperature plate method is the review of the turbulent boundary layer experiments at Stanford by Moffat and Kays (1984). The method was used in a well-regulated wind tunnel and continually refined for over 25 years. To achieve the quoted accuracy of $\pm 2\%$ required meticulous detail to experimental procedure and refinement of the data reduction programs. The latter is a lengthy process to eliminate any small errors and to build up an experience base to include all of the small corrections needed.

Small gages for local heat flux measurements have been produced to actively match the surrounding wall temperatures while measuring power dissipated at the surface. Kraabel et al. (1980) used a cone-shaped copper plug to minimize the gap at the surface while still minimizing the thermal interaction with the housing. A differential thermocouple was used to control the power input to a thermistor heater. The design concept is illustrated in Figure 18.12. The experimental uncertainty for steady-state measurements was given as 2%. It should be noted that this low uncertainty is only possible with the very small gap at the surface, cone shape for the sensor and differential thermocouple for the control. Such experiments, however, are more time consuming to perform.

Measurement of time-resolved heat flux requires active control of the power. Thin-film gages deposited on a low conductivity substrate are used to minimize the system time response. A thin-film resistance element can serve as both the heater and temperature measurement device. There are three important issues that must be addressed for accurate time-resolved heat flux measurements. The first is that the thin film gage temperature must be uniform over the entire gage and match the temperature of the surrounding surface. Temperature controllers usually have a small temperature droop. To match the

FIGURE 18.12 Heated gage concept.

temperature increases the instability of the system, which requires careful tuning of the system. The third problem is the consequent attenuation of the frequency response because of the thermal capacitance of the substrate material, even if it is a good thermal insulator. Higher frequencies may still be seen in the signal, but the amplitude is much smaller than the actual value. A good test of the system is to use a chopped heat input over a range of frequencies from high to a simple on–off. The measured magnitude should be the same independent of the frequency.

To overcome these problems and experimentally observe the temperature of the heater film Campbell et al. (1989) embedded a thermocouple made with $76\text{ }\mu\text{m}$ wire at the surface of the substrate underneath the sensor film. The low conductivity substrate of the sensor was mounted flush with the surrounding aluminum surface. The heated thin film covered the entire surface of the substrate and was actively powered with a modified hot-wire bridge. To match the sensor and surrounding surface temperatures a second matched thermocouple was embedded in the surrounding surface to form a differential thermocouple. A slow response differential controller was used to match the temperatures by driving the differential to zero. Consequently, the hot wire bridge controlled the power to the sensor during fast surface heat flux transients and the second controller matched temperatures over long times by adjusting the power to the surrounding material. This system was capable of maintaining the temperature match within $\pm 0.1^\circ\text{C}$. The compensation tuning of the bridge had to be adjusted very close to the instability point for proper response and no measurable temperature change of the surface. The resulting heat flux uncertainty was estimated to be $\pm 5\%$.

Dinu et al. (1998) performed a numerical solution of the transient response of their actively heated thin film. There are three components to these probes: the heated thin film, the substrate on which it is deposited, and a protective coating layer overtop. The sensor was assumed to be mounted into an isothermal plate, which defined all of the boundary conditions except the surface. The results of their model clearly indicated the importance of precise control over the sensor temperature. With only a 0.5°C higher temperature the heat flux was 20% higher. Even larger errors were seen in the amplitude of a sinusoidal heat flux.

Lee et al. (2001) created an array of actively heated gages consisting of 96 individual thin-film elements, each $270\text{ }\mu\text{m}$ by $270\text{ }\mu\text{m}$. The entire assembly is only 2.7 mm on

a side. It was used for measuring time-dependent boiling events. Because of the very high heat flux associated with boiling, the losses are relatively small and the controller stability is not as crucial as the gages used in air convection.

18.6 CALIBRATION AND ERRORS

There are two basic approaches to calibration of heat flux sensors. The first is to use a system that provides a comparison with a primary standard. The second uses another heat flux sensor as a secondary standard for the comparison. If the gage operating temperature will be outside the normal room temperature range, the sensitivity should be measured over the range of gage temperatures for the intended use because it may be temperature dependent. In addition, the mode of heat transfer can be important to the heat flux sensor response. Therefore, identification and separation of convection from radiation is an issue to address. Errors can be separated into the measurement uncertainty and the bias error of the calibration.

18.6.1 Heat Flux Gage Calibration

There are three methods for absolute radiation calibration of heat flux sensors as illustrated in the facilities at NIST (Murthy et al., 2000). They are all designed for water-cooled sensors that are kept at room temperature for the calibration. One uses an electrical substitution radiometer as the primary standard (Murthy et al., 2001) in a narrow-angle facility. The second is a spherical cavity which uses the temperature of the wall as the standard along with the Stefan–Boltzmann law for the blackbody radiation to the sensor (ISO/DIS 14934, 2009).

$$q''_{\text{inc}} = \sigma T^4 \quad (18.21)$$

The heat flux sensor should be located at the bottom of the sphere or the sphere should be in a vacuum to minimize the effects of convection. The third method is insertion into a graphite tube blackbody cavity with a pyrometer on the opposite side of the center partition for the primary standard. This method has been tested both experimentally and analytically (Abdelmessih and Horn, 2010; Murthy et al., 2004, 2006). It also has some convection effects and is dependent on the sensor placement in the cavity and time response of the temperature controller of the blackbody during its insertion.

The narrow-angle facility has minimal convection effects because the sensor is located outside of the blackbody high-temperature source. However, because of the narrow-angle radiation beam that heats the sensor, the maximum heat flux is relatively low (50 kW/m²) and it has shorter wavelength (higher required source temperature) than the other methods. In addition, most coatings have some angular dependence of the absorptivity (Alpert et al., 2003). The result is a small, but consistent difference in calibration results between the narrow-angle and wide-angle facilities (Murthy et al. 2006).

For all three cases the resulting calibration for the gage sensitivity S_{rad} is based on the incident radiation to the gage surface, q''_{inc} .

$$S_{\text{rad}} = \frac{E}{q''_{\text{inc}}} \quad (18.22)$$

The emissivity of the surface ε is required to calculate the absorbed radiation.

$$q''_{\text{abs}} = \varepsilon q''_{\text{inc}} \quad (18.23)$$

The gage surface is assumed to be gray with the absorptivity equal to the emissivity, ε , and both values constant with angle and wavelength for the conditions of use. The gages are kept at room temperature, using water cooling if necessary. This minimizes any emission from the gage surface, which is neglected.

Once the secondary standard gage has been calibrated against a primary standard, it is used to calibrate other gages by comparison under the same incident heat flux. One method is with simultaneous measurements on either side of an electrically heated flat plate. The other common method is using sequential substitution under a quartz lamp bank. In all cases the size and range of the two gages should be matched to minimize the differences in the radiation experienced.

If the gages are to be used at elevated temperatures, the calibrations are more difficult. First, the gage will experience substantial convection. Second, the emitted energy from the gage will become important. These require corrections and raise the uncertainty of the calibration. Pullins and Diller (2010) have minimized these problems by designing an enclosure that mounts the gage to be calibrated on the hot surface and the secondary standard in a water-cooled cold plate. Convection is minimized by putting the cold plate horizontal and beneath the hot plate. Because the enclosure is insulated, essentially all of the energy from the hot plate necessarily goes to the cold plate, as measured by the secondary standard. Corrections are needed only for the small non-uniformities of temperature of the hot and cold surfaces.

Convection calibrations are more difficult, but have been done to heat flux levels of about 5 kW/m^2 using electrical power measurement as the standard (Borell and Diller, 1987; Holmberg and Womeldorf, 1999). The gage sensitivity is based on the convective heat flux, q''_{conv} , provided by a wind tunnel (Holmberg and Womeldorf, 1999) or a large stagnating air jet (Borell and Diller, 1987)

$$S_{\text{conv}} = \frac{E}{q''_{\text{conv}}} \quad (18.24)$$

The standard is the electrical power input into a constant temperature plate with guard heaters on all sides and operating at steady-state conditions, as discussed in Section 18.5.2. The resulting sensitivity corresponds to the absorbed radiation. Consequently, the usual incident radiation calibration must be adjusted to correspond to the convection sensitivity by the emissivity of the original surface coating.

$$S_{\text{conv}} = \frac{S_{\text{inc}}}{\varepsilon} \quad (18.25)$$

Conduction calibrations are time consuming for the thin flat gages because of the time required to reach steady-state conditions. Guarded hot plate calibration systems are commercially available and can be traced to standards at NIST. An ASTM standard covers the calibration method (ASTM C1130-07, 2009).

$$S_{\text{cond}} = \frac{E}{q''_{\text{cond}}} \quad (18.26)$$

18.6.2 Error Estimates

Heat flux gage calibrations usually are repeatable to within 2–3%. The bias error introduced into the measurement uncertainty will be larger depending on how close the measurement conditions are to the calibration conditions. The precision uncertainty is usually dominated by the voltage measurement uncertainty. This can be minimized by properly specifying the heat flux range of the gage and using quality amplifiers and/or data-acquisition units. For radiation the coating properties may contribute a substantial uncertainty. Taken together the combined uncertainty for heat flux gage measurements that are performed carefully is often between 5% and 10% (Murthy et al., 2005).

19.1 INTRODUCTION

In many industrial applications, such as the transport of oil and natural gas in pipelines and wellbores, the knowledge of nonboiling two-phase, two-component (liquid and permanent gas), heat transfer is required. During the transport of two-phase hydrocarbon fluids from an oil reservoir to the surface, temperature of the hydrocarbon fluids changes due to the difference in temperatures of the oil reservoir and the surface. The difference in temperature results in heat transfer between the hydrocarbon fluids and the Earth surrounding the oil well. In such situation, the ability to estimate the flowing temperature profile is necessary to address several design problems in petroleum production engineering (Shiu and Beggs, 1980).

In subsea oil and natural gas production, hydrocarbon fluids may exit the reservoir with a temperature of 75°C and flow in subsea surroundings of 4°C (Trevisan et al., 2006). As a result of the temperature difference between the reservoir and the surroundings, the knowledge of heat transfer is critical in order to prevent gas hydrate and wax deposition blockages (Furuholt, 1988). Wax deposition can cause severe problems including the reduction of inner pipe diameter causing blockage, increase in surface roughness of the pipe leading to restricted flow line pressure, decrease in production, and various other mechanical problems (McClaflin and Whitfill, 1984). Here are a couple of examples of the economical losses that were caused by wax deposition blockages: (1) a direct cost of \$5 million in removing the blockage from a subsea pipeline, and (2) the cost of an oil platform abandonment by Lasmo Company (UK) that amounted to \$100 million (Singh et al., 2000).

Schemes such as coil-spring wire insert, twisted tape insert, and helical ribs have been used to promote turbulence in pipes for the purpose of enhancing heat transfer. Although such heat transfer enhancement schemes have been proven to be effective, they do come with drawbacks, such as fouling, increases in pressure drop, and even blockage. Celata et al. (1999) presented an approach to enhance heat transfer in pipe flow by injecting small amount of gas into the liquid flow to promote turbulence. In the experimental study performed by Celata et al. (1999), a uniformly heated vertical pipe was internally cooled by water, while heat transfer coefficients with and without air injection were measured. The introduction of a small airflow rate into the water flow resulted in increases of the heat transfer coefficient up to 20–40% for forced-convection, and even larger heat transfer enhancement for mixed-convection (Celata et al., 1999).

Furthermore, since the mechanisms of heat and mass transfers are analogous to one another, the knowledge of two-phase heat transfer can be applicable to two-phase mass transfer. In order to successfully apply the knowledge of two-phase heat transfer to solve mass transfer problems, the appropriate parallels between the two mechanisms have to be first sorted out. Mass transfer in two-phase flow can be found in many chemical processes. One conceivable application is predicting the rate of corrosion in pipes that transport two-phase flow. In cases when chemical reactions between the pipe surface and the two-phase fluids are heavily influenced by mass transfer, the ability to predict the mass transfer coefficient becomes very beneficial to engineers.

In the endeavor to understand and characterize nonboiling two-phase flow heat transfer in pipes, systematic experimental measurements of heat transfer data are necessary. The contents within this article present the experimental setup used for conducting measurements of heat transfer in two-phase flow. In addition, the experimental procedures to properly measure heat transfer data, as well as the functionality of the experimental setup are discussed. Finally, the measured heat transfer results and their characteristics are presented.

19.2 EXPERIMENTAL SETUP FOR HORIZONTAL AND SLIGHTLY INCLINED PIPES

The experimental setup for slightly inclined pipe orientations was constructed with the capability of using it to measure nonboiling two-phase pressure drop and heat transfer, and conduct flow visualization for all major flow patterns and upward inclination angles from 0° (horizontal) to 7°. A schematic diagram of the flow loop for the current

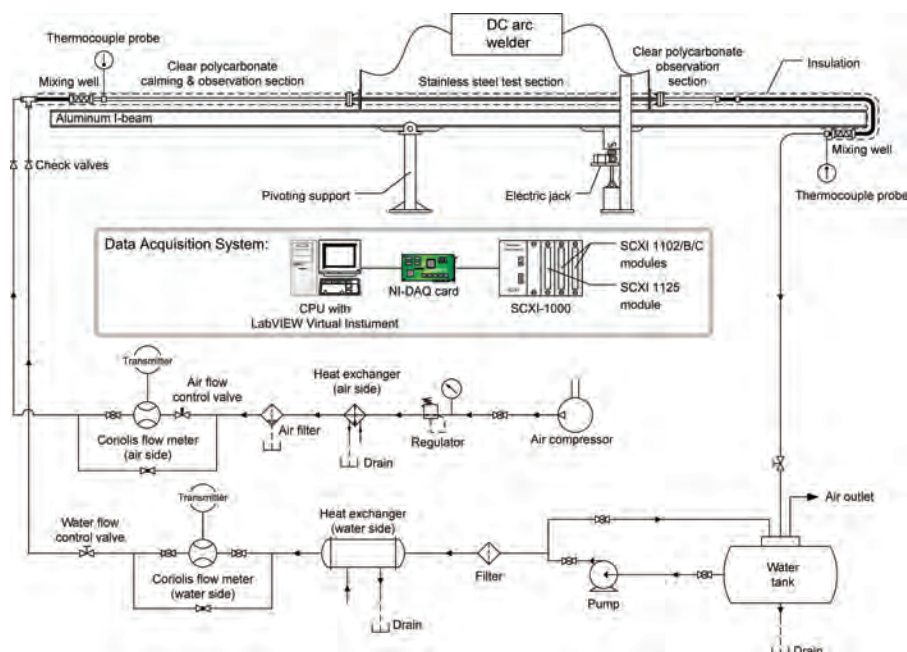

FIGURE 19.1 Flow loop of the experimental setup.

experimental setup is illustrated in Figure 19.1. The mixing section, the calming and observation section, and the stainless steel test section rest on top of an aluminum I-beam. The aluminum I-beam is supported by a pivoting mechanism that is attached to an electric jack. The I-beam is approximately 9.1 m long and the pivoting mechanism could bring the I-beam to an upward inclination of approximately 8° . Inclination angles were measured with a contractor's angle-measuring tool and with a more precise digital x - y axis accelerometer. The minimum resolution of the digital accelerometer is 0.5° .

The working fluids used in this study were air and distilled water. The reservoir used for storing the distilled water is a 208-L (55 gal) polyethylene tank. A Bell & Gossett (Series 1535) coupled centrifugal pump (size 3545 D10) is used to pump the distilled water from the reservoir through an Aqua-Pure AP12T water filter and an ITT Standard (Model BCF 4063) one shell and two-tube pass heat exchanger. The heat exchanger is used to remove heat added to the distilled water during the experiment as well as to maintain a constant inlet liquid temperature. The cooling fluid used by the heat exchanger is tap water taken directly from the wall tap.

From the heat exchanger, the distilled water flowed through a Micro Motion (Model CMF125) Coriolis flow meter. The Coriolis flow meter is connected to a Digital Field-Mount (Model RFT9739) transmitter that conditions the flow information for the data acquisition system. After passing the Coriolis flow meter, the distilled water then passes through a gate valve. The gate valve is used for regulating the amount of distilled water that is flowing into the mixing section. From the gate valve, the distilled water flows through a 25.4 mm I.D. hose, and then through a one-way check valve and into the air-water mixing section.

FIGURE 19.2 Schematic of gas–liquid mixing section.

Air is supplied from an Ingersoll-Rand T30 (Model 2545) air compressor. The air supplied from the air compressor is regulated by a Speedaire (Model 4ZM22) 12.7 mm regulator. The air is then cooled by passing through a copper coil submerged in a vessel of water from the wall tap. The same water from the wall tap that is used for cooling the distilled water is also used for cooling the air. This is to ensure that both air and distilled water have the same inlet temperature. The air is then filtered by a Speedaire (Model 4ZL49) 12.7 mm air filter to remove moisture from the air before the airflow rate is being measured.

From the air filter, the air flows through a Micro Motion (Model CMF100) Coriolis flow meter that is connected to another Digital Field-Mount (Model RFT9739) transmitter. After passing the Coriolis flow meter, the air then passes through a needle valve, which is used to regulate the amount of air flowing into the mixing section. From the needle valve, the air flows through a flexible hose, and then through a one-way check valve and into the air–water mixing section.

The air–water mixing section is attached upstream of the calming and observation section. A schematic of the air–water mixing section is illustrated in Figure 19.2. Similar type of mixing section has been successfully used in two-phase flow experimental studies by Ewing et al. (1999) and Kim (2000). Air and distilled water are converged in a 25.4 mm copper tee and are further mixed in the mixing well. After the mixing well, the temperature of the air–water two-phase flow is measured by an Omega TMQSS-125U-6 thermal probe. Exiting the mixing well, the air–water two-phase flow enters into the calming and observation section.

The 2.24 m long calming and observation section is made of clear polycarbonate pipe with an inner diameter of 25.4 mm. This gives the calming and observation section a length to diameter ratio (L/D) of 88. Air–water two-phase flow leaving the mixing section is allowed to calm and develop through the calming and observation section before entering the test section. The calming and observation section also serves as the section where flow pattern visualization is conducted. Two-phase flow exiting the calming and observation section enters the heat transfer test section.

The heat transfer test section is made of a schedule 10S 316 stainless steel pipe with an inner diameter of 27.9 mm and an outer diameter of 33.4 mm. The heat transfer test section is 2.64 m long, giving a length to diameter ratio (L/D) of about 95. A schematic of the heat transfer test section is illustrated in Figure 19.3. To measure the surface temperatures

FIGURE 19.3 Schematic of heat transfer test section.

of the heat transfer section, 10 thermocouple stations, equally spaced with 25.4-cm interval, are placed along the test section. Each thermocouple station has four thermocouples attached circumferentially around the pipe surface. Figure 19.3 shows the circumferential locations of the thermocouples, with “A” at the top of the pipe, “B” at 90° from the top in the clockwise direction, “C” at the bottom of the pipe, and “D” at 90° from the bottom in the clockwise direction.

The thermocouples attached on the heat transfer section are Omega TT-T-30 copper-constantan insulated T-type thermocouples. Omega EXPP-T-20-TWSH extension wires are used for connecting the thermocouples to the data acquisition system. The thermocouples are cemented on the outside surface of the stainless steel test section with Omegabond 101 epoxy. The Omegabond 101 epoxy has a thermal conductivity of 1.04 W/mK and an electrical resistivity of $1 \times 10^{15} \Omega\text{m}$.

Two 12.7 cm \times 17.8 cm \times 0.64 cm copper plates are attached to one of each end of the stainless steel heat transfer test section. The two copper plates are attached to the ends of the test section by means of silver-soldering. Both copper plates are connected with 4 gauge insulated cables to a direct current arc welder, which provides power to heat the test section with uniform heat flux.

Uniform wall heat flux is supplied to the heat transfer test section by running high amperage direct current through the stainless steel test section from a direct current arc welder. For two-phase flow with superficial liquid Reynolds number above 2,000, the test section is heated by a LINCOLNWELD SA-750 arc welder. The minimum current supplied by the LINCOLNWELD SA-750 arc welder is 300 A, which is too high for flow with superficial liquid Reynolds number, $Re_{SL} < 2,000$, and may cause dry-out and local boiling. To avoid dry-out and local boiling, a Miller Maxtron 450 DC inverter arc welder is used to supply direct current through the stainless steel test section for flow with Re_{SL}

$< 2,000$. Using both arc welders provide a wide range of uniform wall heat flux, which makes measurement of heat transfer for two-phase flow at different gas and liquid flow rates possible, thus covering most major flow patterns.

Along the bottom of the heat transfer test section, there are 11 pressure taps equally spaced at 25.4-cm interval. The pressure tap holes, each with diameter of 1.73 mm, were drilled along the bottom of the test section (see Figure 19.3). The pressure taps are connected to standard self-tapping saddle valves with the tapping core removed. The system pressure is measured by Omega PX242-060G absolute pressure transducers, whereas the pressure drop is measured by a Validyne DP15 differential pressure transducer.

19.3 INSTRUMENTS FOR MEASUREMENT AND DATA ACQUISITION

The airflow rate is measured by Micro Motion (Model CMF100) Coriolis flow meter, and the water flow rate is measured by Micro Motion (Model CMF125) Coriolis flow meter. Both Coriolis flow meters are connected to Digital Field-Mount (Model RFT9739) transmitters. The signals from the Digital Field-Mount transmitters are relayed to the data acquisition system for data recording.

Surface temperatures of the test section are measured with Omega TT-T-30 T-type thermocouples cemented on the test section using Omegabond 101. Air–water mixture temperatures at the inlet and outlet of the heat transfer test section are measured with Omega TMQSS-125U-6 thermocouple probes. Signals from the thermocouples and the thermocouple probes are relayed to the data acquisition system for data recording. Isothermal measurements are conducted periodically, to ensure the accuracy and precision of the thermocouples and thermocouple probes.

Pressure drop between the first and the last pressure taps is measured using Validyne DP15 differential pressure transducer. The Validyne DP15 differential pressure transducer is connected to a Validyne CD15 carrier demodulator. Output signals from the differential pressure transducer are sent to the carrier demodulator to be demodulated, amplified, and filtered. Signals from the demodulator are then relayed to the data acquisition system for data recording.

The voltage drop across the heated test section is measured by a HP 3468B digital multimeter. The current flowing through the test section is determined by measuring the voltage drop across a shunt attached to the copper plate at the downstream of the test section. Knowing the voltage drop and the resistance across the shunt, the current flowing through the test section can be determined. The voltage drop across the shunt is recorded by the data acquisition system, and the corresponding current is determined. Knowing the voltage drop across the test section and the current through the test section, the heat flux on the test section can be determined.

A National Instruments data acquisition system is used for recording and storing the data measured during the experiment. An AC powered four-slot National Instruments SCXI 1000 Chassis houses the data acquisition system. The chassis provides a low noise environment for signal conditioning. There are three National Instruments SCXI control modules housed inside the chassis: two SCXI 1102/B/C modules and one SCXI 1125 module.

Input signals from 40 thermocouples, 2 thermocouple probes, volt and current meters, and flow meters are gathered by the 3 modules and sent to a computer to be recorded. A graphical user interface used for the data acquisition is a customized LabVIEW Virtual Instrument (VI) program developed specifically for this experimental setup. Figure 19.4

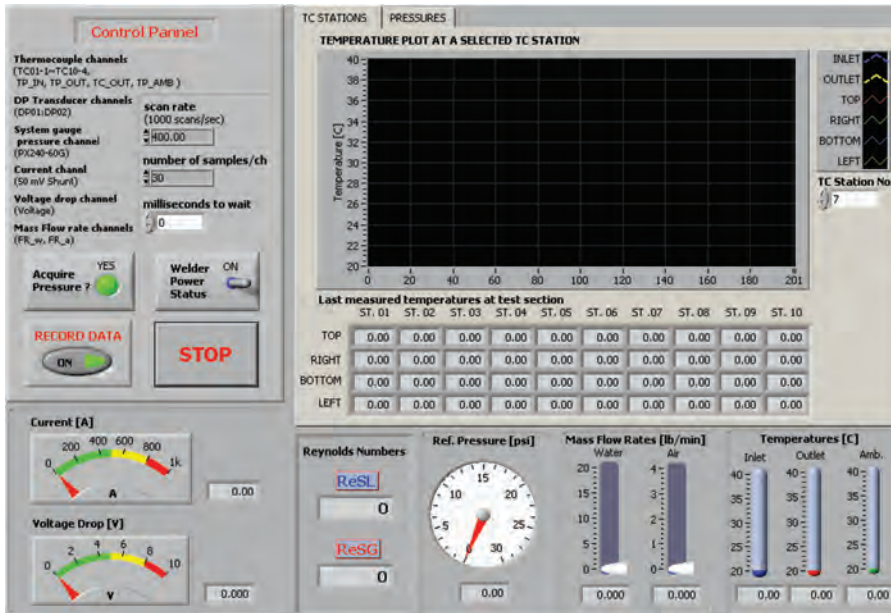

FIGURE 19.4 Graphical user interface of the LabVIEW VI program.

illustrates the graphical user interface of the LabVIEW VI program used for the data acquisition.

The LabVIEW VI graphical user interface provides users with the features to monitor and record data. Data such as inlet, outlet, surrounding, test section surface temperatures, pressure drop, system pressure, air and water mass flow rates, superficial gas and liquid Reynolds numbers, and current supplied by the DC arc welder to the test section are displayed on the graphical user interface. With these features on the graphical user interface, users can monitor the recorded data and readily identify any anomaly during the course of an experiment.

19.4 HEAT TRANSFER EXPERIMENT PROCEDURES

The process of acquiring accurate experimental data requires a consistent adherence to a set of defined experimental procedures. The purpose of adhering to the experimental procedures is to maintain the integrity and repeatability of the experimental data, and proper functioning of the equipments and experimental setup. The experimental procedures are categorized into start-up procedure and measurement procedure. The start-up procedure lists several steps to initiate the experimental setup and prepare it for conducting the measurements. The measurement procedure lists several steps to acquire quality and accurate experimental data.

The start-up procedure is a process that includes several steps to prepare the experimental setup for measurements. The main function of this start-up procedure is to ensure that the experimental setup is operating properly and safely before the process of acquiring experimental data.

The first step in the start-up procedure is turning on all electrical instruments: Digital Field-Mount RFT9739 transmitters for both Coriolis flow meters, Validyne CD15 carrier demodulator for the differential pressure transducer, and the National Instruments data acquisition system. Once the data acquisition system is turned on, the LabVIEW VI program is launched and readings of all the thermocouples are monitored to ensure they are the same with the surrounding temperature. This process of checking the thermocouples' readings with the surrounding temperature provides an initial and quick indication whether the thermocouples are working properly.

The second step in the start-up procedure is checking the Speedaire air filter and the Aqua-Pure water filter. This process of checking the air and water filters is to ensure their functionality, and to maintain periodic replacement of the old filters. Old, dirty, and worn filters not only are unable to function properly but also reduce the flow capabilities of the fluids to the test section.

The third step in the start-up procedure is turning on the tap water, which served as cooling fluid for the copper coil in the air line and the ITT Standard one shell and two-tube pass heat exchanger in the water line. The tap water cooled the air and distilled water flowing into the test section such that both air and distilled water have the same inlet temperature.

The fourth step in the start-up procedure is turning on the Ingersoll-Rand T30 air compressor and the Bell & Gosset centrifugal pump. With the air compressor and centrifugal pump turned on, air and water are supplied to the test section. The final step in the start-up procedure is checking for leakage in the flow loop, and verifying the test section inclination angle. Having completed the steps in the start-up procedure, the experimental setup is ready for the measurement procedure.

The measurement procedure is a process that includes several steps to successfully acquire experimental data. The purpose of the measurement procedure is to ensure the integrity and repeatability of the experimental data, while maintaining the functionality of the experimental setup. Figure 19.5 is a flow chart illustrating the individual steps of the measurement procedure.

Before beginning the measurement procedure, the welder cables connecting the DC arc welder with the copper plates attached to the stainless steel test section is properly checked. This is a precautionary step to ensure all connections are safe and ready for the experiment. Poor condition of cables and improper connections between the DC arc welder and the test section could result in short circuit, which could potentially cause equipment damage, over-heating, or fire hazard.

The first step in the measurement procedure is adjusting the air and water flow rates. The flow of air is regulated by a needle valve, whereas the water is regulated by a gate valve. Using the Digital Field-Mount transmitters, for the Coriolis flow meters, to monitor the air and water flow rates, the needle and gate valves are adjusted until the desired air and water flow rates are achieved.

Once the desired air and water flow rates are set, the second step in the measurement procedure is to turn on the DC arc welder. With the DC arc welder turned on, the current is adjusted to the desired amperage to be supplied to the stainless steel test section. By running DC current through the stainless steel pipe, heat flux is supplied to the test section.

The third step in the measurement procedure is to allow flow to achieve steady state condition. The flow is considered to have achieved steady state condition when each of the two thermocouple probes, which measure the inlet and outlet bulk temperatures, is indicating less than 0.5°C fluctuation for 5 min. The inlet and outlet bulk temperatures

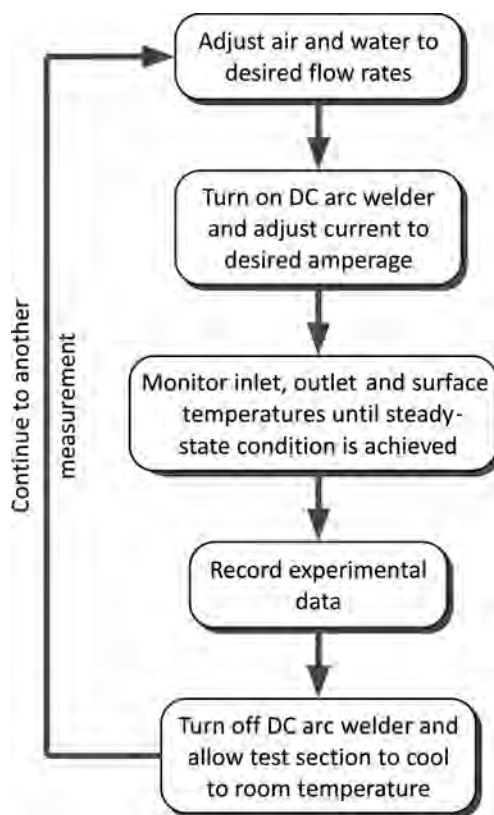

FIGURE 19.5 Measurement procedure for two-phase heat transfer experiments.

are monitored using the graphical user interface of the LabVIEW VI program illustrated in Figure 19.4. The thermocouples measuring the outer surface temperatures of the pipe are carefully monitored to avoid the temperature from rising beyond 60°C . This is to keep the flow strictly nonboiling and avoid the possibility of local boiling.

Once the steady state is achieved, the process of acquiring experimental data can begin, which is the fourth step in the measurement procedure. Experimental data collected are air and water mass flow rates, inlet and outlet bulk temperatures, surface temperatures of the test section, pressure drop, and uniform heat flux supplied to the test section through the current from the DC arc welder. The typical number of samples collected for each measurement run is 1000. When the experimental data are recorded, the following step in the measurement procedure is to turn off the DC arc welder and allow the test section to cool to room temperature. Once the test section is cooled to room temperature, another measurement run can begin.

For a uniform wall heat flux condition, the experiment involved the measurements of outside pipe wall surface temperatures at discrete locations (see Figure 19.3), as well as the inlet and outlet bulk temperatures. The circumferential heat transfer coefficient was calculated based on the knowledge of the heat flux and surface temperature at the inside wall of the pipe. Due to the difficulty of measuring the inside wall temperatures, they are instead calculated from the measured outside wall temperatures and the heat generation

within the pipe wall. The data reduction program developed by Ghajar and Kim (2006) was used for calculating the circumferential heat transfer coefficients and the inside wall temperatures from the outside wall temperatures measured at discrete locations along the uniformly heated pipe.

19.5 VERIFYING THE FUNCTIONALITY OF THE EXPERIMENTAL SETUP

The objective of conducting frictional pressure drop and heat transfer measurements for single-phase flow is to verify the functionality and reliability of the experimental setup. In this section, results of single-phase liquid flow frictional pressure drop and heat transfer measurements conducted with the experimental setup are discussed. The single-phase frictional pressure drop and heat transfer results discussed in this section is focused on horizontal pipe orientation.

19.5.1 Frictional Pressure Drop in Single-Phase Flow

The single-phase frictional pressure drop measurements were conducted using distilled water at the Reynolds number range from approximately 4,000 to 50,000. The measured frictional pressure drop was converted to Fanning friction factor using the following equation

$$c_f = \frac{2\tau_0}{\rho U^2} = \frac{\rho \pi^2 D^5}{32 \dot{m}^2} \frac{\Delta p}{L} \quad (19.1)$$

The single-phase friction factor (c_f) obtained experimentally is compared with the friction factor calculated from correlations available in the literature. Three different friction factor correlations are used in this comparison with the measured results. The first friction factor correlation is the well-cited correlation by Blasius (1913):

$$c_f = 0.079 Re^{-0.25} \quad 4,000 < Re < 10^5 \quad (19.2)$$

The second correlation used for comparison with the measured friction factor is the correlation by Petukhov (1970):

$$c_f = \frac{1}{4} (0.790 \ln Re - 1.64)^{-2} \quad 3,000 < Re < 5 \times 10^6 \quad (19.3)$$

The third friction factor correlation is proposed by Haaland (1983):

$$\frac{1}{2c_f^{1/2}} \approx -1.8 \log \left[\frac{6.9}{Re} + \left(\frac{\varepsilon/D}{3.7} \right)^{1.11} \right] \quad (19.4)$$

In using the friction factor correlation by Haaland (1983), the value for stainless steel pipe wall roughness height of 2 μm is used.

Among the three friction factor correlations selected for comparing with the measured friction factor, two of them are for turbulent flow in smooth pipe: Blasius (1913) correlation, Equation (19.2), and Petukhov (1970) correlation, Equation (19.3). The correlation

FIGURE 19.6 Comparison of measured single-phase friction factor data with correlations available in the literature.

proposed by Haaland (1983), Equation (19.4), takes into consideration the effect of wall roughness. The estimation by Haaland (1983) correlation varies by less than 2% from the Colebrook (1939) correlation (White, 1999).

The results of the comparison between the measured friction factor and the calculated friction factor are illustrated in Figure 19.6. The absolute mean deviation of the measured data from the calculated results using the Blasius (1913) correlation, Equation (19.2), is 4.7%, while the root mean square deviation is 5.5%. The comparison of the measured friction factor with the calculation using the Petukhov (1970) correlation, Equation (19.3), is shown in Figure 19.6. The measured data deviate from the calculated results using the Petukhov (1970) correlation with an absolute mean deviation and root mean square deviation of 3.8 and 4.3%, respectively. Using the Haaland (1983) correlation, Equation (19.4), to compare with the measured friction factor, the comparison also shows very satisfactory agreement. The absolute mean deviation of the measured data from the calculated results using the Haaland (1983) correlation is 4.1%, while the root mean square deviation is 4.8%. Figure 19.6 shows that most of the measured data points are well within $\pm 10\%$ agreement with the three correlations.

The satisfactory comparison of the measured friction factors with the three different friction factor correlations available in the literature verified the functionality of the experimental setup for pressure drop measurements. The highest uncertainty estimated for the measured friction factor is $\pm 4.3\%$. The uncertainties are estimated using the propagation of the uncertainty method described by Kline and McClintock (1953).

19.5.2 Heat Transfer in Single-Phase Flow

The single-phase heat transfer measurements were conducted using distilled water at the Reynolds number range from approximately 3,000 to 50,000. The single-phase heat

transfer coefficient obtained experimentally is compared with the heat transfer coefficient calculated from correlations available in the literature. Three different heat transfer correlations are used in this comparison with the measured results. The first heat transfer correlation is the Sieder and Tate (1936) correlation:

$$Nu = 0.027 Re^{4/5} Pr^{1/3} \left(\frac{\mu_b}{\mu_w} \right)^{0.14} \quad \begin{array}{l} 0.7 \leq Pr \leq 16,700 \\ Re > 10,000 \\ L/D > 10 \end{array} \quad (19.5)$$

The second correlation is the Gnielinski (1976) correlation:

$$Nu = \frac{(c_f/2)(Re - 1000)Pr}{1 + 12.7(c_f/2)^{1/2}(Pr^{2/3} - 1)} \quad \begin{array}{l} 0.5 < Pr < 2,000 \\ 3,000 < Re < 5 \times 10^6 \end{array} \quad (19.6)$$

The Fanning friction factor (c_f) in Equation (19.6) is calculated by the Petukhov (1970) correlation, Equation (19.3). The third heat transfer correlation is the Ghajar and Tam (1994) correlation:

$$Nu = 0.023 Re^{0.8} Pr^{0.385} \left(\frac{L}{D} \right)^{-0.0054} \left(\frac{\mu_b}{\mu_w} \right)^{0.14} \quad \begin{array}{l} 4 < Pr < 34 \\ 7,000 < Re < 49,000 \\ 1.1 < \mu_b/\mu_w < 1.7 \\ 3 < L/D < 192 \end{array} \quad (19.7)$$

The results of the comparison between the measured heat transfer data and the calculated heat transfer results are illustrated in Figure 19.7. When compared with the Sieder and

FIGURE 19.7 Comparison of measured single-phase heat transfer data with correlations available in the literature.

Tate (1936) correlation, Equation (19.5), the absolute mean deviation of the measured data from the calculated results using the correlation is 7.9%, while the root mean square deviation is 9.3%. Using the Gnielinski (1976) correlation, Equation (19.6), to compare with the measured heat transfer data, the comparison also shows very satisfactory agreement. The measured data deviate from the calculated results using the Gnielinski (1976) correlation with an absolute mean deviation and root mean square deviation of 6.5 and 6.9%, respectively. The comparison of the measured heat transfer data with the calculation using the Ghajar and Tam (1994) correlation, Equation (19.7), is shown in Figure 19.7. When compared with the Ghajar and Tam (1994) correlation, Equation (19.7), the absolute mean deviation of the measured data from the calculated results using the correlation is 6.8%, while the root mean square deviation is 8.3%. Most of the measured data points are well within $\pm 15\%$ agreement, when compared with the three heat transfer correlations, see Figure 19.7.

Among the three heat transfer correlations, the measured data agree best with the Gnielinski (1976) correlation, whereas the agreement with the Sieder and Tate (1936) and the Ghajar and Tam (1994) correlations is very satisfactory as well. Thus, verified the functionality of the experimental setup for heat transfer measurements. The highest uncertainty estimated for the measured heat transfer is $\pm 8.7\%$. The uncertainties are estimated using the propagation of the uncertainty method described by Kline and McClintock (1953).

19.6 EXPERIMENTAL RESULTS OF TWO-PHASE FLOW

19.6.1 Flow Patterns and Flow Maps

The different interpretations given to the various flow patterns by different investigators are subjected to the investigators' observations. So far, no uniform procedure exists for describing and classifying flow patterns. For the present study, the identification of flow pattern was based on the procedures suggested by Taitel and Dukler (1976), as well as Kim and Ghajar (2002). All observations of the flow pattern were conducted at the clear polycarbonate observation sections, located at the upstream and downstream of the heat transfer test section (see Figure 19.1). By systematically coordinating the flow rates of air and water, the flow patterns were observed. Flow pattern data were obtained at isothermal condition with the pipe at horizontal position and at 2° , 5° , and 7° inclined positions. Representative digital images of each flow pattern were taken using a Nikon D50 digital camera with Nikkor 50 mm f/1.8D lens. The flow map with the representative photographs of the various flow patterns for horizontal flow is shown in Figure 19.8. The various flow patterns for horizontal flow, depicted in Figure 19.8, show the capability of the current experimental setup to cover a multitude of flow patterns. The shaded lines represent the boundaries of the observed flow patterns.

The flow pattern transition boundaries for horizontal flow were found to be quite different from the flow pattern transition boundaries for inclined flow when slight inclinations of 2° , 5° , and 7° were introduced (see Figure 19.9). The changes in the flow pattern transition boundaries from horizontal to slightly inclined flow are the transition boundaries for stratified flow and slug/wavy flow. When the pipe was inclined from horizontal to slight inclination angles of 2° , 5° , and 7° , the stratified flow region was replaced by slug flow and slug/wavy flow for $Re_{SG} < 4,000$ and $4,000 < Re_{SG} < 10,000$, respectively.

Flow pattern boundaries for plug-to-slug transition and slug-to-slug/bubbly transition were observed to be shifted slightly to the upper left direction as inclination angles were

FIGURE 19.8 Flow map for horizontal pipe with photographs of representative flow patterns.

slightly increased from horizontal to 7° . For slightly inclined flow of 2° , 5° , and 7° , there were no drastic changes in the flow pattern transition boundaries. However, it should be mentioned that although the flow patterns were named the same for both horizontal and inclined flows; it does not mean that the flow patterns in the inclined positions have identical characteristics of the comparable flow patterns in the horizontal position. For

FIGURE 19.9 Change of flow pattern transition boundaries as pipe inclined upward from horizontal orientation.

example, it was observed that the slug flow patterns in the inclined positions of 5° and 7° have reverse flow between slugs due to the gravitational force, which can have a significant effect on the heat transfer.

The flow pattern maps for horizontal and 2° upward inclined pipe were verified with flow patterns data from Barnea et al. (1980). The comparison between the flow patterns data from Barnea et al. (1980) and the flow pattern maps for horizontal and 2° upward inclined flow showed very satisfactory agreement, especially among the distinctive major flow patterns such as annular, slug, and stratified (Ghajar and Tang, 2010). In a recent article, Vaze and Banerjee (2011) showed that their flow pattern data for horizontal pipe are in good agreement with the flow pattern map showed in Figure 19.8. A total of 203 flow pattern data points out of 225, observed by Vaze and Banerjee (2011), are found in the exact flow pattern regions illustrated in Figure 19.8.

19.6.2 Heat Transfer in Horizontal and Slightly Upward Inclined Pipe Flows

In this section, an overview of the different trends that have been observed in the heat transfer behavior of the two-phase air–water flow in horizontal and inclined pipes for various flow patterns is presented. Once the flow maps of the flow patterns for horizontal and inclined flows were established, the heat transfer data for different flow patterns were then collected. The nonboiling two-phase heat transfer data were obtained by systematically varying the air and water flow rates and the pipe inclination angle. Table 19.1 summarizes the two-phase heat transfer data measured for horizontal, 2° , 5° , and 7° inclined flows.

Flow pattern as well as flow rates of gas and liquid has significant influence on the two-phase heat transfer coefficient. Figure 19.10 provides an overview of the pronounced influence of the flow pattern, superficial liquid Reynolds number (water flow rate) and superficial gas Reynolds number (airflow rate) on the two-phase heat transfer coefficient in horizontal and inclined pipe flow. The results presented in Figure 19.10 clearly show that two-phase heat transfer coefficient ($h_{TP,exp}$) is strongly influenced by the superficial liquid Reynolds number (Re_{SL}) for horizontal and inclined flows.

In addition, at a constant superficial liquid Reynolds number, the two-phase heat transfer coefficient is influenced by the superficial gas Reynolds number (Re_{SG}), and each flow pattern shows its own distinguished heat transfer trend for horizontal and slightly inclined flow. Typically, heat transfer increases at low superficial gas Reynolds number (the regime of plug flow), and then slightly decreases at the mid range of Re_{SG} (the regime of slug and slug-type transitional flows), and increases again at the high Re_{SG} (the regime of annular flow).

TABLE 19.1 Summary of Experimental Conditions and Measured Two-Phase Heat Transfer Data for Horizontal and Slightly Upward Inclined Pipe

	Pipe Orientation			
	Horizontal	2° Inclined	5° Inclined	7° Inclined
No. of data points	180	184	184	187
Re_{SL} range	700–26,000	700–26,000	700–26,000	700–26,000
Re_{SG} range	700–48,000	700–48,000	700–48,000	700–48,000
Heat flux range (W/m^2)	1,860–10,800	2,820–10,800	2,900–10,800	2,600–10,900
$h_{TP,exp}$ range (W/m^2K)	101–5,457	242–5,140	286–5,507	364–5,701

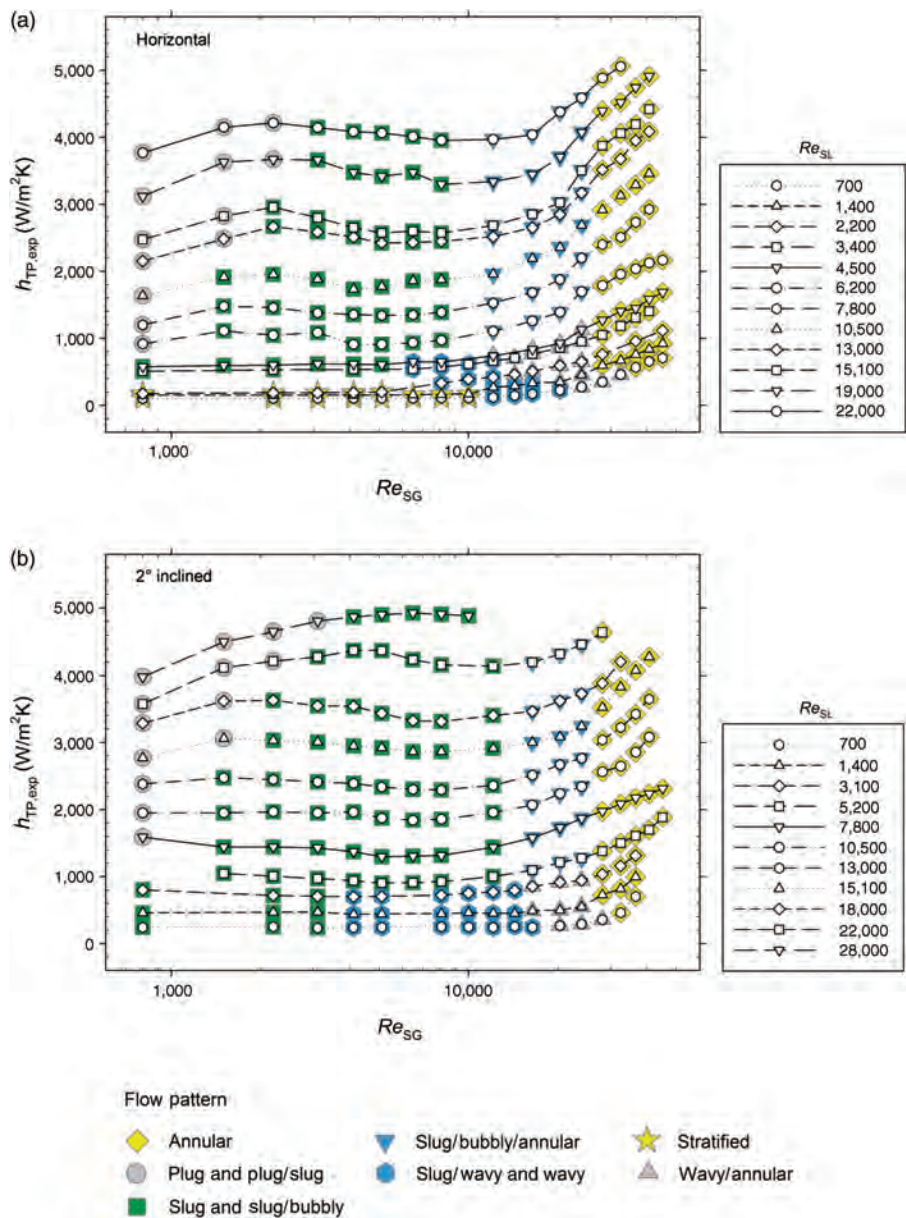

FIGURE 19.10 Variation of two-phase heat transfer coefficient with superficial gas and liquid Reynolds numbers.

Heat transfer in two-phase flow is also influenced by the orientation of the pipe. Heat transfer coefficients measured for slightly upward inclined flow showed some enhancement when compared with data measured for horizontal flow. In order to observe the behavior of heat transfer due to pipe inclination, it is necessary to categorize the experimental heat transfer data into comparable superficial gas and liquid Reynolds numbers.

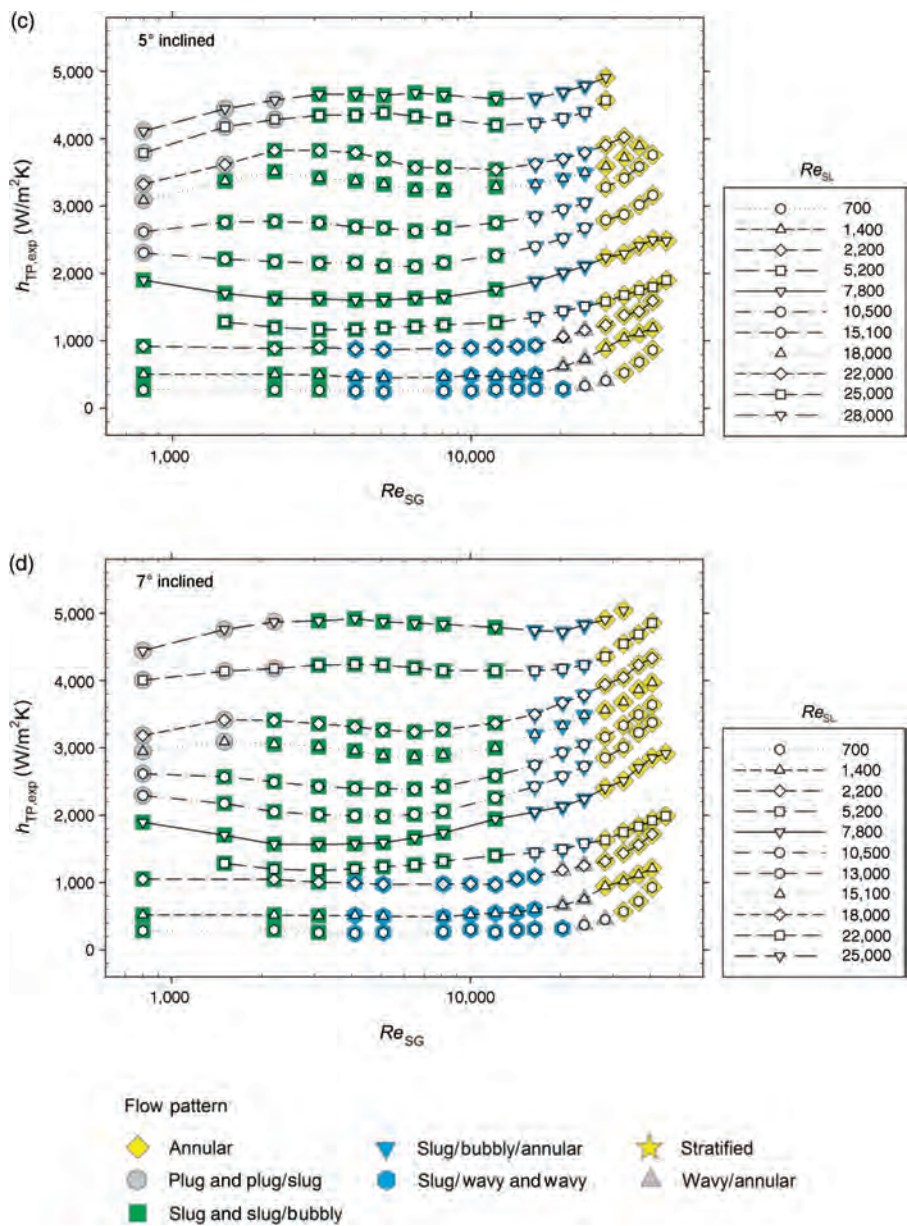

FIGURE 19.10 (Continued)

Figure 19.11 illustrates the influence of pipe inclination on two-phase heat transfer coefficient for varying superficial gas and liquid Reynolds numbers. In Figure 19.11, the ratios of two-phase heat transfer coefficient for inclined pipe to two-phase heat transfer coefficient for horizontal pipe ($h_{TP,\theta}/h_{TP,0}$) versus the superficial liquid Reynolds numbers (Re_{SL}) for various superficial gas Reynolds numbers (Re_{SG}) are plotted.

For low superficial liquid Reynolds number ($Re_{SL} = 1,400$), pipe inclination has a significant influence on the two-phase heat transfer coefficient. In the region of $Re_{SL} < 2,500$

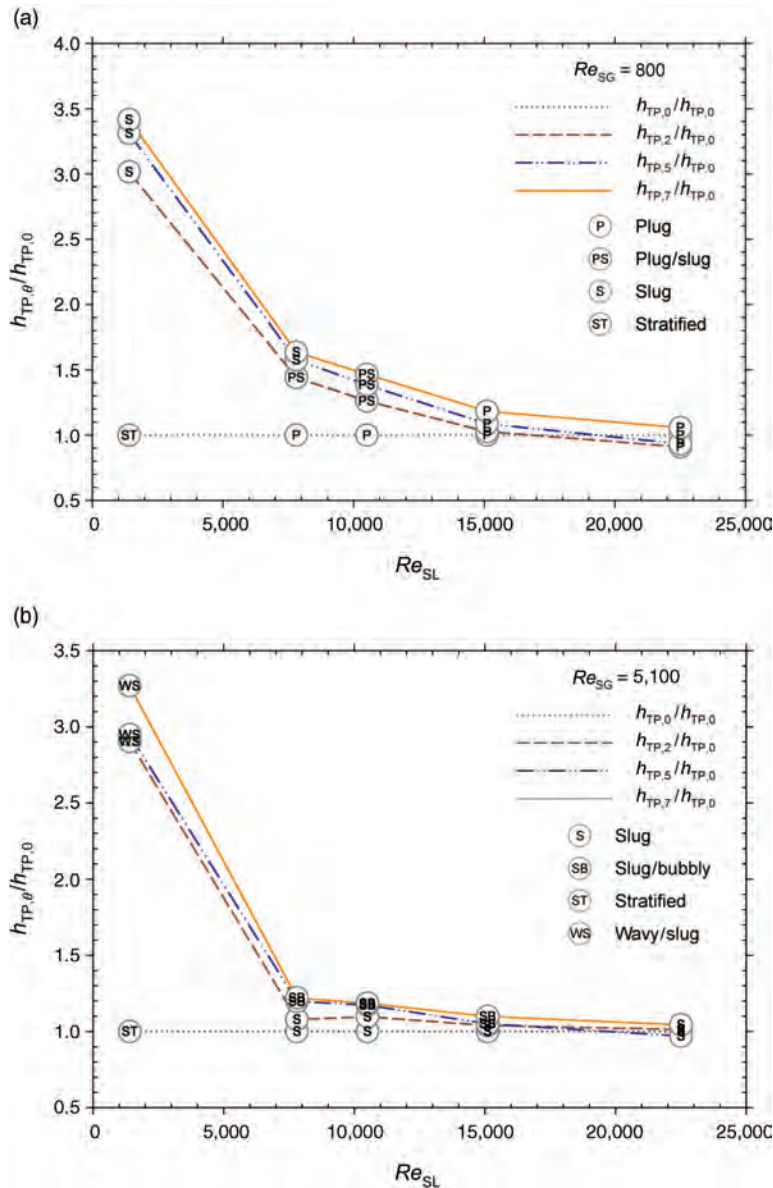

FIGURE 19.11 Influence of pipe inclination on two-phase heat transfer coefficient for varying superficial gas and liquid Reynolds numbers.

and $Re_{SG} < 10,000$, pipe inclined from horizontal position to 2° , 5° , and 7° can experience as much as 250% enhancement in two-phase heat transfer coefficient. The main reason that can be attributed to this enhancement in heat transfer coefficient is the change in flow pattern from stratified for horizontal flow to slug or wavy/slug for inclined flow.

For instance, at the respective superficial gas and liquid Reynolds numbers of 800 and 1,400, inclination of pipe from horizontal to 2° , 5° , and 7° resulted in enhancements of

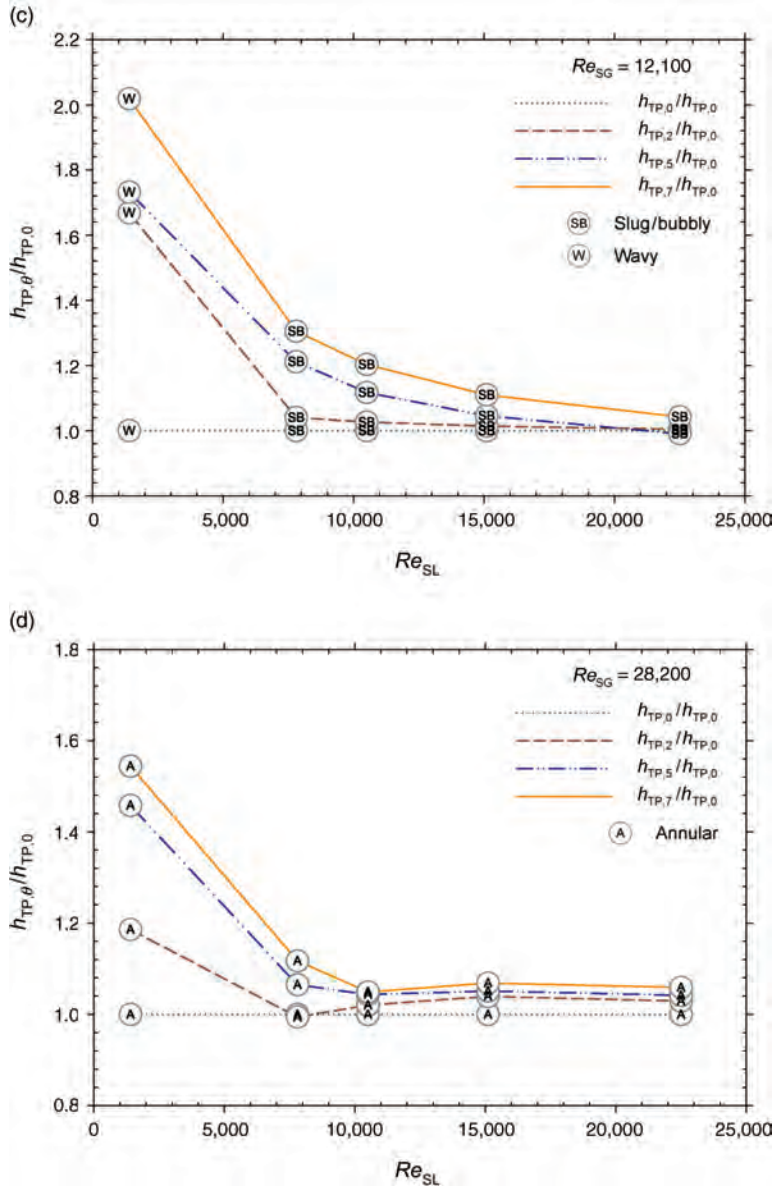

FIGURE 19.11 (Continued)

two-phase heat transfer coefficient by 200, 230, and 240%, respectively (see Figure 19.11a). In this particular case, the inclination of pipe from horizontal to 2°, 5°, and 7° caused a change in the flow pattern from stratified to slug. At the respective superficial gas and liquid Reynolds numbers of 5,100 and 1,400, inclination of pipe from horizontal to 2°, 5°, and 7° resulted in enhancements of two-phase heat transfer coefficient by 190, 195, and 230%, respectively (see Figure 19.11b). In this particular case, the inclination of pipe from horizontal to 2°, 5°, and 7° caused a change in the flow pattern from stratified to wavy/slug.

For wavy flow, an increase in inclination angle caused enhancement in the two-phase heat transfer coefficient. For instance, at the respective superficial gas and liquid Reynolds numbers of 12,100 and 1,400, Figure 19.11c shows that there are enhancements in two-phase heat transfer coefficient by 67, 73, and 102% for pipe inclinations from horizontal to 2°, 5°, and 7°, respectively. From flow pattern visual observations, increase in inclination angle for wavy flow caused the liquid backwash to become more significant, adding to the wave height and causing larger and more frequent splashes on the top part of the inner pipe surface, thus increasing the two-phase heat transfer coefficient.

For annular flow with superficial liquid Reynolds number below 7,000, pipe inclination brings enhancement to two-phase heat transfer coefficient. For instance, at the respective superficial gas and liquid Reynolds numbers of 28,200 and 1,400, Figure 19.11d shows that there are enhancements in two-phase heat transfer coefficient by 19, 46, and 54% for pipe inclinations from horizontal to 2°, 5°, and 7°, respectively. Visual observations revealed that the increase in inclination angle for annular flow caused the liquid film of the annular flow to thicken due to the effects of gravity. The thicker annular liquid film enhanced heat transfer capability, thus increasing the two-phase heat transfer coefficient.

Another perspective in the observation of heat transfer enhancement due to pipe inclination in nonboiling two-phase flow is by focusing on the two-phase heat transfer coefficient measured at the top part of the pipe (see Figure 19.3 for circumferential location “A”). Figure 19.12 shows the variation of the two-phase heat transfer coefficient at the top part of the pipe ($h_{TP,top}$) with superficial gas Reynolds number (Re_{SG}) for different pipe inclinations. The heat transfer coefficients at the top part of the pipe for an inclined pipe are consistently higher than those for a horizontal pipe. Figure 19.12 also shows that subsequent increase in pipe inclination from 2° to 7° caused increase in heat transfer coefficient.

FIGURE 19.12 Variation of the two-phase heat transfer coefficient ($h_{TP,top}$) with the superficial gas Reynolds number for $Re_{SL} = 5,000$ (A = annular, S = slug, SB = slug/bubbly, SBA = slug/bubbly/annular, WA = wavy/annular, WS = wavy/slug).

For inclined pipes, the higher heat transfer coefficients at the top part of the pipe contributed to the overall heat transfer enhancement. The higher $h_{TP,top}$ suggests that the top part of the pipe experienced higher level of contact with the liquid phase for an inclined pipe than for a horizontal pipe. Depending on the flow pattern, the increase in the level of liquid contact with the top part of the pipe can be in terms of liquid film thickness or turbulence and speed of traversing slug.

Figure 19.13 shows the heat transfer coefficient of two-phase flow at different circumferential locations of the pipe. For inclined pipes, Figure 19.13 shows that the heat transfer coefficients are higher than those for horizontal pipe at all circumferential locations.

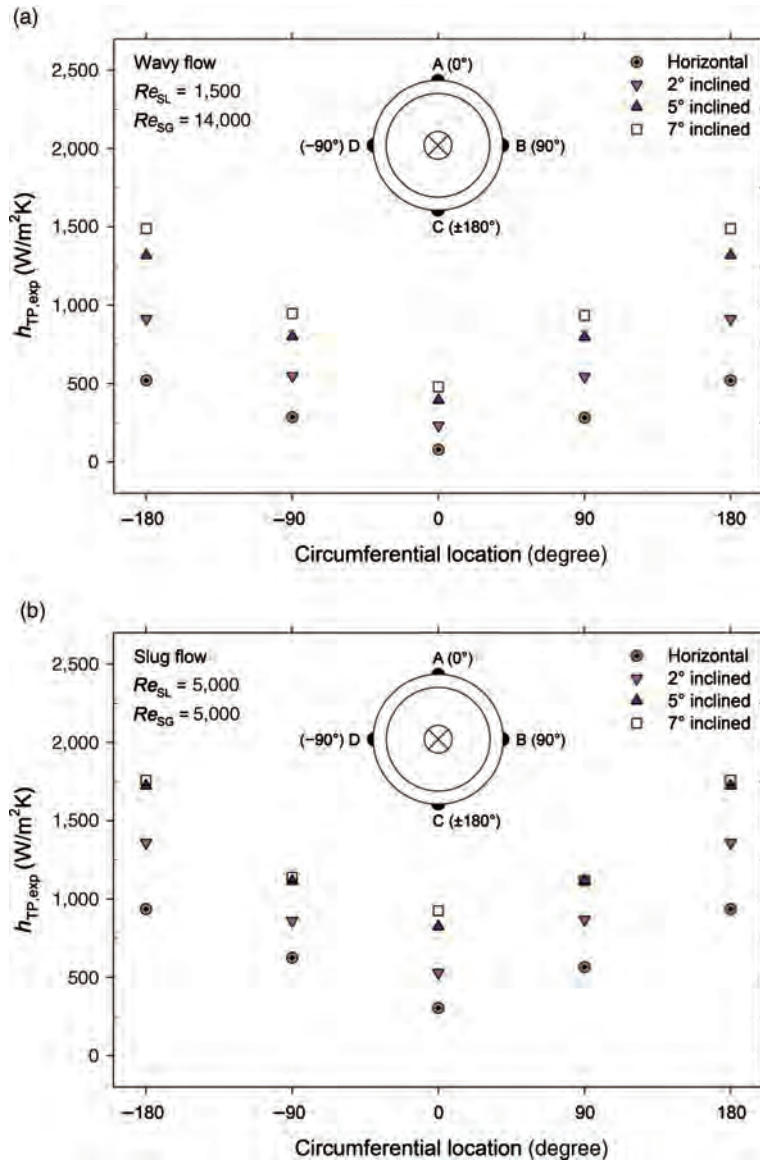

FIGURE 19.13 Two-phase heat transfer coefficient at circumferential locations of the pipe.

FIGURE 19.13 (Continued)

For annular flow (Figure 19.13c), the differences in the circumferential heat transfer coefficient for various pipe inclinations are less significant than those for wavy and slug flows (Figure 19.13a and b). The inertia force in annular flow is higher than that in wavy and slug flows. With inertia force dominant over buoyancy force, the influence of pipe inclination on heat transfer coefficient diminishes.

19.7 CONCLUDING REMARKS

The characterization and measurement of heat transfer in two-phase flow in pipe with different inclinations require a functional experimental setup as well as proper experimental procedures. Heat transfer in single-phase pipe flow generally produces uniform heat transfer coefficient circumferentially at an axial location. Unlike single-phase flow, two-phase flow in pipe is influenced by forces such as buoyancy, inertia, viscosity, and surface tension, which result in various flow patterns. The existence of flow patterns in two-phase flow leads to the occurrence of nonuniform heat transfer coefficient circumferentially at an axial location. The positions of the thermocouples on the heat transfer section, with four thermocouples positioned at equal interval circumferentially for each station, are employed to properly measure heat transfer coefficient of two-phase pipe flow.

The results of the present study had prompted the need of further investigation for nonboiling two-phase flow in pipe inclinations not addressed presently. A more comprehensive experimental study of two-phase flow heat transfer requires a new robust experimental setup that is equipped for measuring heat transfer, pressure drop, void fraction, and also conducting flow visualization of nonboiling two-phase flow for all major flow patterns and inclination angles from 0° (horizontal) to $\pm 90^\circ$ (upward and downward vertical). Details of the design and construction of this experimental setup as well as the validation of its functionality were documented by Cook (2008). With the new

experimental setup, the influences of void fraction, pressure drop, and flow patterns on nonboiling heat transfer can be evaluated. Void fraction plays an important role in the modeling of two-phase pressure drop, flow pattern transition, and heat transfer. Since void fraction is a very important parameter in characterizing two-phase flow, systematic measurements of void fraction for all pipe inclinations are important for establishing the fundamental understanding of two-phase flow. At the time of this writing, experiments on measuring void fraction for air–water flow in horizontal, upward and downward vertical pipes have been conducted. The results were documented by Ghajar and Tang (2010), Godbole et al. (2011), and Bhagwat and Ghajar (2012).

The experimental results that can be generated from the new experimental setup would provide further understanding of nonboiling two-phase flow and heat transfer in pipes. Experimental results for flow patterns, heat transfer, pressure drop, and void fraction, which cover the entire range of pipe inclinations, will be a significant milestone in the road map of establishing a fundamental understanding for two-phase flow.

NOMENCLATURE

c_f	Fanning friction factor, $c_f = 2\tau_0/(\rho U^2)$, dimensionless
c_p	Specific heat, J/kgK
D	Pipe inner diameter, m
h	Heat transfer coefficient, W/m ² K
$h_{TP,exp}$	Measured two-phase heat transfer coefficient, W/m ² K
$h_{TP,top}$	Two-phase heat transfer coefficient at the top part of the pipe, W/m ² K
$h_{TP,0}$	Two-phase heat transfer coefficient for horizontal pipe, 0°, W/m ² K
$h_{TP,\theta}$	Two-phase heat transfer coefficient for a specific inclination angle, θ , W/m ² K
k	Thermal conductivity, W/mK
L	Length, m
\dot{m}	Mass flow rate, kg/s
Nu	Nusselt number, $Nu = hD/k$, dimensionless
Pr	Prandtl number, $Pr = c_p\mu/k$, dimensionless
Δp	Pressure difference, N/m ²
Re	Reynolds number, $Re = \rho UD/\mu$, dimensionless
Re_{SG}	Superficial gas Reynolds number, $Re_{SG} = \rho_G U_{SG} D/\mu_G$, dimensionless
Re_{SL}	Superficial liquid Reynolds number, $Re_{SL} = \rho_L U_{SL} D/\mu_L$, dimensionless
U	Average velocity, m/s
U_{SG}	Superficial gas velocity, m/s
U_{SL}	Superficial liquid velocity, m/s

Greek Symbols

ε	Pipe wall roughness height, m
θ	Pipe inclination angle, degree
μ	Dynamic viscosity, Ns/m ²

μ_b	Dynamic viscosity evaluated at bulk temperature, Ns/m^2
μ_G	Gas phase dynamic viscosity, Ns/m^2
μ_L	Liquid phase dynamic viscosity, Ns/m^2
μ_w	Dynamic viscosity evaluated at wall temperature, Ns/m^2
ρ	Density, kg/m^3
ρ_G	Gas phase density, kg/m^3
ρ_L	Liquid phase density, kg/m^3
τ_0	Wall shear stress, N/m^2

20.1 INTRODUCTION

20.1.1 Radiation Measurement History

The Basra born Physicist Abu Ali al-Hasan ibn al-Hasan ibn al-Haytham was one of the first scientists who made a systematic attempt at understanding the transmission of solar radiation through terrestrial atmosphere. Al-Haytham was born in the year 965 and in his treatise “Balance of Wisdom,” he discusses the density of the atmosphere and the phenomenon of atmospheric refraction. He also attempted to measure the height of the atmosphere, which has now been confirmed to be 99% accurate (Rozenberg, 1966).

The invention of telescope by Galileo in the 16th century might have been the time when the sun was investigated with any reported significance. Since then, great many discoveries have been made and physical laws formulated and explained such as radiation electromagnetic theory, color of sunlit sky, solar radiation absorption by water vapor, and wave theory of light.

The electrical compensation pyrheliometer invented by Knut Ångström in 1893 was among the earliest radiation measurement instruments. This instrument is still used in many countries as the standard for absolute radiant energy determination (Coulson, 1975).

The advancement of measurement instrument development started after WWII when technology was furthered. The replacement of conventional resistance strips in Ångström-type pyrheliometer with thermopile is one of the many examples. Furthermore, the use of computerized data logging and data acquisition has replaced the conventional manual, time-consuming methods.

The World Meteorological Organization (WMO) has recommended a standard terminology for various radiation fluxes and the classification of the associated instruments. The units have been chosen on the basis of standard use and ease of physical interpretation. Some of the relevant basic concepts are explained in the following sections.

20.1.2 Solid Angle

Refer to Figure 20.1 wherein an elemental solid angle, $d\omega$, is shown. The concept of solid angle can be illustrated as a straight line through point 0 moving in space and intersecting an arbitrary surface located at some distance s from point 0. If the locus of the point of intersection forms a closed path on the surface but does not intersect itself, then a unique area is defined on the surface. Assume the area is an elemental area, da , the surface normal of which makes an angle with the direction to point 0.

FIGURE 20.1 Illustration of solid angle and its interpretation in spherical coordinates.

For purpose of illustration, assume it is the surface of a sphere of radius, r , as shown in Figure 20.1. For this case, the solid angle subtended at the center of the sphere by area dA on its surface is $d\omega = dA/r^2$. For the special case of a unit sphere ($r = 1$), $d\omega$ and dA have the same numerical value if $d\omega$ is expressed in steradians (sr) and dA and r are expressed in the same system of units. Because the area of the surface of a sphere is $4\pi r^2$, the total solid angle subtended at a point by the entire surrounding sphere is $4\pi r^2/r^2 = 4\pi$ sr.

A hemispheric solid angle is 2π sr. As can be seen from Figure 20.1, an elemental solid angle is conveniently expressed in a spherical coordinate system as

$$d\omega = \frac{(r d\theta)(r \sin\theta d\phi)}{r^2} \quad (20.1)$$

20.1.3 Intensity and Flux

Consider a pencil of radiation crossing the elemental area $d\sigma$ of Figure 20.2 and confined to the elemental angle $d\omega$, which is oriented at some angle θ to the normal of $d\sigma$. The energy dE_v contained in the frequency interval $d\nu$, which crosses $d\sigma$ in the time increment dt is given by

$$dE_v = I_v d\nu dt d\omega d\sigma \cos\theta \quad (20.2)$$

This relation defines the monochromatic specific intensity in the most general way as

$$I_v = \frac{dE_v}{d\nu dt d\omega d\sigma \cos\theta} \quad (20.3)$$

FIGURE 20.2 Beam of radiation passing through an elemental area.

Thus, the definition of specific intensity implies directionality. The term flux, however, is flow of energy, and it may or may not have an implied direction. For instance, the monochromatic flux of energy across $d\sigma$ is given by the integration of the normal component of I_v , over the entire spherical solid angle Ω . Thus,

$$F_v = dv dt d\sigma \int_{\Omega} I_v(\omega) \cos \theta d\omega \quad (20.4)$$

or, in terms of spherical coordinates,

$$F_v = dv dt d\sigma \int_0^{2\pi} \int_0^{\pi} I_v(\theta, \phi) \sin \theta \cos \theta d\theta d\phi \quad (20.5)$$

20.1.3.1 Terminology in Radiation Instruments Considerable confusion in the terminology applied to various types of solar radiation instruments has built up over the years. For instance, an instrument measuring the total hemispherical flux of solar radiation has been variously called pyrheliometer, pyranometer, solarimeter, actinograph, and sunshine recorder.

To standardize terminology, the WMO, through its Commission for Instruments and Method of Observation, has recommended the following classification of radiation instruments:

Pyrheliometer: An instrument for measuring “the intensity of direct solar radiation at normal incidence.”

Pyranometer: An instrument for measuring “the solar radiation received from the whole hemisphere. It is suitable for the measurement of the global or sky radiation.”

A pyranometer for measuring the radiation on a spherical surface is a “spherical pyranometer.”

Pyrgeometer: An instrument for measuring “the net atmospheric radiation on a horizontal upward-facing black surface at ambient air temperature.”

Pyrradiometer: An instrument for measuring “both the solar and terrestrial radiation (total radiation).”

Net Pyrradiometer: An instrument for measuring “the net flux downward and upward total (solar, terrestrial, surface, and atmospheric) radiation through a horizontal surface.” A net radiometer is sometimes termed a balance pyrradiometer or radiation balance meter.

20.1.4 Radiation Units

The principal units of radiation are given in Table 20.1.

20.1.5 Radiation Laws

1. *Planck's Law:* Max Planck showed that the spectral density emitted by a blackbody at temperature T is given by the Planck function to the following, the first being expressed on the basis of frequency ν and the second on the basis of wavelength λ of the radiation:

$$B_{\nu}(T) = \frac{2h\nu^3}{c^2(e^{h\nu/kT} - 1)} \quad (20.6)$$

$$B_{\lambda}(T) = \frac{C_1\lambda^{-5}}{(e^{C_2/\lambda T} - 1)} \quad (20.7)$$

The values of the constants are

h = Planck's constant = 6.6256×10^{-27} erg s

k = Boltzmann's constants = 1.3805×10^{-16} erg deg $^{-1}$

c = speed of light *in vacuo* = 2.998×10^{10} cm s $^{-1}$

C_1 = first radiation constant = $2hc^2 = 3.74150 \times 10^{-5}$ erg cm 2 s $^{-1}$

C_2 = second radiation constant = $hc/k = 1.43879$ cm deg.

2. *Kirchhoff's Law:* Gustav Kirchhoff stated that for a medium in thermodynamic equilibrium, the ratio between the mass emission coefficient and mass absorption coefficient has a value, which is independent of the nature of the material and is dependent only on wavelength of the radiation and temperature of the medium.

A note on the limits of applicability of Kirchhoff's law to the terrestrial radiation field of the atmosphere is appropriate. The law requires thermodynamic

TABLE 20.1 The Principal Units of Radiation

Quantities	Units
Wavelength	Micrometer (μm) or angstrom (\AA)
Frequency (ν)	s $^{-1}$
Wave number	cm $^{-1}$
Specific intensity: spectral	W/cm 2 /sr/cm
Specific intensity: total	W/cm 2 /sr
Radian flux: spectral	W/cm 2 / μm
Radian flux: total	W/cm 2

equilibrium, one characteristic of which is that the radiation field be isotropic. Obviously, the radiation field for the atmosphere as a whole is not isotropic. On the other hand, the field in the localized volume of the troposphere or stratosphere is approximately isotropic, and it is in the context of this local thermodynamic equilibrium that Kirchhoff's law is applicable to the atmosphere. A second characteristic of local thermodynamic equilibrium is that the populations of atomic and molecular states be those of their equilibrium distribution. In such a case, the energy transitions are controlled by molecular collisions and not by interaction of particles with the radiation field itself. In the atmosphere, molecular collisions dominate the energy transitions at all altitudes below 60–70 km, indicating that local thermodynamic equilibrium is a good approximation through more than 90% of the mass of the atmosphere.

3. *Stefan–Boltzmann Law*: By integrating the monochromatic blackbody function of Equation (20.7) over the entire wavelength range from 0 to ∞ , an expression for the total rate of energy emission E by a unit area of blackbody surface in terms of its absolute temperature T may be derived as,

$$E = \sigma T^4 \quad (20.8)$$

where σ is the Stefan–Boltzmann constant which is $5.6704 \times 10^{-8} \text{ W/m}^2/\text{K}^4$.

4. *Wien Displacement Law*: Wien's displacement law is obtained by differentiating the Planck function with respect to wavelength, setting the result equal to 0 and thereby determining the value λ_{\max} at which $B_{\lambda}(T)$ is a maximum. Hence,

$$\lambda_{\max} T = \text{const} \quad (20.9)$$

The value of the constant is 0.2897 cm deg if λ is in centimeter.

Important data related to solar radiation measurement are provided in Table 20.2.

20.1.6 Thermal Detector

The mode of operation of thermal detector starts when the radiant energy transfers into heat energy, with consequent rise of temperature of some material. They respond only to total energy absorbed, and thus, at least theoretically, nonselective as to the spectral distribution of the energy. Because of the limitation of the absorbing materials, this non-selective feature is difficult to achieve completely in operation, but it is more closely achieved in thermal detectors than in any other type. The main types of thermal detectors are calorimeters, thermocouples or thermopiles, and bolometer.

20.1.7 Photo Detectors

The advantage of photo detectors is that the sensor is activated by discrete events of photons striking the material and not by a change in temperature because of the absorption of radiation, as in the thermal detectors. The advantage of sensing discrete events is that much faster responses and higher sensitivities can be achieved than with thermal devices. There are three principal types of photo detectors, namely, photovoltaic, photoconductive, and photo-emissive cells.

TABLE 20.2 Highlights of Solar Radiation Instruments Development

Year	Events
1825	Herschel's pyrheliometer (actinometer) developed
1837	Invention of Pouillet's pyrheliometer
1840	Invention of first photographic sunshine recorder by Jordan
1879	Campbell–Stokes sunshine recorder started in used
1885	Invention of photographic sunshine recorder by Jordan
1885	Invention of new form polarimeter and of pole-star recorder by Pickering
1886	Invention of new type of radiometer by Ångström
1891	Concept of Maring–Marvin sunshine recorder by Maring
1893	Invention of electric compensation pyrheliometer by Ångström
1898	Invention of Callender pyranometer
1902	Secondary standard silver-disk pyrheliometer developed by Abbot
1905	Ångström electrical compensation pyrheliometer adopted as a WMO standard
1908	Invention of Michelson pyrheliometer
1910	Invention of Marvin pyrheliometer
1915	First bolometer constructed
1916	Pyranometer for measuring global radiation devised.
1917	Ultrasensitive vacuum bolometer constructed
1919	Honeycomb (melikeron) pyranometer constructed
1922	Dorno's pyrheliograph invented
1923	Invention of Kimball–Hobbs pyranometer (forerunner of first Eppley pyranometers)
1923	Invention of Moll thermopile
1924	Moll thermopile used by Gorczynski, later known as Kipp solarimeter
1927	Double water-flow pyrheliometer developed by Shulgin
1932	First standard design of Robitzsch pyranometer developed
1948	Menzel developed sensitive sky photometer
1953	Invention of sunshine switch by Foster and Foskett of U.S Weather Bureau
1957	International Pyrheliometric Scale 1956' put into effect; original Ångström scale increased by 1.5% and 1913 Smithsonian scale decreased by 2.0%
1962	Adoption of the Campbell–Stokes sunshine recorder as an 'Interim Reference Sunshine Recorder' by the Commission on Instruments and Methods of Observation, WMO
1965	Introduction of Eppley precision pyranometer
1965	Development of automatic control of Ångström pyrheliometer by Marsh
1969	Introduction of Eppley black and white (star-type) pyranometer
1990	Wide-scale use of programmable data loggers for recording irradiance
2001	Invention of BF3 sensor by Delta-T company of Cambridge, England. The instrument integrates sunshine duration recorder with global and diffuse irradiance measurement

20.1.8 Classification of Pyrheliometer

The Commission for Instruments and Method of Observation of the WMO (1965), pyrheliometers are classified as standard, first, or second class, in accordance with the criteria given in Table 20.3. On the basis of these criteria, the commercially available pyrheliometer are classified as in Table 20.4.

20.1.9 Working Standard

Working standard pyrheliometers of Ångström type (referenced to Davos) are maintained at the regional and national centers designated by the WMO for the purpose of

TABLE 20.3 Classification of Pyrheliometers by WMO

	Standard	First Class	Second Class
Sensitivity (mW/cm^2)	± 0.2	± 0.4	± 0.5
Stability (% change in year)	± 0.2	± 1	± 2
Temperature (maximum error due to changes of ambient temperature, %)	± 0.2	± 1	± 2
Selectivity (maximum error due to departure from assumed spectral response, %)	± 1	± 1	± 2
Linearity (maximum error due to nonlinearity not accounted for, %)	± 0.5	± 1	± 2
Time constant (maximum)	25 s	25 s	1 min

TABLE 20.4 Classification of Commercial Pyrheliometers

Class	Type
Standard	Ångstrom electrical compensation pyrheliometer Abbot silver-disk pyrheliometer
First class	Michelson bimetallic pyrheliometer Linke–Feussner iron-clad pyrheliometer New Eppley pyrheliometer (temperature compensated) Yanishevsky thermoelectric pyrheliometer
Second class	Moll-Gorczynski pyrheliometer Old Eppley pyrheliometer

reproducing the International Pyrheliometric Scale 1956 (IPS). To a limited extent, the Abbot silver-disk pyrheliometer is still used at such centers. The secondary transfer instruments in current use are the other Ångstrom pyrheliometer and instruments of Eppley, Linke–Feussner, and Michelson types.

20.2 MEASUREMENT EQUIPMENT

According to European Solar Radiation Atlas (ESRA), solar radiation measurements can be broadly classified as ground-based measurements derived from geostationary satellites, which measures the energy reflected by the system (earth/atmosphere) in different wavelength bands (ESRA, 2000).

20.2.1 Pyranometer

This instrument measures global solar radiation. Figure 20.3 shows the structure of the CM11 Kipp and Zonen pyranometer. The pyranometer has the spectral response of between 335 and 2200 nm. A thermal detector in the sensing element responds to the total power absorbed from the solar radiation at any spectral distribution. The absorption of radiation on the black disk generates heat, and the heat energy flows to the heat sink through a thermal resistance. The temperature difference across the thermal resistance of the disk is converted into a small voltage, which can be detected by the logging system or computer. To avoid temperature fluctuation and reduce thermal radiation losses to the

FIGURE 20.3 Kipp and Zonen CM11 pyranometer (Anon, 2010b).

atmosphere, the pyranometer is built with a double glass envelope. Furthermore, silica gel crystal is used to prevent moisture within the pyranometer. Periodic cleaning of the glass dome is recommended as debris may be collected over time. The working principle of the pyranometer given here is as discussed by Muneer (2004).

20.2.2 Pyranometer with Shading Device

This type of pyranometer measures the diffuse solar radiation. The shadow ring or disk shades the sun's direct beam from the pyranometer. Figure 20.4 shows a Kipp

FIGURE 20.4 Kipp and Zonen CM11 pyranometer with shading device (Clima, 2010).

and Zonen CM11 pyranometer with shadow ring. The shadow ring needs to be adjusted according to the sun's declination angle. A more expensive approach has been designed to track the sun's declination, where the disk will move accordingly or synchronous with the sun's movement. Hence, it produces a more accurate estimation of diffuse radiation.

The WMO classified pyranometer according to the features like stability, sensitivity, and so on. Classifications of pyranometer are divided into three classes, that is, first, second, and third class. The same features of classification apply to pyrheliometer where they are divided only into two classes, first and second class as mentioned before. The WMO characteristics of operational pyranometers are given in Table 20.5. Figure 20.5 shows the shade ring correction factors for the measurement of diffuse sky radiation.

TABLE 20.5 WMO Characteristic of Operational Pyranometer (Instruments, E. 2004)

Characteristic	High Quality ^a	Good Quality ^b	Moderate Quality ^c
Response time (95% response)	<15 s	<30 s	<60 s
Zero offset:			
(a) Response to 200 W/m ² net thermal radiation (ventilated)	7 W/m ²	15 W/m ²	30 W/m ²
(b) Response to 5 K/h change in ambient temperature	2 W/m ²	4 W/m ²	8 W/m ²
Resolution (smallest detectable change)	1 W/m ²	5 W/m ²	10 W/m ²
Stability (change per year, percentage of full scale)	0.8	1.5	3
Directional response for beam radiation (the range of errors caused by assuming that the normal incidence responsivity is valid for all directions when measuring, from any direction, a beam radiation whose normal incidence irradiance is 1000 W/m ²)	10 W/m ²	20 W/m ²	30 W/m ²
Temperature response (percentage maximum error due to any change of ambient temperature within an interval of 50 K)	2	4	8
Nonlinearity (percentage deviation from the responsivity at 500 W/m ² due to any change of irradiance within the range 100–1000 W/m ²)	0.5	1	3
Spectral sensitivity (percentage deviation of the product of spectral absorptance and spectral transmittance from the corresponding mean within the range 0.3–3 μ m)	2	5	10
Tilt response (percentage deviation from the responsivity at 0° tilt (horizontal) due to change in tilt from 0° to 90° at 1000 W/m ² irradiance)	0.5	2	5
Achievable uncertainty, 95% confidence level:			
Hourly totals	3%	8%	20%
Daily totals	2%	5%	10%

^aNear state-of-the-art, suitable for use as a working standard; maintainable only at stations with special facilities and staff.

^bAcceptable for network operations.

^cSuitable for low-cost networks where moderate to low performance is acceptable.

FIGURE 20.5 Shade ring correction factors for measured sky diffuse radiation.

20.2.3 Pyrheliometer

A pyrheliometer is used to measure beam (direct) radiation at normal incidence. Figure 20.6 shows a DN5 pyrheliometer used in an active tracking system. The long barrel of the pyrheliometer may be seen below the glass dome of the pyranometer in this picture. This equipment is equipped with a sun tracking system to enable it to

FIGURE 20.6 Middleton Solar-DN5 pyrheliometer (in active solar tracking system) (Anon, 2010a).

FIGURE 20.7 Eppley normal incidence pyrheliometer (EPLAP, 2010).

measure direct radiation as the sun moves. Inside the pyrheliometer there is a collimator with an optimum aperture of 6° , which can completely include the sun's disk. A multi-junction thermopile, which converts the heat from the sun's radiation to an electrical signal, is used so that the data can be read and recorded by data logger. To obtain the equivalent radiant energy flux (W/m^2) a calibration factor is applied. Other types of pyrheliometer are shown in Figures 20.7 and 20.8. Table 20.6 gives the characteristics of operational pyrheliometers.

The direct equipment cost of a pyrheliometer is approximately six times than a shaded pyranometer (Muneer, 2004). Because the measurement cost of direct normal radiation

FIGURE 20.8 The EKO-instrument's Sky scanner MS-321LR (Instruments, E. 2004).

TABLE 20.6 WMO Characteristic of Operational Pyrheliometers (Instruments, E. 2004)

Characteristic	High Quality ^a	Good Quality ^b

^aNear state-of-the-art, suitable for use as a working standard; maintainable only at stations with special facilities and staff.

^bAcceptable for network operations.

is high, a simple relationship relating horizontal of global (I_G), diffuse (I_D), and beam (I_B) radiation may be used to estimate the latter component. The relation can be given as

$$I_G = I_D + I_B \sin \text{SOLALT} \quad (20.10)$$

where SOLALT is the solar altitude.

According to Perez et al. (1990) and Gueymard (2003), the present state of solar radiation and daylight model is such that they are approaching the accuracy limits set out by the measuring equipment. Hence, modeling procedures are now used to crosscheck the measurements.

20.2.4 Pyrgeometer

Pyrgeometer is used to measure long wave radiation, which falls within the infrared radiation spectrum (4.5–100 μ m). It consists of a thermopile with a 200–100 μ m radiation band sensitivity, a dome mirror with solar blind filter coating, which eliminates short wave radiation, a temperature sensor which measures the body temperature of the

FIGURE 20.9 EKO M-S202 pyrheliometer (Instruments, E., 2005).

instrument and a sun shield to reduce heat from radiation. Figure 20.9 shows an EKO MS-202 pyrheliometer.

20.2.5 Albedometer

The term “ground albedo” or simply “albedo” is often used interchangeably with “ground reflectance.” On the other hand, as Monteith (1959) has pointed out, the term “albedo” or “whiteness” refers to the reflection coefficient in the visible range of the spectrum, whereas “reflectance” denotes the reflected fraction of short wave energy. In this book, the term “albedo” has been used synonymously with reflectance, applying to the total short wave energy.

The importance of knowing the albedo for the determination of radiation balance of macro- and microclimates is well known. A good estimate of albedo of the surrounding terrain is a prerequisite for representative calculations related to the energy balance of vegetation, amount of potential transpiration, energy interception of walls, windows, roofs, and solar energy collectors. Therefore, the small- and large-scale variation of albedo is of interest. The variation in albedo is spatial and temporal owing to the changing landscapes of the earth and due to the seasonal presence of snow and to some extent moisture deposition.

As the name of the instrument suggest, it measures the reflected radiation as well as the global radiation. Figure 20.10 shows an albedometer. Generally, albedometer is constructed with two pyranometers. One is facing upward to measure incident global radiation and the other facing downward to measure the ground-reflected radiation. Both pyranometers provide output individually. Albedo can be calculated from the output data of the two pyranometers. To obtain the albedo value, the following equation may be used:

$$\text{Albedo} = \frac{\text{reflected radiation}}{\text{global radiation}} \quad (20.11)$$

FIGURE 20.10 Kipp and Zonen CMA 6 Albedometer (Envco., 2009).

20.2.6 Sunshine Recorder

According to the WMO, definition of sunshine duration is “*sunshine duration during a given period is defined as the sum of that sub-period for which the direct solar irradiance exceeds 120 W/m^2* ” (WMO, 2003).

In many countries, diurnal duration of bright sunshine is measured at a wide number of places. For over a century, these data have been measured using the well-known Campbell–Stokes sunshine recorder as shown in Figure 20.11, which uses a solid glass spherical lens to burn a trace of the sun on a treated paper, the trace being produced whenever the beam irradiation is supposedly above the aforementioned critical level. Although the

FIGURE 20.11 240-1070-L Campbell–Stokes Pattern Sunshine Recorder (Corporation, N., 2010).

critical threshold varies loosely with the prevailing ambient conditions, the sunshine recorder is an economic and robust device and hence used widely.

The limitations of the Campbell–Stokes sunshine recorder are well known and have been discussed in *Observers' Handbook* (1969), Painter (1981), and Rawlins (1984). Some of the associated limitations with this device are that the recorder does not register a burn on the card below a certain level of incident radiation (about 150–300 W/m²). On a clear day with a cloudless sky, the burn does not start until 15–30 min after sunrise and usually ceases about the same period before sunset. This period varies with the season. On the other hand, under periods of intermittent bright sunshine the burn spreads. The diameter of sun's image formed by the spherical lens is only about 0.7 mm. However, a few seconds' exposure to bright sunshine may produce a burnt width of about 2 mm. As such, intermittent sunshine may be indistinguishable from a longer period of continuous sunshine. In the past, a more sophisticated photoelectric sunshine recorder called the Foster sunshine switch (Foster and Foskett, 1953) has been used by the US Weather Service. This device incorporates two photovoltaic cells, one shaded and the other exposed to solar beam. Incident beam irradiation above a given threshold produces a differential output from the above two cells, the diurnal duration of which determines the hours of bright sunshine.

Suehrcke (2000) has presented an elegant and simple relationship that enables estimation of \bar{G} from the monthly averaged daily bright sunshine fraction and clear sky clearness index, $\bar{G}_{\text{clear}}/\bar{E}$. Thus:

$$\bar{G}/\bar{E} = (n/N)(\bar{G}_{\text{clear}}/\bar{E}) \quad (20.12)$$

where \bar{G} and \bar{E} are the monthly averaged daily terrestrial and extraterrestrial irradiation, \bar{G}_{clear} the monthly averaged daily terrestrial irradiation on clear day, n the average daily hours of bright sunshine, and N the day length.

Suehrcke has argued that $\bar{G}_{\text{clear}}/\bar{E}$ varies narrowly between 0.65 and 0.75. Given this small range of variation, in the absence of specific site information, an average

FIGURE 20.12 Driesse and Thevenard's (2002) evaluation of Suehrcke's "universal" relationship, see Equation (20.12).

value of 0.7 may be assumed for $\bar{G}_{\text{clear}}/\bar{E}$, thus giving Equation 20.12 the potential for worldwide application.

Driesse and Thevenard (2002) have evaluated the above claim. They have used measurements from 700 sites, compiled by the World Radiation Data Center with over 70 000 sunshine and radiation data. The relevant plot is shown in Figure 20.12. It may be noted that there is a considerable dispersion in the values of solar radiation. This variation (root mean square errors, RMSEs) was found to be around 12%. The latter team has fitted the above data to find regressed values of globally applicable Ångström a and b coefficients. These values are 0.2336 and 0.4987, respectively. Using the latter “universal” coefficients the performance of Suehrcke and Ångström procedures for estimating \bar{G} was found to be on par.

20.3 EQUIPMENT ERROR AND UNCERTAINTY

With any measurement there exist errors, some of which are systematic and others inherent of the equipment used. Angus (1995) has provided an account of the measurement errors associated with solar irradiance and illuminance measurements. These are summarized herein. The most common sources of error arise from the sensors and their construction. These are broken down into the most general types of error as follows:

- (a) cosine response,
- (b) azimuth response,
- (c) temperature response,
- (d) spectral selectivity,
- (e) stability,
- (f) nonlinearity,
- (g) thermal instability,
- (h) zero offset due to nocturnal radiative cooling.

To be classed as a secondary standard instrument (such as the CM11) pyranometers have to meet the specifications set out by WMO.

Of all the aforementioned errors, the cosine effect is the most apparent and widely recognized. This is the sensor’s response to the angle at which radiation strikes the sensing area. The more acute the angle of the sun, that is, at sunrise and sunset, the greater the error is (at altitude angles of sun below 6°). Cosine error is typically dealt with through the exclusion of the recorded data at sunrise and sunset times.

The azimuth error is a result of imperfections of the glass domes and in the case of solarimeters, the angular reflection properties of the black paint. This is an inherent manufacturing error, which yields a similar percentage error as the cosine effect. Like the azimuth error, the temperature response of the sensor is an individual fault for each cell. The photometers are thermostatically controlled, and hence the percentage errors due to fluctuations in the sensor’s temperature are reduced. However, the CM11 pyranometers have a much less elaborate temperature control system. The pyranometers rely on the two glass domes to prevent large temperature swings. Ventilation of the instrument is an additional recommended option.

The spectral selectivity of the CM11 is dependent on the spectral absorptance of the black paint and the spectral transmission of the glass. The overall effect contributes only

a small percentage error to the measurements. Each sensor possesses a high level of stability with the deterioration of the cells resulting in approximately $\pm 1\%$ change in the full-scale measurement per year. Finally, the nonlinearity of the sensors is a concern especially with photometers. It is a function of illuminance or irradiance levels. It, however, tends to contribute only a small percentage error toward the measured values. In addition to the above sources of equipment-related errors, care must be taken to avoid operational errors such as incorrect sensor leveling and orientation of the vertical sensors, as well as improper screening of the vertical sensors from ground-reflected radiation.

20.4 OPERATIONAL ERRORS

In Section 20.3, the likely errors resulting from equipment were introduced. Understanding and an assessment of operational errors are also of equal importance, and these are addressed below:

- (a) complete or partial shade-ring misalignment,
- (b) dust, snow, dew, water droplets, bird droppings, and so on,
- (c) incorrect sensor leveling,
- (d) shading caused by building structures,
- (e) electric fields in the vicinity of cables,
- (f) mechanical loading on cables,
- (g) orientation and/or improper screening of the vertical sensors from ground-reflected radiation,
- (h) station shutdown,
- (i) improper application of diffuse shade-ring correction factor,
- (j) inaccurate programming of calibration constants.

The sources of operation-related errors itemized above are self-explanatory. It is a good practice to protect cables from strong electric fields such as elevator shafts. Another source of error that may arise is from cables under mechanical load (piezoelectric effects). The piezoelectric effect is the production of electrical polarization in a material by the application of mechanical stress. Failure to protect cables from the above sources may produce “spikes” in the data, and these are shown as unusually high values of irradiance. Figure 20.13 demonstrates the sources of error categorized under items (a) and (b) discussed above. Such errors are best highlighted via cross plotting the diffuse ratio (the ratio of horizontal sky diffuse and the total or global irradiance) against clearness index (the ratio of horizontal global to extraterrestrial irradiance). Any serious departure of data from the normally expected envelope is thus identified. Figure 20.14 highlights error categorized under item (f).

20.5 DIFFUSE RADIATION DATA MEASUREMENT ERRORS

Historically, meteorological offices worldwide have used shade-ring correction procedure that is based on the assumption of an isotropic sky. However, during the past 15 years, a number of alternate, more precise methods that are based on a realistic, anisotropic sky

FIGURE 20.13 Demonstration of the sources of measurement errors.

have been established. The older, isotropic-sky corrected diffuse irradiation records are slightly higher for overcast conditions and lower by up to 10% for clear sky conditions. It is imperative that due care is taken in using a precise and validated shade-ring correction procedure since any errors in horizontal diffuse irradiance records will be multiplied by a large factor when horizontal beam irradiance and subsequently the total slope energy computations are undertaken.

The diffuse irradiance can be calculated from measurements of global parameter and the beam normal irradiance by using the following equation:

$$I_d^{\text{true}} = I_g - I_n \sin \alpha \quad (20.13)$$

FIGURE 20.14 Demonstration of problems associated with mechanical loading on cables connecting data logger to irradiance sensor. Note: 5 min averaged data for Bahrain for December 12, 2001 (x-axis: the time of the day, y-axis: irradiance, W/m²).

where I_d^{true} is the diffuse horizontal irradiance which is referred hereafter as “true” diffuse, I_g the global irradiance on a horizontal surface, I_n the beam normal irradiance, and α the solar altitude. Measurements of beam normal irradiance are made using a pyrheliometer. Unfortunately, the collection of pyrheliometric data can be very expensive; the direct equipment cost alone is almost six times the expense of alternate collection methods, for example, prices quoted for Kipp and Zonen, premium grade equipment (>ISO 9000 standard) in February of 2003, were (USD) \$18909 for a pyrheliometric system and \$3245 for a pyranometer with a shadow band (Omni Instruments, 2012). The overall expense is most certainly directly related to the equipment cost but has a significant indirect cost, which is linked to the high level of daily maintenance required while using the system. An alternate and relatively inexpensive approach that is often used is to use a pyranometer with an occulting device to block the beam direct component from reaching the sensor. The most commonly used occulting devices are shadow-bands or shade rings. All shading devices are usually coated with a low albedo black paint to reduce any reflected radiation from the shadow band. The shadow bands are aligned and fixed parallel to the earth’s polar axis matching the sun’s track in the sky. This method produces a constant shadow on the pyranometer’s sensor, effectively blocking the beam direct irradiance and theoretically leaving only the diffuse irradiation. Shadow-band use is economical and effectively shades direct beam irradiation. Regrettably, shadow bands also shade a portion of the sky and the corresponding slice of the diffuse irradiance that is obscured by the band itself. This shading introduces errors that can markedly influence the accuracy of measurements. Because of this error, a correction factor needs to be introduced to the diffuse irradiance readings. The correction factor can be derived by accounting for the physical amount of sky that is blocked by the band and the amount of diffuse irradiance that is representative of that blocked portion. Various authors (Drummond, 1956; Stanhill, 2000; Pollard and Langevine, 1988; Dehne, 1984; LeBaron et al., 1990; Batlles et al., 1995; Muneer and Zhang, 2002; Painter, 1981; Kasten et al., 1983; Kudish and Ianetz, 1993; Batlles et al., 1998) have proposed many models, isotropic and anisotropic in nature, to correct the diffuse irradiance component when deploying a shadow band.

Historically, Drummond (1956) suggested a theoretical, isotropic model based on solar geometric calculations for shadow-band correction. The model could be applied anywhere in the world, but Drummond noted that as much as 7% additional correction was needed under cloudless sky to account for anisotropic conditions. The additional correction required for overcast or cloudy skies was 3%. Stanhill (2000) found that additional corrections for anisotropic conditions actually ranged between 14 and 30% to the isotropic correction. Other models have been investigated using various parameters such as solar declination, clearness index, cloud cover, and atmospheric turbidity (Pollard and Langevine, 1988). Dehne (1984) reported that attempts to use these models or duplicate the results proved disappointing for sites other than the site that was used to develop the models. LeBaron et al. (1990) suggested a model using four parameters covering both isotropic and anisotropic conditions. More recently, Batlles et al. (1998) and Muneer and Zhang (2002) introduced correction models describing an improved methodology accounting for both the isotropic and anisotropic correction contribution to “true” diffuse irradiance. The objective of this work is to evaluate the overall performance of the shadow-band correction models proposed by LeBaron et al. (1990), Batlles et al. (1998), and Muneer and Zhang (2002), against the benchmark Drummond’s model (Drummond, 1956), using data collected in disparate locations to those where models were originally developed.

20.5.1 Description of Models

All four of the diffuse shadow-band correction models considered herein (Drummond, 1956; LeBaron et al., 1990; Muneer and Zhang, 2002; Batlles et al., 1998) are well established and widely used by metrological offices worldwide. They have been adequately described in sufficient detail in the previously cited references. For the sake of brevity, these models are described in the following sections of this article. Hereafter, we refer to each model by the name of the first author.

1. *Drummond (1956)*: Drummond's model assumes an isotropic sky condition. The portion of the horizontal irradiance intercepted for the shadow band X is calculated according to the following equation:

$$X = \frac{2b}{\pi r} \cos^3 \delta \left[\left(\frac{\pi}{180} \varpi_0 \right) \sin \phi \sin \delta + \cos \phi \cos \delta \sin \varpi_0 \right] \quad (20.14)$$

where r is the radius of the shadow band, b the width of the shadow band, ϖ_0 the sunset/sunrise hour angle, ϕ the latitude, and δ the declination. The Drummond correction factor C_D is then expressed as

$$C_D = \frac{1}{1 - X} \quad (20.15)$$

By using Drummond's model, the corrected diffuse irradiance I_{dD} may be obtained by applying the following formula:

$$I_{dD} = C_D I_d \quad (20.16)$$

2. *LeBaron et al. (1990)*: This model uses four parameters that take into account varying (isotropic and anisotropic) sky conditions. Three of the parameters used within this method are solar altitude and two dimensionless indices introduced by Perez et al. (Pollard and Langevine, 1988), termed, respectively, as the clearness of the sky, ε , and the brightness of the sky, Δ . The forth parameter is the Drummond's correction factor C_D describe earlier. Using these four parameters, LeBaron et al. (Gueymard, 2003) clustered the data according to 256 categories. For each one of these categories, they determined an appropriate value of the correct factor.
3. *Batlles et al. (1995)*: Batlles et al. (WMO, 2003) developed a piecewise multiple linear model using the same four parameters used in LeBaron's approach. The correction factor C_B is then expressed as an analytical function of C_D , α , and Δ , which is parameterized against ε . The set of equations are

$$\varepsilon \leq 3.5 \quad C_B = 1.178C_D + 0.207 \log \Delta + 0.122e^{-1/\sin \alpha} \quad (20.17a)$$

$$3.5 \leq \varepsilon \leq 8 \quad C_B = 1.454C_D + 0.665 \log \Delta + 0.4756e^{-1/\sin \alpha} \quad (20.17b)$$

$$8 \leq \varepsilon \leq 11 \quad C_B = 1.486C_D + 0.495 \log \Delta \quad (20.17c)$$

$$\varepsilon > 11 \quad C_B = 1.384C_D + 0.363 \log \Delta \quad (20.17d)$$

Measurements of diffuse irradiance are then corrected for isotropic and anisotropic conditions using:

$$I_{dB} = C_B I_d \quad (20.18)$$

4. *Muneer and Zhang (2002)*: This model is based on the sky patch radiance distribution work of Moon and Spencer (Dehne, 1984). The model incorporates both isotropic and anisotropic elements by means of the following equation:

$$D = \left(\frac{\pi L_Z}{6} \right) \left[\frac{3 + 2b_1}{1 + b_1} + \frac{3 + 2b_2}{1 + b_2} \right] \quad (20.19)$$

where D is the diffuse irradiance calculated in terms of the radiance indices and L_Z . Parameters b_1 and b_2 are the radiance distribution indices for the two sky quadrants containing sun and opposed to sun, given as
for $k > 0.2$,

$$b_1 = \frac{3.6 - 10.462k_t}{-0.4 + 6.974k_t} \quad (20.20)$$

$$b_2 = \frac{1.565 - 0.990k_t}{0.957 - 0.660k_t} \quad (20.21)$$

for $k \leq 0.2$, $b_1 = b_2 = 1.68$. The correction factor C_M may be calculated as follows:

$$I_1 = \cos \phi \cos \delta \sin \omega_0 + \omega_0 \sin \phi \sin \delta \quad (20.22)$$

$$I_2 = \omega_0 \sin^2 \phi \sin^2 \delta + 2 \sin \omega_0 \sin \phi \cos \phi \sin \delta \cos \delta + \cos^2 \phi \cos^2 \delta \left[\frac{\omega_0}{2} + \frac{\sin 2\omega_0}{4} \right] \quad (20.23)$$

$$F = \frac{2b}{r} L_Z \cos^3 \delta \frac{I_1 + b_1 I_2}{1 + b_1} \quad (20.24)$$

$$C_M = \frac{1}{1 - \frac{F}{D}} \quad (20.25)$$

Tables 20.7–20.9 give the statistical results of the models discussed above for different types of sky condition. Figure 20.15 shows corrected diffuse irradiance versus true diffuse irradiance.

The performance of the models considered are analyzed by the residual differences (calculated as corrected diffuse irradiance minus true diffuse irradiance values) against clearness index and solar altitude. Figures 20.16a,b and 20.17a,b show the residuals

TABLE 20.7 Statistical Results for All-Sky Conditions (Mean Value of the True Diffuse Irradiance is 153.8 W/m²)

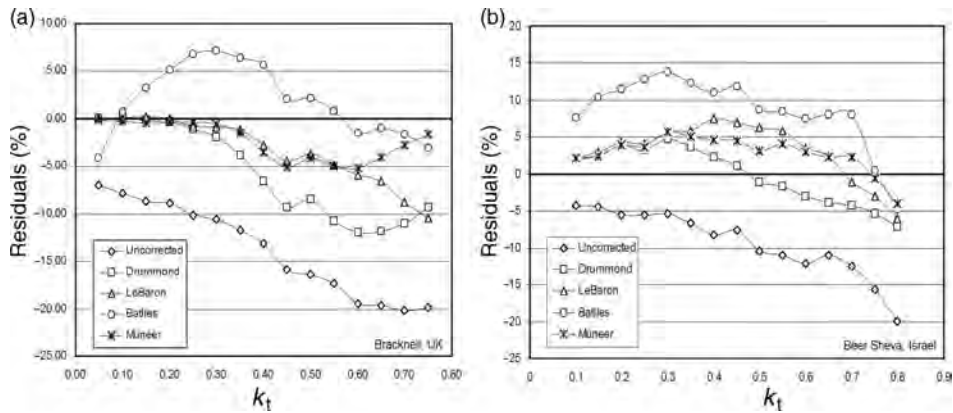

FIGURE 20.16 Residual differences against clearness index. (a) Bracknell, UK, and (b) Beer Sheva, Israel.

expressed as percentage of the mean value of true diffuse irradiance, respectively, for each interval of k_t and solar altitude. Uncorrected measurements of diffuse irradiance present estimates ranging from -5% for low k_t values to -20% for k_t values around 0.8. Residuals from Drummond's isotropic model present almost no deviation for $k_t < 0.2$, whereas an accentuated underestimation is noted for $k_t > 0.6$ with residuals lower than -8 to -10% . This result shows that under cloudy conditions, diffuse irradiance can be considered isotropic, and thus, a correction factor accounting only for isotropic conditions, such as the one proposed by Drummond, leads to fairly accurate corrections. Under cloudless conditions, sky anisotropy plays a major role and an isotropic correction factor is not enough. It is interesting to note that residuals from LeBaron's and Muneer's model present a similar profile, with the worst performers being the Drummond and Battles models.

Four models for correcting diffuse irradiance measurements using shadow band have been analyzed. The Drummond's model treats the sky as an isotropic entity, while the

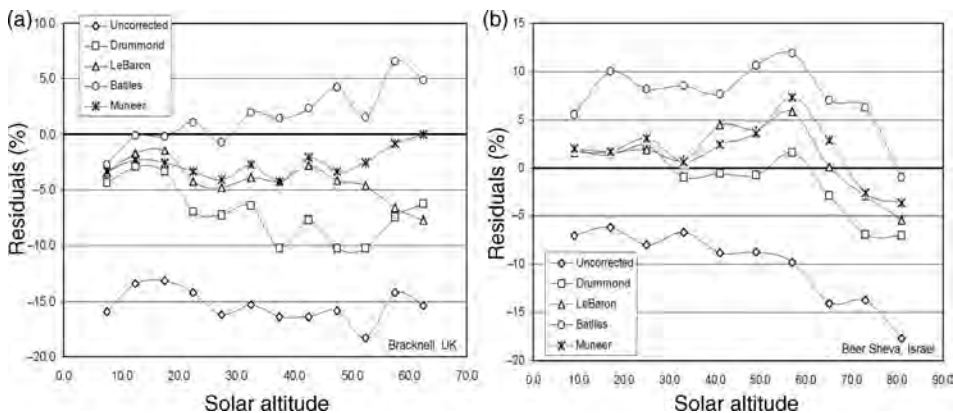

FIGURE 20.17 Residual differences against solar altitude. (a) Bracknell, UK, (b) Beer Sheva, Israel.

other three newer models are of an anisotropic nature. As shown above, using an isotropic correction factor leads to an overall underestimation of the actual diffuse irradiation of 4–11%. The use of anisotropic correction schemes will considerably reduce the above underestimation depending on the model that is chosen. The results showed that the improvement in accuracy is even further improved under a cloudless sky and that the LeBaron and Muneer's models were better in performance than the Drummond and Batlles procedures. Finally, owing to the large errors it generates, particularly in the higher clearness index range where the capture of solar energy is most crucial, it is recommended that Drummond's model is dropped as the *de facto* procedure currently used by numerous meteorological organizations.

20.6 TYPES OF SENSORS AND THEIR ACCURACY

A survey of radiation instruments undertaken by Lof et al. (1965) showed that of the 219 sensors in use across Europe, 65 were of the CM11 type pyranometers while 107 sensors were the simpler and less expensive Robitzch actinographs with a bimetallic temperature element. The latter instrument is also quite popular in the developing Asian (89 such sensors were reported to be in use), African (20.20.16 sensors), and South American (20.47 sensors) countries where maintenance is often the key factor. The lead author (Muneer) has in the past visited a solar radiation measurement station in the middle of the Sahara desert and seen the Robitzch actinograph faithfully recording a regular trace of irradiation. The weekly changeover of the recording chart makes this instrument an ideal choice for remote locations. Although not in use with the North American meteorological network, it is known to be of use over there in biological and agriculture-related work (Coulson, 1975). Drummond (1965) estimates that accuracies of 2–3% are attainable for daily summations of radiation for pyranometers of first-class classification. Individual hourly summations even with carefully calibrated equipment may be in excess of 5%. Coulson (1975) infers that the errors associated with routine observations may be well in excess of 10%. Isolated cases of poorly maintained equipment but those that are in the regular network may exhibit monthly averaged errors of 10% or more. The Robitzch actinograph, even with all the modifications to improve its accuracy, is suitable only for daily summations. At this interval, it provides an accuracy of around 10%. However, not all designs of the latter sensor can claim even this level of accuracy. These figures must be borne in mind when evaluating the accuracy of the relevant computational models.

20.7 MODERN DEVELOPMENTS

Delta-T device of Cambridge, England, has produced a relatively new instrument that measures the horizontal global and diffuse irradiance as well as sunshine duration from a single, stationary sensor. Unlike the Campbell–Stokes sunshine recorder, the Delta-T device neither requires any cards or shade ring for the measurement of sky-diffuse irradiance. The BF3 model, shown in Figure 20.18, enables simultaneous recording of the abovementioned three sets of data in a sensor that used no moving parts and required no specific polar alignment or routine adjustment. The electronic outputs are compatible with electronic data loggers and work at any latitude.

FIGURE 20.18 The BF3 sensor (D-T Devices, 2010). (Photo courtesy of Delta-T, Cambridge, England).

The device uses a system of photodiodes and a shading pattern such that wherever the sun is in the sky at least one photodiode is always exposed to the full solar beam and at least another one diode is always completely shaded. All photodiodes receive an equal sampling of diffuse light from the rest of the sky hemisphere. A special layout of seven photodiodes on a hexagonal grid, covered by a hemispherical shading pattern, ensures the satisfaction of the above constraints. A sketch of the shading pattern of BF3 is shown in Figure 20.19, plotted in a 180° fisheye lens view.

The sensor has a digital output of sunshine presence. As pointed out above, bright sunshine is defined by the WMO as the duration with irradiance greater than 120 W/m^2 in the

FIGURE 20.19 Hemispherical shading pattern for Delta-T BF3 irradiance sensor.

TABLE 20.10 Statistical Summary of BF3 Hourly Average with Respect to Kipp CM11 Readings, Feb 22–Jul 3, 2000

	Calibration Error (%)	R^2	Standard Error W/m ²
Global	4.7	0.994	16.5
Diffuse	1.4	0.980	13.4

direct beam measured perpendicular to the beam. The microprocessor algorithm within the BF3 sensor uses the measured global and diffuse irradiance to provide an estimate of sunshine duration. An account of BF3's performance, evaluated against Kipp and Zonen irradiance sensors and Campbell–Stokes sunshine recorders, has been presented by Wood et al. (2003).

Table 20.10 gives the results of regression analysis of the BF3 sensor with respect to the Kipp CM11 using the following indicators:

1. calibration error, the deviation of the slope of the line of best fit from unity (expressed in percentage terms),
2. coefficient of determination (R^2),
3. standard error, the root mean square deviation of the measured BF3 values from the line of best fit.

These results show a good match between the global and diffuse outputs of the BF3, and those measured using the Kipps and shade ring.

For evaluation against Campbell–Stokes recorders, two recorders were placed adjacent to each other, namely, CS1 and CS2. These are compared to each other, and also to the WMO reference, for the days when all the data are available. Cards from the CS1 were independently analyzed by two different people, giving results CS1 (SY) and CS1 (JW). Table 20.11 gives a summary of these different regressions. Figure 20.20 shows the BF3 and CS1 values plotted against the WMO reference.

These results show that the Campbell–Stokes recorder is a relatively poor performer when judge against the WMO sunshine definition. It shows a typical error of nearly an hour, some four times greater than the BF3. Although the two adjacent C–S recorders gave fairly consistent results when interpreted by the same person, the two independent operators gave very different interpretations of the same set of record cards, despite working from the same set of guidelines. The variability in interpretation was nearly half as

TABLE 20.11 Sunshine Hour Regressions

Regression	Calibration Error (%)	R^2	Standard Error Hr
BF3 v WMO	−0.2	0.993	0.23
CS1(JW) v WMO	1.3	0.902	0.86
CS1(SY) v WMO	7.5	0.893	0.91
CS2(SY) v WMO	6.3	0.893	0.90
CS1(JW) v CS1(SY)	6.1	0.980	0.38

FIGURE 20.20 BF3 and Campbell–Stokes recorders compared to WMO reference. Note: BF3 = Delta-T BF3 irradiance sensor, CS1 (JW) = Campbell–Stokes recorder 1, CS1 (SY) = Campbell–Stokes recorder 2. Names of observers: John Wood (JW) and Serge Younes (SY).

much as the total error relative to the WMO standard, though neither operator was in fact consistently more accurate than the other.

20.8 DATA QUALITY ASSESSMENT

Data quality assessment is a process or a procedure to avoid spurious data to be included in the data set. Gueymard and Kembezidis (2004) pointed out that even though a data set has passed the quality assessment process or procedure, the data must be examined for its uncertainty that has been transferred from a measuring sensor to the actual measurement. Here, in this section, a summary of a few assessment methods will be discussed.

20.8.1 United State National Renewable Energy Laboratory (NREL), 1993 (NREL, 1993)

The US NREL developed a quality assessment procedure named SERI QC. This procedure will assess the three radiation data elements, namely, global horizontal, diffuse horizontal, and direct normal. Summary of the key features are discussed as follows:

- At the beginning, SERI QC will perform one-element test by defining a range of acceptable values for K_t , K_d , or K_n between minimum and maximum, which depends on the element that is being tested, based on air mass regimes and month of the year.
- If the zenith angle is less than or equal to 80° and all three elements are present, then SERI QC will perform a three-element test. A range of acceptable values will be defined so that the equation $K_t = K_d + K_n$ is satisfied within the arbitrary error limit of ± 0.03 , which accounts for the measurement uncertainties.
- If the data pass the three-element test or two elements pass the one-element test, SERI QC will perform a two-element test by defining a range of acceptable values within the boundaries empirically to determine three different air mass regimes for each month using data collected from the site.

- Flags are assigned to the data after the test. The flagging system of SERI QC permits the assignment of uncertainties that depend on the nature of the test performed (one, two, or three elements) and the distance by which the data point exceed the expected limit.

The values of K_t , K_d , K_n can be defined as follows:

K_t = clearness index or global horizontal transmittance or global horizontal radiation/extraterrestrial horizontal radiation,

K_d = diffuse horizontal transmittance or diffuse horizontal radiation/extraterrestrial horizontal radiation,

K_n = direct normal transmittance or direct normal radiation/extraterrestrial direct normal radiation.

For more in-depth information regarding the procedure, readers are referred to the following website: http://rredc.nrel.gov/solar/pubs/seri_qc/

20.8.2 Commission Internationale de l'éclairage (CIE) Automatic Quality Control (Kendrick, 1994)

Brief summary of the five tests in CIE quality control for radiation and illuminance is presented below:

1. A rough boundary limits for global and diffuse irradiance and direct irradiance is set to be less than the extraterrestrial irradiance.
2. To ensure consistency, it utilize the redundancy among three solar radiation components or the diffuse component to be less than the global component plus a 10% allowance for shade ring correction where beam component is not measured.
3. Each aspect of the global irradiance and illuminance is tested, that is, north, east, south, and west.
4. Intercomparisons tests is done between irradiance and illuminance.
5. Tests to compare the zenith luminance with either diffuse irradiance or illuminance were also included.

Bear in mind that CIE noted that automatic testing should not be performed when global irradiance is below 20 W/m^2 and solar elevation is less than 4° .

20.8.3 Page Model

The Page model is based on the work undertaken for the production of the European Solar Radiation Atlas (ESRA) and the Chartered Institution of Building Services Engineers (CIBSE) Guide on weather and solar data (ESRA, 2000; Page, 1997). Page sets out the following steps to control all daily totals of solar radiation data:

- Values for global solar radiation have to be less than the extraterrestrial radiation, and sunshine values have to be less than or equal to corresponding astronomical values.
- Solar radiation values have to lie within the range of the expected clear sky extreme values by considering the influence of the atmospheric layer.

- Basic relationship between different radiation components should be fulfilled.
- Values of solar radiation parameters have to be in specific range compared to nearby station's value with allowance for spatial variability.
- The variation of relative terms (G/E) of the Ångström regression should lie within a defined range.

Note that further details and software for the Page model are provided by Muneer (2004).

20.8.4 Muneer and Fairooz Quality Control Procedure (Muneer and Fairooz, 2002)

This quality control procedure consists of four levels of tests, which emphasize on the global and diffuse radiation. The procedure was developed based on CIE recommendation for first-level test and Page irradiance model for fourth-level test. Those levels of tests are summarized as follows:

1. Adopted from CIE quality control;

$$0 < G < 1.2 E_n,$$

$$0 < D < 0.8 E_n,$$

where E_n is the normal incidence extraterrestrial irradiance.

2. Consistency test that compares between diffuse and global irradiation and between global and horizontal extraterrestrial irradiation.
3. Test based on an expected diffuse ratio-clearness index envelop. This check is to make sure that the diffuse irradiation data is conformed to the limit that set out by the envelope of acceptance.
4. Check on the quality of diffuse irradiance is performed by comparing its value with the diffuse irradiance under two extreme conditions as define by Page.

A further test is carried out on the diffuse and global irradiance by investigating the Linke turbidity values, for example, when the Linke turbidity value is less than 2.5 or greater than 12, a close inspection of the corresponding data is required.

Refer to the graphical procedure as mentioned in level three tests above, Younes et. al. (2005) proposed a new standard deviation procedure to produce an envelope of acceptance. This procedure basically categorize diffuse ratio-clearness index in the band of k_t . For any given band of k_t , outliers are identified as data points lying outside the envelope, which is defined by $\bar{k} \pm 2\sigma_k$ boundaries. For more in-depth discussion, readers are referred to the reference article.

20.9 STATISTICAL EVALUATION OF MODELS

As pointed out in Section 20.1, the accuracy of mathematical models for estimating solar radiation is approaching the measurement accuracy of instruments. A number of routines, therefore, now use mathematical models for assessing the quality of measured data. Thus, in this section, an account of crosschecking the two set of procedures, that is, relationship or trend between the two sets of quantities, that is, models and measured data is presented.

FIGURE 20.21 Plot of residuals for evaluating the adequacy of the model: (a) adequacy, (b) Y_o needs transformation, (c) missing linear independent variable, and (d) missing linear or quadratic independent variable.

Checking on the adequacy of the mathematical model describing any physical process such as a given solar radiation model is important not only in the final stages of the work program, but more particularly in the initial phase. An examination of residuals is recommended. The procedure is to produce a graph of the residuals d (the difference between observed Y_o and calculated Y_c values of the dependent variable) plotted against the independent variable X or the observed value Y_o .

If the residuals fall in a horizontal band as shown in Figure 20.21a, the model may be judged as adequate. If the band widens as X or Y_o increases, displayed in Figure 20.21b, it indicates a lack of constant variance of the residuals. The corrective measure in this case is a transformation of the Y variable. A plot of the residuals such as Figure 20.21c indicates the absence of an independent variable in the model under examination. If, however, a plot such as Figure 20.21d is obtained, a linear or quadratic term would have to be added.

Often correlation between two quantities is also to be examined. In solar energy literature, it has become a common practice to refer regression models as “correlation equations.” Strictly speaking, this is wrong usage of statistician’s language. Correlation is the degree of relationship between variables, and one seeks to determine how well a linear or other model describes the relationship. On the other hand, regression is a technique of fitting linear or nonlinear models between a dependent and a set of independent variables. Thus, fitting an equation of the form:

$$Y = a_0 + a_1X \quad (20.26)$$

for n pairs of (X, Y) is an example of linear regression. On the other hand, fitting:

$$Y = a_0 \exp(a_1X) + b_0 \sin(b_1X) \quad (20.27)$$

is an example of a nonlinear model. A number of low-priced software packages are available, which adequately cover the requirements of fitting linear and nonlinear models. The popular spreadsheet packages such as Lotus 1-2-3 (a product of Lotus Corporation) and

Excel (a product of Microsoft Corporation) as well as more specialist statistical packages such as SOLO and BMDP (products of BMDP Statistical Software Inc., California) are a few examples. For handling very large data arrays, one has to resort to FORTRAN and C environments. The text *Numerical Recipes* by Press et al. (Press, 1992), with its companion electronic suite of programs, offers solutions at this end. All of the above packages use robust and efficient routines, which obviate any particular need for developing optimization programs from scratch. In the following paragraphs, a brief discussion on the statistical examination of models is provided.

20.9.1 Slope of the Best-fit Line, s

The slope of the best-fit line, given by Equation 20.28, between the computed and measured variable is desired to be as close as possible to unity. Slope values exceeding one indicate overestimation, while slope values under one indicate underestimation of the computed variable,

$$s = \frac{\sum(Y_m - \bar{Y}_m)(Y_c - \bar{Y}_c)}{\sum(Y_m - \bar{Y}_m)^2} \quad (20.28)$$

Note that Y_c is the calculated value of the dependent variable, Y_m the measured or observed value, and \bar{Y}_m the mean value of the measured variable.

20.9.2 Coefficient of Determination, r^2

The coefficient of determination (r^2) is the ratio of explained variation to the total variation. r^2 lies between zero and one,

$$r^2 = \left[\frac{\sum(Y_m - \bar{Y}_m)(Y_c - \bar{Y}_c)}{\sqrt{\sum(Y_m - \bar{Y}_m)^2 \sum(Y_c - \bar{Y}_c)^2}} \right]^2 \quad (20.29)$$

A high value of r^2 , thus indicating a lower unexplained variation, is desirable. r^2 is often used to judge the adequacy of a regression model, but it should not be the sole criterion for choosing a particular model. In the present context, r^2 provides an indication of the order of scatter between Y_c and Y_m . Further information may be obtained in Montgomery and Peck (1992) and Draper and Smith (1998).

20.9.3 Coefficient of Correlation, r

The square root of the coefficient of determination is defined as the coefficient of correlation r . It is a measure of the relationship between the variables based on a scale ranging between +1 and -1. Whether r is positive or negative depends on the inter-relationship between x and y , that is, whether they are directly proportional (y increases and x increases) or vice versa. Once r has been estimated for any fitted model, its numerical value may be interpreted as follows. Let us assume that for a given regression model $r = 0.9$. This means $r^2 = 0.81$. It may be concluded that 81% of the variation in Y has been explained (removed) by the model under discussion, leaving 19% to be explained by other factors.

20.9.4 Student's t -Distribution

Often the modeler is faced with the question as to what quantitative measure is to be used to evaluate the value of r^2 obtained for any given model (Owen and Jones, 1990). Clearly, r^2 would depend on the size of the data population. For example, a lower value of r^2 obtained for a model fitted against a large database may or may not be better than another model that used a smaller population. In such situations, the Student's t -test may be used for comparing the above two models. The following example demonstrates the use of this test of significance for r^2 .

EXAMPLE 20.1: *For a given location, a regression model between average clearness index (\bar{K}_T) and monthly averaged sunshine fraction (n/N) gives $r^2 = 0.64$ for 12 pairs of data points. Using Student's t -test investigates the significance of r .*

The test statistic $t = (n - 2)^{0.5} [r / \sqrt{(1 - r^2)}]$, where n is the number of data points and $(n - 2)$ is the degrees of freedom (d.f.).

Thus,

$$\text{Test statistic } t = (12 - 2)^{0.5} [0.8 / \sqrt{(1 - 0.64)}] = 4.216.$$

In this example there are 10° d.f. Thus from Table 20.12, the value of $r = 0.8$ is significant at 99.8% but not at 99.9% (note that for d.f. = 10 and $t = 4.216$ lies between 4.144 and 4.587 corresponding to columns for 0.998 and 0.999, respectively). In layman terms, this means that using the above regression model, \bar{K}_T may be estimated with a 99.8% confidence.

TABLE 20.12 Percentile Values for Student's t -Distribution (EPLAP, 2010)

d.f	$P = 0.95$	0.98	0.99	0.998	0.999
1	12.706	31.821	63.657	318.310	636.620

500	1.965	2.334	2.586	3.107	3.310
1000	1.962	2.330	2.581	3.098	3.300
∞	1.960	2.326	2.576	3.090	3.291

20.9.5 Root Mean Squared Error, RMSE

The root mean squared error (RMSE) gives a value of the level of scatter that the model produces. This is an important statistical test as it highlights the readability and repeatability of the model. It provides a term-by-term comparison of the actual deviation between the predicted and the measured values. Because it is a measure of the absolute deviation, RMSE is always positive. A lower absolute value of RMSE indicates a better model. Mathematically, it is given by the following equation:

$$\text{RMSE} = \sqrt{\sum \left[\frac{(Y_c - Y_m)^2}{n} \right]} \quad (20.30)$$

20.9.6 Mean Bias Error, MBE

The mean bias error (MBE) provides an indication of the trend of the model, whether it has a tendency to underpredict or overpredict the modeled values. MBE can be expressed either as a percentage or as an absolute value. Nevertheless, within a data set, an overestimation of one observation can cancel an underestimation of another. A MBE nearest to zero is desired. It is given by the following equation:

$$\text{MBE} = \frac{\sum (Y_c - Y_m)}{n} \quad (20.31)$$

20.9.7 Mean of Absolute Deviations, MAD

Another metric that is often used in such analysis is the mean of absolute deviations, (MAD), and is given by,

$$\text{MAD} = \frac{\sum |Y_c - Y_m|}{n} \quad (20.32)$$

Unlike MBE, the MAD metric provides an insight into the scatter between Y_c and Y_m . Note that the MAD is similar to RMSE and provides a measure of absolute deviations.

20.9.8 Nondimensional MBE, MAD, and RMSE

The above formulas provide MBE, MAD, and RMSE, which have the same physical units as the dependent variable, Y . In some instances, nondimensional MBE (NDBE), MAD (NDMAD), and RMSE (NDRMSE) are required. These are obtained as follows:

$$\text{NDBE} = \frac{\sum \left[\frac{(Y_c - Y_m)}{Y_m} \right]}{n} \quad (20.33)$$

$$\text{NDMAD} = \frac{\sum \left| \left[\frac{(Y_c - Y_m)}{Y_m} \right] \right|}{n} \quad (20.34)$$

$$\text{NDRMSE} = \sqrt{\frac{\sum \left[\frac{(Y_c - Y_m)}{Y_m} \right]^2}{n}} \quad (20.35)$$

20.9.9 Figure of Merit, ψ

One of the important steps in the evaluation of different functions is the interpretation of different statistical parameters, namely, slope, r^2 , MBE, MAD, and RMSE. Often when two or more models are intercompared for their relative strengths and weaknesses, there may be a tie between the above-mentioned metrics. For example, a model may have a lower MBE but a higher RMSE. Therefore, an overall accuracy score is highly desirable to facilitate a discrete comparison between different models. In this article, a novel statistical tool combines the five metrics mentioned above to produce an overall score. With the view to demonstrate this point, Figure 20.22a shows a slope that has a large deviation from the ideally sought value of 1 but a high value of r^2 , whereas in Figure 20.22b the slope is very close to the ideal value, but a low value of r^2 is realized due to large data scatter. Therefore, case in Figure 20.22b would be preferable over case in Figure 20.22a. Similarly, Figure 20.22c presents a smaller but systematic trend of deviation, notice the negative deviations in the middle range, with positive outcomes at the lower and higher ends. In the case of Figure 20.22d, an almost equal spread of positive and negative but larger deviations is noticed. Although case in Figure 20.22d would provide a much higher value of MBE, case in Figure 20.22d would, however, be preferable over case in Figure 20.22c. Overall, it can be concluded that the slope parameter provides a much more important indication of the validity of any given model. The r^2 of the line fitted between computed and observed data, MBE, MAD, and RMSE for the given model's deviation provide second order information as higher values of r^2 or lower values of MBE, MAD, and RMSE do not warrant a better model. Ideally, the latter four parameters ought to be examined in conjunction with the value of slope. The following overall accuracy score is

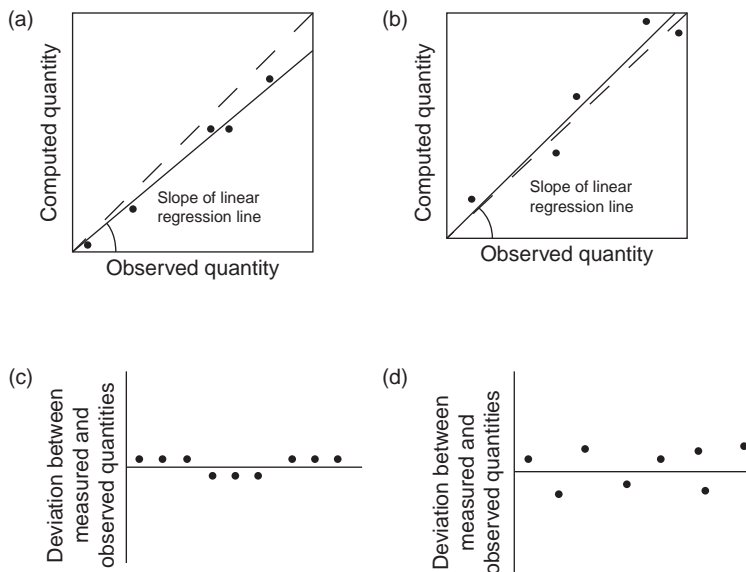

FIGURE 20.22 Basic concepts for the statistical parameters used. (a) Slope has a large deviation but with a reduced data scatter about the fitted line. (b) Slope is very close to ideal value but with an enhanced data scatter. (c) Smaller but a systematic trend of deviations. (d) An almost equal spread of positive and negative but larger deviations.

proposed with varying weighing factors of 3, 1, 1, 1, and 1 for s , r , RMSE, MBE, and MAD, respectively,

$$\Psi = 3[s] + [r] + \left[1 - \frac{\text{RMSE}}{\text{RMSE}_{\max}}\right] + \left[1 - \frac{|\text{MBE}|}{|\text{MBE}|_{\max}}\right] + \left[1 - \frac{\text{MAD}}{\text{MAD}_{\max}}\right] \quad (20.36)$$

Note that s and r are dimensionless, unlike RMSE, MBE, and MAD, and therefore, the latter three are, respectively, divided by the values of RMSE_{\max} , $|\text{MBE}|_{\max}$, and MAD_{\max} . Ψ is a convenient figure of merit, by means of which it is possible to compare the performance of any suite of models. Therefore, for a perfect fit, the overall accuracy score Ψ will be 7.

20.10 OUTLIER ANALYSIS

Often in solar radiation studies, we encounter data that lie unusually far removed from the bulk of the data population. Such data are called “outliers.” One definition of an outlier is that it lies three or four standard deviations or more from the mean of the data population. The outlier indicates peculiarity and suggests that the datum is not typical of the rest of the data. As a rule, an outlier should be subjected to particularly careful examination to see whether any logical explanation may be provided for its peculiar behavior. Automatic rejection of outliers is not always very wise. Sometimes, an outlier may provide information that arises from unusual conditions. Outliers may however be rejected if the associated errors may be traced to erroneous observations due to any one or a combination of factors described in previous sections of statistical analysis.

Statistically, a “near outlier” is an observation that lies outside 1.5 times the interquartile range. The interquartile is the interval from the 1st quartile to the 3rd quartile.

The *near outlier* limits are mathematically defined by:

$$\text{Lower outlier limit : 1st quartile} - 1.5 (\text{3rd quartile} - \text{1st quartile}) \quad (20.37)$$

$$\text{Upper outlier limit : 3rd quartile} + 1.5 (\text{3rd quartile} - \text{1st quartile}) \quad (20.38)$$

Likewise, *far outliers* are defined as the data whose limits are defined below:

$$\text{Lowerlimit : 1st quartile} - 3 (\text{3rd quartile} - \text{1st quartile}) \quad (20.39)$$

$$\text{Upper limit : 3rd quartile} + 3 (\text{3rd quartile} - \text{1st quartile}) \quad (20.40)$$

A high number of outliers in a given data set signify that the observations have a high degree of variability or a large set of suspect data indicating poor station operation. For a more rigorous discussion on outlier analysis, readers are referred to the reference made to Draper and Smith (1998) and Montgomery and Peck (1992).

ACKNOWLEDGMENTS

This contribution has relied heavily on the work of a number of contributions, all of which have been presently referenced. However, the three sources that were of

particular and significant use were the following: *Solar and Terrestrial Radiation* by Coulson (1975), *Solar Radiation and Daylight Models* by Muneer (2004), and photographs of sensors and equipment that were obtained from Delta-T of England, EKO Instruments of USA, Eppley of USA, Kipp and Zonen of Netherlands, and Middleton Solar of Australia.

21.1 INTRODUCTION

Understanding the wind is critical to any wind energy application. The starting point in any wind energy project is the wind resource assessment (WRA) that quantifies the wind resource available at a given location, as well as establishes several other important parameters. The wind resource assessment feeds into the site suitability analysis, which determines the suitability of a particular wind turbine to the local wind conditions. As part of the site suitability process, a mechanical loads analysis (MLA) may be performed to assess turbine hardware constraints against the loading and fatigue expected at the site given the output of the wind resource assessment, thus establishing the suitability of the proposed turbine hardware to the proposed site. The wind is the fuel for a wind turbine power plant and so wind is a critical input in the energy estimation.

21.1.1 Terms and Definitions

- a. *Anemometer*: a device used to measure wind speed.
- b. *Hub Height Wind Speed*: for a horizontal axis turbine, the wind speed at the turbine rotor centerline.
- c. *Mechanical Loads Analysis (MLA)*: a detailed engineering study to calculate the mechanical stresses for a specific wind turbine configuration which factors in the specific atmospheric conditions at a given location.
- d. *Rated Wind Speed*: the wind speed at which a turbine achieves rated power.
- e. *SCADA*: system control and data acquisition.
- f. *Shear*: the gradient of wind speed with height above the ground.
- g. *Stable Atmosphere*: an atmospheric condition where the atmosphere forms thermal layers, characterized by a high temperature gradient, a high wind speed gradient (shear), and low turbulence.
- h. *Turbulence*: departure from smooth, laminar flow or fluctuations in the speed and direction of the flow.
- i. *Turbulence Intensity*: the standard deviation of wind speed divided by the mean wind speed over a 10-min period, which is used as a numerical quantification of turbulence.
- j. V_{Ref} (*Reference Wind Speed*): 50-year extreme 10-min average wind speed.
- k. V_{50} : the 50-year maximum 3 s gust wind speed.

21.2 CONCEPTS

21.2.1 Power in the Wind

The power in the wind available to a wind turbine is determined from the momentum of the mass flowing through the turbine. The mass flow rate is determined by the wind speed, air density, and rotor area. Of course not all of the energy in the wind is converted into electrical energy as that would result in a velocity of zero downwind of the turbine, so a

term is added for the efficiency of the energy capture called the power coefficient, C_p . Thus, the power in the wind is given by the equation:

$$P = 0.5 \times \rho \times V^3 \times A \times C_p \quad (21.1)$$

where P = power, W; ρ = air density, kg/m³; V = wind speed, m/s; A = rotor area, m²; and C_p = power coefficient.

From this equation it can be seen that power is proportional to air density and more important to this discussion, power is proportional to the cube of wind speed. Thus, the sensitivity of the wind speed measurement to our parameter of interest, power, is very high. The accuracy of the wind speed measurement is, therefore, critical for most wind energy applications, and in particular for wind energy assessment and for evaluation of wind turbine performance.

The maximum theoretical efficiency for a wind turbine is the Betz limit, which is 59.3% or 0.593.

21.2.2 Power Curve

The power output of a wind turbine is characterized by its power curve, which is simply the electric power output of the wind turbine plotted against wind speed. Power curves vary by turbine type and technologies employed, but power curves typically have several characteristics:

- *Cutin Wind Speed*: the minimum wind speed for the turbine to produce power, typically over 3 m/s.
- *Cutout Wind Speed*: the storm shut down wind speed above which the turbine does not operate for safety reasons.
- *Rated Wind Speed*: the wind speed at which the turbine achieves rated power.
- *Rated Power*: this is typically the maximum output of the wind turbine. Power is proportional to the cube of wind speed; however, a wind turbine limits its maximum power output due to limits of the turbine hardware.

There are two strategies commonly employed to limit the power output of Horizontal Axis wind turbines so that it does not exceed the turbine's rated power. These are active pitch control and stall control.

Active pitch-controlled turbines pitch the blades to reduce the aerodynamic efficiency once rated power is reached. The blades can be pitched to maintain a constant power output once rated power is reached. Figure 21.1 shows an example of a power curve for an active pitch-controlled turbine.

Stall-controlled turbines typically have fixed blades that do not pitch. Instead the blades are designed such that above a certain wind speed, flow separation occurs sending the blades into aerodynamic stall, thus reducing the efficiency of the turbine. The power output of stall-controlled turbines usually decreases once rated power is reached because the stall becomes more severe with increasing wind speed. Figure 21.2 shows an example power curve for a stall-controlled turbine.

FIGURE 21.1 Example pitch control turbine power curve.

21.2.3 Micrositing

Micrositing is the process of locating and spacing wind turbines to optimize the power production, maintain loads within the turbine design limits, and balance the number of turbines with land constraints. Micrositing takes several factors into account, including

- *Terrain Effects:* ideally turbines will be located in positions that maximize power production. For example, it is best to locate a wind turbine at the top of a hill or ridge line so that it is exposed to the most wind and takes advantage of the natural speedup effect as the wind moves over the ridge.

FIGURE 21.2 Example stall control turbine power curve.

- *Layout and Turbine Spacing*: upwind turbines remove energy from the wind for downwind turbines to capture, called waking. Also turbine wakes increase turbulence, which can impact the mechanical loads on the downwind turbines. Ideally turbines should be laid out in rows that are perpendicular to the wind and spaced far apart to allow for more energy capture and minimal wake effects.
- *Turbine hub height*: for horizontal axis turbines, the hub height may be optimized to capture the most energy. In general, taller turbines capture more energy; however, there are rare situations where lower hub height turbines are more desirable, such as along a ridge line. Also there is more cost associated higher hub heights and there may be loads limitations.
- *Setbacks to roads and residences*: this mainly driven by noise and safety concerns such as ice shedding.

21.3 MEASUREMENTS

21.3.1 Basic Setup

A typical measurement involves a meteorological tower with sensors at different heights. At a minimum, wind speed and wind direction are measured near the top of the tower. These should be measured at the hub height of the turbine. If this is not the case, then shear must be measured to allow the wind speed to be extrapolated to the turbine hub height. In order to measure wind shear and veer, wind speed and wind direction measurements should be made at lower elevations. Temperature and pressure are measured to record the site air density, and also the temperature measurement is useful for sensor icing detection. A precipitation sensor may also be included.

21.3.2 Meteorological Towers

There are several types of meteorological towers commonly used. Each has its advantages and disadvantages. The most common types are discussed below.

21.3.2.1 Tilt-Up Towers Tilt-up towers are low cost and relatively easy to transport and install. Typically, a tilt-up tower is a tubular design supported by guywires. Also a tilt-up tower may be mounted on a base plate staked into the ground, not requiring a concrete foundation. The segments are bolted together with the tower lying horizontally on the ground. Booms are added and the sensors are mounted while the tower is still on the ground. The tower then is winched up to a vertical position and the guywires are tightened to secure it. Tilt-up towers are popular for wind resource assessment because they are low cost, easy to transport and set up in remote locations, and do not require a crane to install. The main drawbacks to tilt-up towers are that they are limited in height, typically to not more than 60 m, and if a sensor fails the tower must be lowered to replace it.

21.3.2.2 Guyed Lattice Towers Guyed lattice towers are very sturdy and may be erected to very high heights. Very tall towers used for research (up to 200 m) are guyed lattice. They are erected vertically in place using either a crane or a gin-pole. Typically, the

FIGURE 21.3 Guyed lattice tower.

tower and guywire anchors require concrete foundations. If a sensor fails, a guyed lattice tower may be climbed to replace it. Figure 21.3 shows an example of a guyed lattice tower.

21.3.2.3 Freestanding Towers The main advantage of freestanding tower is that it has a smaller footprint than a guyed lattice tower while it is still able to reach the hub heights of modern large wind turbines (typically 60–100 m). This makes it ideal for use in farmland where the guywires and guywire anchors would otherwise be an obstacle to farm equipment, making the land around the tower base unusable. The main drawback is that the smaller footprint comes at a higher cost relative to guyed lattice towers. Figure 21.4 shows an example of a freestanding meteorological tower.

21.3.3 Remote Sensing Devices

Remote sensing devices are becoming more common with recent advances in remote sensing technology. The most common remote sensing devices are LIDAR and SODAR. Both technologies operate on the same principles

Beams of energy (light in the case of LIDAR and sound in the case of SODAR) are shot up into the atmosphere at various angles and directions forming a cone. The energy

FIGURE 21.4 Freestanding meteorological towers.

is reflected back to the device either by particles in the air or from atmospheric turbulence. The device then uses Doppler effect and determines the wind speed, direction and flow angle from the measurements at different points in the cone at several predetermined heights. See Figure 21.5 for an illustration.

The main advantage of this technology over met tower measurements is that the devices are portable, very easy and fast to set up, and may not require any permitting. Note that meteorological towers require extensive permitting for installation, which can be costly and time consuming.

The advantages and disadvantages will vary by device and manufacturer. In general, LIDAR provides data up to very high heights (200 m) with very low data loss rates; however, LIDAR also tends to have a very high power consumption and may require an external power source such as a generator or connection to the power grid. SODAR will also provide measurements up to similar heights; however, SODAR tends to have higher data loss rates at the higher heights. However, the data quality at the typical range of hub heights for large wind turbines, 60–100 m, is generally very good. SODAR typically has lower power consumption than LIDAR, and there are SODAR units commercially available that are self-powered via solar panel.

21.3.4 Wind Speed

The most important measurement and also the most sensitive is wind speed. Power is proportional to the cube of wind speed, so relatively small errors in wind speed translate to large errors in power/energy.

FIGURE 21.5 Remote sensing device versus a meteorological tower.

Devices that measure wind speed are called anemometers. Considerations when selecting an anemometer include the device accuracy (including operational response to turbulence, flow inclination, and temperature effects), durability for long-term field use, and resistance to icing and cost. The most common types will be discussed in the following sections.

21.3.4.1 Cup Anemometers Cup anemometers are the most common anemometer type in use. A cup anemometer consists of three cups mounted on a horizontal rotor. When the wind blows, the cups catch the wind, spinning the rotor. The rotor shaft is connected to an electronic sensor that typically registers a certain number of pulses each time the shaft rotates. The wind speed is determined by the number of pulses counted over a time interval, typically 1 s.

Cup anemometers typically have very low power consumption, making them ideal for remote applications where power supply is limited. Also, cup anemometers are usually designed to measure the horizontal wind speed, not a vector component, so the device measures the same regardless of the direction that the wind is coming from.

Cup Anemometer Operational Characteristics Cup anemometers are mechanical systems, and their accuracy will change in different wind conditions depending on the anemometer aerodynamics, rotor inertia, and other operational characteristics.

The IEC 61400-12-1 contains a classification scheme to determine the accuracy of cup anemometers in different environmental conditions. Three factors in particular stand out

FIGURE 21.6 In-flow angle.

Upflow: Wind turbine performance is defined in terms of the horizontal wind speed component, as that is what the turbine converts to energy. Most cup anemometers are designed to measure the horizontal wind speed component; however, their ability to do this at increasing flow angles depends on the anemometer aerodynamics and differs by make and model. See Figures 21.6 and 21.7 for an example of how anemometer accuracy varies with inflow angle. At the example inflow angle of 11° , this anemometer would have an error of about 0.5% versus the ideal cosine response. This may not seem significant, but recall that power is proportional to the cube of wind speed.

Turbulence: A good illustration of the impact of turbulence on a wind sensor is the pinwheel, which is essentially a propeller on a stick. When you blow into it the propeller will spin but it does not stop spinning right away when you stop blowing. When talking about an anemometer, this is called over-speeding and causes the average wind speed recorded to be higher than the actual wind speed over time. The response time of an anemometer depends on the rotor inertia and aerodynamics, and so it will vary for different makes and models.

FIGURE 21.7 Anemometer upflow response.

Temperature: The friction characteristics of the anemometer bearings will change with temperature. The degree to which they change will impact the anemometer accuracy at those temperatures.

Note that this is different from icing of the anemometer cups, which will have a significant impact on the anemometer. Data where the device is believed to be iced are normally filtered out. Some anemometers have heated cups to prevent icing.

Also note that the sensor accuracy may change over time as the sensor bearings wear or if the cups become damaged.

The IEC 61400-12-1 provides a procedure to classify anemometer operational characteristics through controlled wind tunnel and laboratory tests. The anemometer classification report can be used to select a device with sufficient accuracy at the expected local conditions.

21.3.4.2 Ultrasonic Anemometers Ultrasonic anemometers measure the wind speed with sound waves and using the Doppler effect. Unlike SODAR that measures the wind at a distance, ultrasonic anemometers measure the wind as it passes through a gap or open area in the device.

Ultrasonic anemometers are either two-dimensional, measuring the two horizontal wind speed components, or three-dimensional, measuring the two horizontal components and the vertical component of the wind speed.

Since Ultrasonic anemometers measure the wind speed vectors, they also measure wind direction.

Ultrasonic anemometers do not have moving parts that may wear out over time; however, they do have higher power consumption than cup anemometers. Also the geometry of the device may cause flow distortion, which is different depending on the wind direction, for example, if the wind is along the axis of the device that is obstructed by the sensor prongs. The device may or may not compensate for this.

21.3.4.3 Propeller Anemometers There are some propeller anemometer devices commercially available; however, these are generally not considered to have sufficient accuracy for wind power measurements. If the propellers are fixed (do not move with wind direction), then the off-axis measurements will not have sufficient accuracy. If the propeller is mounted on a wind vane so as to keep the propeller pointed into the wind, then the flutter of the wind vane will interfere with the wind speed measurement.

21.3.4.4 Pitot Tube Devices Pitot tube devices are rarely used in wind energy applications. Typically, they are not very accurate at low wind speeds, they have the same issues as propeller anemometers with respect to orientation to the wind, and the narrow tubes are not well suited for outdoor, long-term measurement applications where they are exposed to dust, insects, and precipitation, which may clog the tubes.

21.3.4.5 Remote Sensing Devices Remote sensing devices previously discussed offer an attractive alternative to meteorological tower mounted sensors in some applications. It should be noted that remote sensing devices such as SODAR and LIDAR do not measure the same thing as meteorological tower mounted sensors. Meteorological tower mounted sensors measure the wind speed and direction at a point location, while a remote sensing device measures the wind speed and direction over an area. Although the results are

similar, this makes it difficult to compare them directly. This is especially evident in the turbulence intensity measured by a remote sensing device compared with that measured by a met tower. A remote sensing device may not be as well suited to long-term measurement than a met tower. Also remote sensing devices may not work in certain conditions. This limits the ability to determine the extreme wind conditions with these devices. At the time of print of this chapter, the industry consensus is for most applications remote sensing works best to compliment meteorological tower data rather than replace it. The intended use of the data must be considered when deciding whether to employ a remote sensing device for replacing met tower data.

21.3.5 Wind Direction

Wind direction measurements are typically made with a wind vane. Most wind direction sensors consist of a wind vane mounted on a shaft and connected to a potentiometer mounted in the sensor body. Thus, the resistance of the potentiometer is a function of the orientation of the wind vane. Note that there may be a small dead-band, typically at zero degrees, where the device passes through a gap in the potentiometer.

Wind direction may also be measured by the wind speed sensor, as discussed for ultrasonic sensors and remote sensing devices.

Two items worth discussing for wind direction measurement are the accuracy of the vane orientation and north jump.

21.3.5.1 Wind Direction Sensor Orientation Critical to the accuracy of the wind direction measurement is to know which way true north is relative to the sensor north. All wind direction sensors should have a zero degree mark or some indication of what the device considers zero degrees to be.

For a boom-mounted device, a best practice is to mount the device such that its zero degree mark is in line with the boom. Once installed, the direction of the boom can be determined from the ground using binoculars and a GPS or compass. The direction of the boom relative to north is the offset that must be applied to the wind direction signal.

Note that when using a compass, the measured boom direction must be corrected for magnetic declination; that is corrected from magnetic north to true north. The correction for magnetic declination can be as high as 15° or more for many locations within the continental United States. The National Oceanic and Atmospheric Administration (NOAA) has information on magnetic declination on its website, www.noaa.gov.

21.3.5.2 North Jump North jump is an error introduced by averaging. If over a 10-min period, the wind vane spends on average 5 min at 355° and 5 min at 5° , then the wind is clearly from the north, but the average of 355° and 5° is 180° , which is from the south. North jump is typically corrected for in the data logger program by using a vector average. It is difficult to correct by postprocessing the data.

North jump is easily detected by plotting wind direction standard deviation versus wind direction. If the data have not been corrected properly for north jump, a rainbow is observed with its peak at 180° . North jump may also be detected by plotting one wind vane against another (see Figure 21.8).

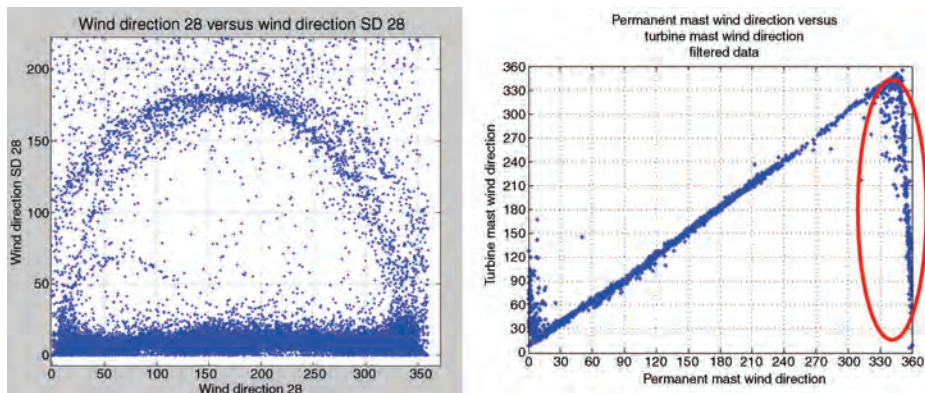

FIGURE 21.8 Detecting north jump.

21.3.6 Air Density

Power in the wind is proportional to air density. Air density varies with altitude, with weather patterns and seasonally. Over the course of a year, the air density at a site may vary by 8% or more from the average value. Air density is also an input to loads calculations. Therefore, it should be included in the measurement campaign to characterize the site and to allow for correction of the data to a reference air density where applicable.

Air density is not measured directly but is calculated from temperature and barometric pressure. Note that humidity is also a factor in the calculation of air density. The impact is small for low temperatures but can be significant at high temperatures, especially in humid climates.

21.3.7 Barometric Pressure

The barometric pressure measurement should be made at hub height if possible; however, if it is measured at a different elevation, the measured value may be corrected for elevation using the method in ISO 2533 (ISO standard atmosphere).

21.3.8 Temperature

Temperature may be measured with any number of temperature sensing devices. Resistance temperature devices (RTDs) are most common.

Since the measurements are made outdoors and exposed to the elements, the temperature sensor should be mounted inside a radiation shield to prevent the sun from heating up the device directly, which will bias the measurement. Also the temperature sensor should be mounted away from any walls, vents, enclosures, or surfaces that will absorb energy from the sun, raising the temperature in the immediate vicinity of the surface (including the ground).

Unlike pressure, which has a consistent gradient with altitude, the temperature gradient varies significantly with atmospheric stability. Therefore, the temperature measurement should be made at the top of the tower or as close to hub height as possible. Placing additional temperature sensors at lower altitudes on the meteorological tower will help to capture information about atmospheric stability.

21.3.9 Humidity

Humidity has a small influence on air density, but the impact can become significant, especially in hot and humid climates. It is therefore recommended that humidity be measured in hot and humid climates; however, in many applications it may be ignored or an assumed reference value used with minimal error to the air density calculation.

21.3.10 Precipitation

In some cases, precipitation may be a desired measurement. Although not used in any calculations, it may be a useful reference parameter. The type of sensor should be selected based on the intended use of the data.

Simple Boolean type sensors provide a signal indicating whether or not precipitation is detected; however, they typically do not provide information about the type or quantity of precipitation. These sensors will typically work for all types of precipitation and may be useful for detection of sensor icing.

A tip-bucket sensor captures information about the quantity and intensity of precipitation; however, these devices may not work for snow and ice.

21.3.11 Wind Turbine Measurements

If an assessment of an actual wind turbine is being made, a minimum of two measurements needs to be made at the turbine: the turbine status or availability and the electric power being produced by the wind turbine.

The turbine status simply needs to indicate whether the turbine is ready and available to produce power or if it is shut down or faulted. This is often a simple Boolean signal and may be obtained using a relay to monitor the main turbine generator circuit breaker or other suitable location.

Power may be output by the turbine control system, or SCADA, or from a wattmeter if a power signal is not available or a higher degree of accuracy is desired. Note that current transformers may be necessary, particularly for larger wind turbines and should be instrument class transformers of accuracy class 0.5 or better. Potential transformers are often not needed as the voltage is often within the range of most wattmeters, even for large wind turbines. However, if voltage transformers are used, they should also be instrument class devices with an accuracy class of 0.5 or better, depending on the accuracy desired.

21.4 EVALUATION

21.4.1 Data Cleaning

The wind data must be cleaned such that invalid data are filtered out. At a minimum, the data should be filtered for the following

1. Icing of the sensors
2. Sensor failure
3. Sensor in the wake (or “shadow”) of the met tower or of another sensor

Other filters may be applied, depending on the intended use of the data.

21.4.2 Data Calculations, Correction, and Processing

21.4.2.1 Method of Bins Wind data are evaluated using the method of bins. Each data point is sorted into wind speed bins, typically the bin size is 0.5 m/s, but bins of 1 m/s are also used.

The data is also sorted into wind direction bins. The wind direction bin size varies depending on the application. For wind resource assessment, bins of 30° are standard. For power curve measurement, a bin size of 10° is used if the terrain is complex, as the data are corrected for flow distortion due to terrain based on wind direction and more granularity is needed.

21.4.2.2 Air Density Calculation Air density may be calculated from the temperature, pressure, and humidity may be calculated from equation (x) below. If the humidity is not measured, a reference humidity typical for the site may be used.

$$\rho_{10 \text{ min}} = \frac{1}{T} \left(\frac{B}{R_{\text{air}}} - \phi P_w \left(\frac{1}{R_{\text{air}}} - \frac{1}{R_w} \right) \right) \quad (21.2)$$

where ρ = air density, kg/m³; T = temperature, K; B = barometric pressure, hPa; ϕ = relative humidity, ratio; R_{air} = gas constant for dry air (21.287.05 J/kgK); R_w = gas constant for water vapor (21.461.5 J/kgK); and P_w = water vapor pressure.

$$P_w = 0.0000205 e^{0.0631846 \times T} \quad (21.3)$$

21.4.2.3 Turbulence Intensity For each 10-min data point, the turbulence intensity is calculated as the standard deviation of the wind speed divided by the mean.

21.4.2.4 Wind Shear Wind shear is the gradient of wind speed with height above the ground. It is calculated from the wind speed measured at different heights for each data point. There are different ways of modeling and expressing wind shear. The most commonly used is the power law, equation (x).

$$v_h = v_{\text{ref}} \left(\frac{h}{h_{\text{ref}}} \right)^a \quad (21.4)$$

where v_h = velocity of wind at height h ; v_{ref} = velocity of wind at reference height h_{ref} ; and A = shear exponent (aka Hellman exponent).

Shear is often a function of atmospheric stability. Atmospheric stability often follows a diurnal pattern of unstable atmosphere during the day and stable atmosphere at night. During the day, the sun heats the ground which causes thermal rises, mixing and higher turbulence, which results in low shear. At night the atmosphere forms thermal layers with a high temperature gradient, high wind shear, and low turbulence. For example, during the day a site might have a shear exponent of 0.2 or less while at night it may be as high as 0.4 or more.

21.4.2.5 Extrapolation of Wind Speed to Hub Height If the wind speed is measured at a height other than the hub height of the turbine, the wind speed at the turbine rotor

centerline may be interpolated or extrapolated using the power law and the shear exponent. This should be done for each 10-min data point rather than adjusting the averaged results because the shear conditions will vary significantly and there may be a correlation between wind speed and certain shear conditions.

21.4.3 Wind Resource Assessment

The goal of a Wind Resource Assessment is to quantify the wind resource and to determine the inputs for the site suitability analysis. It characterizes the frequency of wind speed, the frequency of wind direction, the average site air density, the site wind shear characteristics, and the turbulence intensity profile. The data are also used to estimate 50-year maximum 10-min windspeed (V_{Ref}) and the 50-year maximum 3-s gust (V_{50}).

Wind conditions vary seasonally and so a minimum of 1 year of data is required for an accurate wind resource assessment; however, there are longer multiyear trends in weather patterns and wind conditions and so in general, more is better.

Wind data are captured at one or more locations at or near the intended wind turbine or wind farm location. For larger wind farms, more data collection locations are desirable.

The WRA data are then extrapolated to the individual turbine locations factoring in the influence of terrain, surface roughness, wakes from neighboring turbines, and other factors.

The output of the WRA is a necessary input to the site suitability analysis, which analysis the design life of a specific turbine to the site conditions, and is used to estimate the expected energy production.

21.4.3.1 Wind Speed Distribution The speed distribution is determined from the count of the occurrence of each wind speed bin. The result is then normalized to a frequency of occurrence (percent of time spent in each bin) or normalized to 1 year and expressed, as the number of hours spends in each bin (hours per year). This is expressed as a table of values, with wind speed bin in one column and hour or percent in the other.

Instead of a table of values, the data may be fitted to a Weibull distribution, which is characterized by a shape factor (k) and a scale factor (A) (see Figure 21.9).

The probability distribution function for a Weibull distribution is

$$F(V, A, k) = \frac{k}{A^k} V^{k-1} e^{-(V/A)^k} \quad (21.5)$$

where V is the wind speed; A is the Weibull scale factor; and k is the Weibull shape factor.

A site's wind distribution is sometimes referred to as its Weibull. Also it is sometimes useful to calculate the annual average wind speed from the distribution as a reference.

The wind speed distribution is calculated including all wind directions. A wind distribution is also calculated for each wind direction bin.

21.4.3.2 Wind Rose The wind direction frequency is characterized by the wind rose. The frequency of occurrence for each wind direction bin is determined. The data are typically plotted on a radar-graph. The result looks the petals of a flower, which give the wind rose its name (see Figure 21.10).

FIGURE 21.9 Example wind distribution.

The wind rose may also be expressed as an energy rose, which combines information about the wind speed in each wind direction bin to provide a further level of detail.

21.4.3.3 Average Air Density The average air density is determined from the data. It is usually not necessary to subdivide air density by wind speed or measurement sector.

21.4.3.4 Turbulence Intensity For each 10-min data point, the turbulence intensity is calculated as the standard deviation of the wind speed divided by the mean. This data are then sorted into wind speed bins and averaged, giving a profile of turbulence intensity versus wind speed. This is typically not broken down by wind direction, but this may be useful to do if the terrain is significantly different on one side of the site.

FIGURE 21.10 Example wind rose.

Note that the IEC 61400-1 defines a reference turbulence intensity profile. If a site is referred to as having a specific turbulence intensity value this usually means the turbulence intensity at 15 m/s only, for example, if a site is said to have a turbulence intensity of 12%, this means that the turbulence intensity at 15 m/s is 12%. The turbulence intensity at other wind speeds will be different. Also note that the actual site turbulence profile may be significantly different from the IEC reference profile. The standard also defines a characteristic Turbulence Intensity (CTI) as the mean Turbulence intensity plus once standard deviation.

21.4.3.5 Wind Shear The wind shear conditions for the site are determined. Shear conditions at a site are often described by the value of the shear exponent, for example, a site may be said to have an average shear exponent of 0.2. The average shear exponent is reported.

21.4.3.6 V_{Ref} The 50-year maximum 10-min average wind speed (sustained gust wind speed, also called V_{Ref}) is determined statistically from the wind speed data. V_{Ref} is an important parameter for the site suitability analysis. A wind turbine manufacturer will specify a V_{Ref} for a turbine, which is the maximum sustained wind speed for which the turbine is designed for. Thus, this is an important value to know for selecting a turbine.

As a rule of thumb, the IEC 61400-1 standard suggests that V_{Ref} is five times the annual average wind speed. This is a very rough approximation and may be somewhat limiting. There are other methods to calculate V_{Ref} statistically from the wind distribution data collected, for example, by using the method of independent storms.

Note that the extreme winds are associated with extreme weather events, specifically storms and hurricanes. It is, therefore, very important to have a long enough time series that captures a sufficient number of extreme events in order to make a good estimate of V_{Ref} .

21.4.3.7 V_{50} The 50-year maximum 3-s gust wind speed, also known as V_{50} , is another important factor for assessing the site suitability of a wind turbine and is compared with the survival wind speed of the turbine. It is calculated from the wind data similar to V_{Ref} . The IEC 61400-1 suggests that V_{50} be approximated as seven times the annual average wind speed, but as with V_{Ref} a better result may be obtained statistically from the data.

21.4.3.8 Correlation to a Known Reference Wind patterns do not just follow seasonal trends, but also multiyear trends as weather patterns change and follow longer term cycles. For example, the phenomenon known as El Niño affects weather patterns globally and occurs about once every 7 years. Therefore, it is preferable to have data sets longer than 1 year when conducting a wind resource for a site as that will provide some insight into the multiyear wind trends. Of course this is not always practical.

To estimate the longer term trends, it may be useful to correlate the wind data collected for the site to a nearby reference that goes back several years, such as a weather station at a nearby airport. For example, if the annual average wind speed at the reference station for the same time period is lower than from previous years, then it is likely that the winds at the site are lower as well. This is useful in adjusting estimates of annual energy production and also in estimating V_{Ref} and V_{50} .

21.4.3.9 Wind per Turbine If multiple wind turbines are to be installed, the data collected at the meteorological towers may be used to predict the wind conditions at each turbine, factoring terrain and surface roughness effects as well as losses due to turbines being waked by other turbines. This is typically done using computer software.

Note that adjustments must be made to factor in higher turbulence for turbines, which will be waked by other turbines.

21.4.4 Site Suitability, Wind Turbine Performance Characteristics, and Turbine Selection

Wind turbines come in many different sizes and designs. There are vertical axis turbines, horizontal axis turbines, small wind turbines and utility scale wind turbines, different designs varying numbers of blades, and so on. However, regardless of the design being deployed there are several concepts all designs have in common.

Wind turbine design requirements are specified by the international standard IEC 61400-1 Wind Turbines—Part 1: Design Requirements. Small wind turbines are also covered under IEC 61400-2. This document gives standard “engineering and technical requirements to ensure the safety of the structural, mechanical, electrical and control systems” of wind turbines. Of particular interest to this discussion is Section 21.6, which discusses the classification of wind turbines based on wind conditions. A turbine will typically be rated for an IEC wind class (I, II, or III) and for reference turbulence intensity (A or B). A turbine will also be rated for a maximum sustained wind speed, V_{Ref} , and a survival wind speed, V_{50} .

The results of the WRA are compared with the turbine class and turbine rated conditions to establish site suitability for the turbine. However, it is important to note that the actual site conditions will deviate significantly from the reference conditions specified by the IEC for turbine rating. This may allow for some flexibility in the turbine rated conditions. For example, V_{Ref} for a turbine is calculated assuming sea level air density. If the site is at a lower air density, a higher V_{Ref} may be permissible. A detailed MLA following the requirements of IEC 61400-1 may be used to verify the suitability of the turbines for the site wind conditions and planned site layout. The MLA estimates fatigue and extreme loads that the turbine will encounter at the specified location and compares them to the design conditions.

21.4.5 Estimation of Annual Energy Production

A wind turbine manufacturer will typically provide a power curve that characterizes the performance of that wind turbine versus wind speed. The y-axis of the curve is power, and the x-axis is wind speed, usually in 0.5 m/s increments. Note that from Equation 21.1, power is also proportional to air density, so the power curve will specify a reference air density that it is valid for.

For horizontal axis turbines, the wind speed is defined as the wind speed at the turbine rotor centerline, called the hub height wind speed. Note that for large wind turbines, the wind speed likely varies across the plane of the rotor and so wind speed is defined at a common location that will be most representative of the average wind speed across the entire rotor plane for most cases.

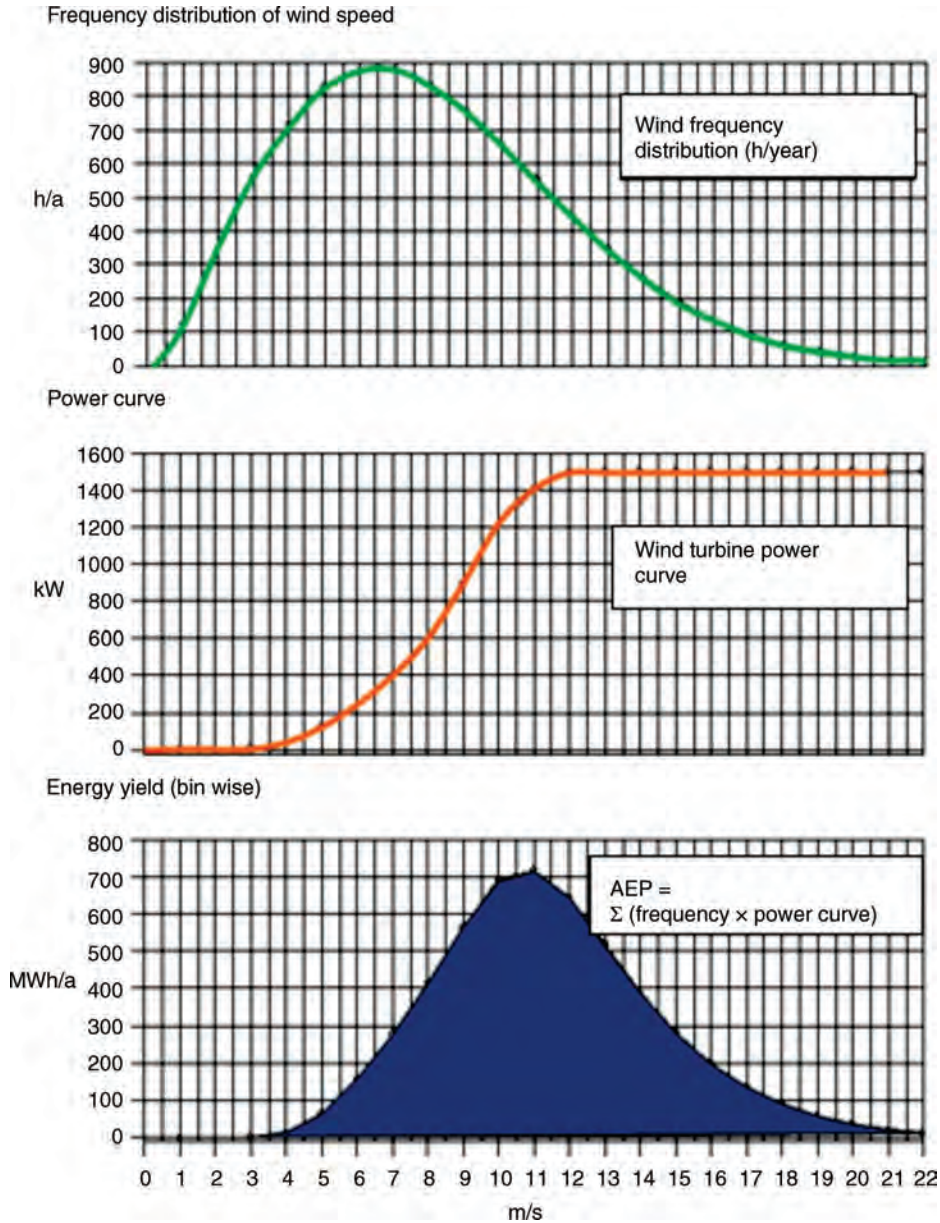

FIGURE 21.11 Calculating annual energy production.

The annual energy production (AEP) may be estimated by multiplying the power in each wind speed bin from the power curve by the frequency in each wind speed bin from the WRA expressed in hours-per-year, and summing the result (see Figure 21.11).

The AEP should be calculated using a power curve that is valid for the site average air density.

If estimating expected revenue generation, the AEP should be adjusted for turbine down time for maintenance, repair and grid and weather-related outages, transmission

and transformer losses, and other miscellaneous losses. If multiple turbines are planned, then the wind per turbine data should be used as this will include estimates for wake losses and the local terrain and roughness effects for each turbine.

21.4.6 Power Curve Measurement

If desired, the power curve of the wind turbine may be verified by measurement. The IEC 61400-12-1 provides a detailed procedure for power curve measurement; however, in general the steps are as follows.

The power curve is the electrical output of the turbine verses wind speed. It is typically not practical to measure the wind speed at the turbine location because there is significant flow distortion due to the turbine rotor and nacelle, which means that the wind speed measured at the turbine will not be reflective of the true free-stream wind speed. Therefore, wind speed must be measured at a meteorological tower away from the turbine, but too far away from the turbine and the winds measured at the met tower may not be the same as those measured at the turbine. This is particularly a problem for larger turbines because distance involved and the fact that wind speed data are recorded in 10-min intervals means that a gust at the met tower several 100 m upwind of the turbine may take several minutes to reach the turbine. The IEC 61400-12-1 specifies that the met tower must be between 2 and 4 rotor diameters from the turbine being tested.

Since the wind speed is not being measured at the turbine rotor centerline but at a location some distance away, flow distortion due to terrain may have an impact on the accuracy of the wind speed. For example, if the turbine is on top of a hill and the met tower is on the bottom, the wind conditions at the met tower will not be the same as the wind conditions at the turbine. A terrain assessment is necessary to assess the potential impact of the local terrain around the met tower and turbine. A similar assessment must be taken to identify any obstacles such as buildings, trees, or other structures will also influence the result.

If the terrain analysis shows that the wind at the met tower cannot be assumed to be the same as the wind at the turbine location, a site calibration may be undertaken to correct for this effect. In a site calibration, a met tower is erected at the turbine location prior to turbine construction, and another met tower is erected at the measurement location. Data are collected, and corrections for flow distortion are empirically developed from the data and based on wind direction.

For the power curve test, a met tower is erected between 2 and 4 rotor diameters from the test turbine (or the permanent met tower from the site calibration is used). Data are collected until sufficient data have been collected to sufficiently characterize the power curve of the wind turbine. Note that in order to characterize the power curve across the full range of wind speeds, data must be collected at all of the wind speeds of interest.

The data are filtered as follows:

1. Wind directions for which neither the turbine nor met tower are in the wake of a neighboring, operating wind turbine
2. Failure or icing of the wind sensors
3. Data when the wind turbine is shut down and unable to operate are removed
4. Other conditions may be filtered out as needed.

The power available to the wind turbine is a function of the air density (see Eq. 21.1) so the data should be density corrected to correct for density variations over the course of the test, and also to correct to the air density of the reference power curve, if applicable.

The filtered and density corrected data set are then sorted using the method of bins into 0.5 m/s wind speed bins. The data in each bin are averaged to give an average wind speed and power for that bin. The result is the measured power curve for the wind turbine. Note that the average wind speed for the bin may not necessarily be the exact bin center.

It is usually not practical to collect data for every single wind speed bin for which the turbine is rated to produce power, as the very high wind speed bins will only occur during rare storm events. If the measured power curve is being compared with a reference power curve or is used for energy production estimates, extrapolation of the power curve for the missing bins may be necessary. Not doing so assumes that the turbine produces zero power in the bins for which no data were collected, which may not be the case.

22.1 INTRODUCTION

Making movements and detecting and interpreting the movement of others are critically important for humans. We can make movements more complex than any robot can replicate, and we can recognize and interpret the movement of others more quickly and more efficiently than any computer vision system. Using their ability to recognize and interpret the movement of others, humans can learn by imitation, enjoy athletic and artistic performances, diagnose abnormal movements, detect threats, and effectively communicate and interact with others in the society. Technology is constantly creating new opportunities where human movement must be observed and interpreted but human observers are not or could not be present or their qualitative interpretations are inadequate. It is in these areas that motion measurement technologies can be most beneficial. Motion measurement technologies can complement our own abilities because they excel where humans are deficient or inefficient. They can systematically quantify human movement by accurately measuring external and internal motion variables (Yack, 1984) and they can be used in applications for which human observers are either costly or impractical.

The constantly expanding areas of application for human motion measurement include diagnosis and treatment of movement disorders, computer-assisted surgical operations, virtual reality training of motion in sport and art, studying the motor control of movement, monitoring of physical activity in daily life activities, interactive video games, character animation in movies and video games, and surveillance. These applications have motivated the development or adoption of a number of measurement technologies including optical, magnetic, and inertial motion measurement systems. These measurement systems have been used successfully in many applications but they have limitations and their application has faced many challenges that are fueling continued research. The difficulties arise from the limitations of the measurement technologies but more importantly from the complex nature of human movement. Human movement can take many forms and can be performed in many different environments. It is generated by complex interactions between the central nervous system and the highly coupled musculoskeletal system with many redundancies and irregular joint structures. Further, the movement of the skeletal system must be inferred from the motion of sensors that can only be attached to the skin over the bones and intervening deformable tissue. Existing measurement technologies are powerful but none has the capability to overcome these challenges, and reliably and accurately measure human motion in all its variations. Because there are no silver bullets, it is important to be aware of the strengths and weaknesses of alternative measurement technologies so that the best technology for a specific requirement can be selected and applied successfully (Welch and Foxlin, 2002).

In addition to acquiring raw data about human movement, it is important to consider how the data will be analyzed and presented. Depending on the application, the same human motion can be described in varying levels of detail and from different perspective. The levels of detail in human motion measurement will be described first. This will be followed by the review of the common human motion measurement technologies including their operating principles, their strengths and weaknesses, and examples of their successful applications from the literature. Finally, the current state-of-the-art and emerging technologies for human motion measurement will be discussed.

22.2 CHARACTERIZATION OF HUMAN MOVEMENT

To fully capture the motion of the human body, one must measure the linear and angular motions of all segments in the body with respect to a ground-fixed reference frame. With these measurements one can reconstruct the motion of the whole body and derive other application-specific representations of motion such as the relative angles, velocities and accelerations between the neighboring body segments. The full motion of a body segment includes its linear and angular position, velocity, and acceleration but not all have to be measured directly. Usually one of these quantities (position, velocity, or acceleration) is measured directly and then the other motion variables are derived by numerical differentiation or integration. Full body motion measurement is seldom necessary or practical. In most applications a subset of motion variables is measured.

In some applications the motion of the whole body is measured by treating the human target as a single point. In team sports, for example, the large-scale motion of the players can be tracked while ignoring the relative motion of the individual segments

(Pers et al., 2002). Similarly, in studies of balance and falls, the whole body motion characterized by the motion of the body's center of mass is more important. The motion of the body's center of mass can be estimated by various methods such as measuring the motion of a point on the surface of the body such as waist that is close to the body's center of mass (Karantonis et al., 2006). In most other applications where the motion of the individual segments and their relative motion are important, the motion of any number of segments may be measured. These could include the measurement of the motion of all segments involved in gross movements for character animation in movies and video games, detailed study of specific limbs in reaching, grasping, standing, and gait to diagnose movement disorders, a single joint such as the knee or wrist, or a single segment such as the trunk to monitor general physical activity.

If the motions of all individual segments are available and their underlying mechanical linkage at the joints is understood, then it is possible to derive mathematically any kinematic or kinetic information that is desired. Therefore, despite the variations in methods and technologies, the goal of full body motion capture is to measure the full motion of individual body segments. This is commonly achieved by measuring the motion of multiple markers or sensors that are attached to the body segments or analyzing the remotely captured videos of the whole body movements.

22.3 OPTICAL MOTION CAPTURE SYSTEMS

Optical motion capture systems use multiple cameras to track the position of passive or active markers attached to the body segments (Figure 22.1). In the passive marker system, light sources around the camera's lens emit infrared light parallel to the axis of the camera. The reflected light from the marker is then captured by the cameras as a 2D image (Richards, 1999). Passive markers are usually spherical balls with retroreflective coating and come in various sizes. In active marker systems, that are less common, infrared light-emitting diodes actively emit the light that is imaged by the cameras (Maletsky et al., 2007). This has the disadvantage of requiring wires to each active marker but the advantage of allowing their light to be sequenced so the detection system knows exactly which marker's position is being sensed at any instant.

To identify the 3D position of a marker, the marker must be imaged by at least two cameras (Figure 22.2). One camera can identify the position of the marker in a 2D plane but it cannot provide any information on the axis perpendicular to the plane (Figure 22.2). The 2D images from two cameras with nonparallel image planes, however, can be used to reconstruct the 3D position of the marker center by stereo triangulation (Baca, 1997; Chen et al., 1994).

The full motion of a rigid body segment can be expressed by the 6D motion of a reference frame (three translations, three rotations) that is attached to and moves with the segment. Defining the three orthogonal unit vectors of such a reference frame requires at least three noncollinear points that can be provided by the positions of three optical markers whose positions in the reference frame are known (Figure 22.1). The marker positions must be recorded by the cameras at frame rates high enough to capture the movement details. The temporal and spatial resolution required of these data may be quite high for applications in which the observed motion will be used to compute the forces acting on the body through the method of inverse dynamics.

FIGURE 22.1 Optical motion capture system. Motion of the skeletal system is tracked by capturing the motion of the markers on the skin or a tight closing with respect to a ground-fixed coordinate system (G). The motion of a body segment is the same as its body-fixed coordinate system (B) that can be defined by the position of three noncollinear markers on the segment. The captured motion data can be used to create realistic character animations in movies and video games. With the motion data, internal causes of motion such as joint and muscle forces can be examined to diagnosis and treat movement disorders.

Because of the constraints on the marker attachment points, the axes of the body-fixed reference frame defined by them may not have the desired origin or alignment. For example, in biomechanical and clinical applications, a set of standard anatomical axes is defined to facilitate the comparison of anatomical data and their clinical interpretation (Wu and Cavanagh, 1995; Grood and Suntay, 1983). The misalignment between the body-fixed and anatomical reference frame is a fixed transformation that can be obtained in the calibration process. Further, the motion of the body-fixed reference frames that are described by transformation matrices, cannot be directly used or easily interpreted in most applications. For character animation for example, the motion data must be represented in the joint space as the relative angles between the neighboring segments (Xiao et al., 2009). Similarly in biomechanical applications, the relative motion between the anatomical axes of the neighboring segments are described by Euler angles with standard order of rotations (Wu and Cavanagh, 1995; Grood and Suntay, 1983). These alternative representations of the segment motion can be obtained by matrix manipulation and coordinate transformations.

Optical motion capture systems offer powerful capabilities for human motion measurement and have often been used as the gold standard for evaluation of other motion capture

FIGURE 22.2 Reconstruction of 3D marker positions from 2D images. Each camera captures a 2D projection of the marker on its plane and cannot capture the position of the marker on the third axis perpendicular to the camera's plane. To reconstruct the 3D position of the marker, it must be imaged by, at least, two cameras. When a marker is larger or closer to the camera and its image occupies more pixels, the position of its center can be identified with more accuracy than a marker that is smaller or farther away from the camera.

systems. They can track large number of markers in a relatively large area enabling whole body tracking of human movement. They are not susceptible to noise from electromagnetic interference or electrical wiring and can use markers of different sizes to track both large and small-scale motions.

Optical motion capture systems have been applied in many areas including character animation in movies and video games (Xiao et al., 2009; Delaney, 1998), and analysis of movement in patients with gait abnormalities (Chambers and Sutherland, 2002). In gait analysis laboratories, the captured trajectories of the patient's joints are compared to the normal values to diagnose movement abnormalities and recommend treatments such as physical therapy and orthopedic surgical interventions such as osteotomy, tendon transfer, and muscle lengthening. During or after the treatment, follow up motion captures are used to systematically monitor patient's progress and evaluate treatment outcomes (Chambers and Sutherland, 2002). The systematic and objective analysis of gait with the help of motion capture systems has been shown to produce superior outcomes over treatments based on subjective analysis of clinicians, often avoiding unnecessary or inappropriate surgical interventions (Chambers and Sutherland, 2002). Further, with the captured motion, internal and invisible motion variables such as joint moments and muscle forces can be derived and used in treatment decisions that consider the underlying causes of the movement disorder (Seth and Pandy, 2007).

Optical systems have important limitations, however. To capture the motion of a marker, it must be visible to at least two cameras at all times. Therefore the marker cannot be tracked if it is occluded by the body segments or overlaps with other markers. The system may lose track of the occluded marker or confuse it with another marker. The use of more cameras can help but it adds to the cost and complexity of the system and does not completely solve the occlusion problem. Knowledge of human body constraints, signal processing techniques, and optimization methods have been used to identify plausible marker movements and track the momentarily occluded markers (Herda et al., 2001; Zakotnik et al., 2004; Cerveri et al., 2003). The required setup and the algorithms are

often too complex for application in clinical settings and often manual editing may still be necessary. Optical systems are costly and they require extensive calibration and configuration for each patient. They are usually installed in a dedicated indoor space. Although the capture area is relatively large, the precision and accuracy decreases with the distance between the marker and the camera (Maletsky et al., 2007). As the marker's distance from the camera increases, its image becomes smaller and more difficult to capture robustly and accurately (Figure 22.2). The measurement resolution itself is limited by the pixel count of the camera, the size of the marker, and its distance from the camera. Higher pixel count, larger marker size, and closer distance to the camera can result in higher resolution (Baca, 1997). The availability of high-resolution cameras and advanced center detection algorithms with subpixel resolution have made this less of a concern (Baca, 1997). Skin movement artifact is another source of significant errors, but it affects all motion capture systems that most attach their sensors to the skin above the bone. This is not an issue when the objective is to measure the motion of the soft tissue itself (e.g. capturing the motion of the key points on the face for face animation). In most applications, however, the objective is to measure the motion of the underlying skeleton, so the relative motion of the skin can introduce significant errors in the measurement. The soft tissue artifact arises from the movement associated with muscle bulging, skin sliding, and soft tissue inertia. Its amplitude depends on the physical characteristics of the individual, marker location, and the nature of the movement. A systematic review by Peters et al. (2010) found that the soft tissue artifact in thigh and tibia could be as high as 30 and 15 mm, respectively. For a specific marker attachment, the skin movement correlates with the joint motion, so methods have been developed to model and compensate for the errors (Cerveri et al., 2005). Variations in marker attachment in different sessions and laboratories, and differences in the physiognomy of the subjects make the application of these compensatory methods impractical for most clinical situations. In fact, differences in marker placement have been found to be the main source of discrepancies between movements captured by different laboratories (Gorton et al., 2009).

Because the immediate output of the optical systems are the linear and angular positions of the body segments, they can be directly used in most applications such as character animation, movies, and interactive games. Many biomechanical applications, however, require computation of kinetic variables such as joint forces and energetics that necessitates the numerical differentiation of the position data to obtain velocities and accelerations. The numerical differentiation disproportionately magnifies the noise present in the measured data, especially noise at higher frequencies (Pezzack et al., 1977). Because measurement noise has a wide bandwidth, even small amplitude noise in the position data can significantly deteriorate the signal-to-noise ratio of the differentiated data. Fortunately, the high-frequency noise can be easily removed from the motion data by low-pass filtering because the actual human motion is relatively slow. In addition, numerical differentiation algorithms have been developed that have better frequency domain characteristics and produce smoother velocity and acceleration data (Pezzack et al., 1977; Bortolami et al., 1997).

22.4 MAGNETIC MOTION CAPTURE SYSTEMS

Magnetic motion capture systems infer the 6D motion of a body segment using magnetic sensors (Figure 22.3). Only one magnetic sensor or receiver is attached to each body

FIGURE 22.3 Magnetic motion capture system. Motion of a body segment is tracked by capturing the 3D position and 3D orientation of a magnetic receiver attached to it. Three orthogonal coils in the transmitter and the receiver define the axes of the ground-fixed (G) and body-fixed (B) coordinate systems, respectively. Magnetic systems are faster than optical systems and more appropriate for real-time interactive applications.

segment. The receiver has three orthogonal coils with ferrite core that form the axes of the body-fixed reference frame. The receivers measure the strength of the magnetic field generated by a transmitter. The transmitter is fixed to the ground and has three orthogonal magnetic coils that form the axes of the ground-fixed reference frame. It emits magnetic pulses from its coils while the corresponding magnetic inductions in the three orthogonal coils of the receivers are measured. The strength of the induced magnetic field in the receiver coils depend on and determine the receiver's relative distance and orientation with respect to the transmitter. As described earlier, once the full motion of each body segment is measured, they can be used to derive other representations of motion.

Compared to the optical systems, magnetic systems are relatively inexpensive. Unlike the optical systems that have a high initial cost but can be used with an arbitrary number of passive markers, the price of the magnetic systems grows with the number of active receivers. They are therefore more economical choices and have been used more often when limited numbers of segments must be tracked such as the motion of the upper extremities and the head movement (Kaliki et al., 2011). The receivers on the upper extremity and head are also farther away from the floor and therefore less susceptible to the magnetic distortion from the metals in the flooring. Magnetic systems have the

advantage that each receiver can measure the complete position and orientation of a body segment, whereas this normally requires three noncollinear markers in an optical system. Because the magnetic field can travel through human tissue, they are not susceptible to marker occlusion. The magnetic sensors are mounted over the skin and experience soft tissue artifact but finding one desirable attachment site on a segment with minimal soft tissue movement is easier than finding the sites for three optical markers. Because the magnetic systems directly measure the position and orientation of the body segment, they require less processing time to obtain the desired motion variables (Richards, 1999). This results in lower latencies that are important for real-time applications such as computer-assisted surgery, motion training in virtual reality, and interactive video games (Richards, 1999; Kaliki et al., 2011; Poulin and Amiot, 2002).

Errors due to the magnetic distortion caused by the metals in the flooring and any nearby instrumentation is the main disadvantage of the magnetic systems (Richards, 1999). The sources of interference may be hidden in the building and the instrumentation and therefore difficult to detect. The distortion itself is also invisible to the user and may go undetected. Errors due to magnetic field distortion can be large. Meskers et al. found that the magnetic distortion by the metal reinforced concrete in the flooring can cause position errors over 20 mm in each axis (Meskers et al., 1999). A study of various sources of interference in an operating room environment found that some devices can introduce position and orientations errors as high as 8.4 mm and 166°, respectively (Poulin and Amiot, 2002). They recommended identifying the sources of distortion and keeping them away from the capture volume to minimize the errors. By removing sources of distortion and careful calibration, measurement accuracies comparable to optical systems can be achieved (Hassan et al., 2007; Mills et al., 2007; Day et al., 2000). Because the strength of the transmitter's magnetic field drops sharply with distance (according to the inverse square law), the range of the magnetic systems is limited to a small area around the transmitter. The wiring could also be limiting because both the transmitter and the body-mounted receivers must be connected to the motion capture electronics. The useful capture area is limited to a hemisphere on either side of the transmitter with radius less than a few meters (Richards, 1999; Meskers et al., 1999). Even within the capture area, measurement errors increase with the distance between the receiver and the transmitter (Richards, 1999; Schuler et al., 2005), somewhat as they do with camera distance in optical systems. The range of the magnetic systems would be unlimited if the earth's magnetic field was used as the source. But the earth's magnetic field is weak and difficult to sense reliably and quickly and has been used mainly in hybrid inertial-magnetic systems to occasionally reset the measurements obtained by inertial sensors (see Section 22.5).

22.5 INERTIAL MOTION CAPTURE SYSTEMS

Inertial sensing with accelerometers and gyroscopes has been developed primarily for and used widely in inertial navigation of missiles, aircraft, and ships. These were too bulky and too expensive for human motion tracking until they could be produced in smaller form factor and at lower cost thanks to micro-electro-mechanical systems (MEMS) technology (Barbour and Schmidt, 2001). These miniaturized inertial sensors can be packaged in small sizes that can be attached to the body segments to track their motion. Inertial sensing of body segments' motion, however, poses specific challenges that have led to adaptations of this measurement technology.

The motion of a vehicle such as an aircraft that moves as a single rigid body can be measured by a set of three orthogonal gyroscopes and three orthogonal accelerometers. In older inertial navigation systems, the accelerometers were attached to a moving platform on the vehicle whose orientation was always aligned with a ground-fixed reference frame. This was accomplished by continually sensing the angular motion of the vehicle by the gyroscopes and rotating the platform in the opposite direction to maintain its alignment. As the result, the acceleration measurements were in the axes of the ground-fixed reference frame and could be directly integrated once to obtain the vehicle's velocity, and twice to obtain its position. The resulting computations were simple and could be performed by onboard analog computers but the precision mechanical devices were expensive and prone to occasional failure. The availability of fast microprocessors allowed the accelerometers and gyroscopes to be attached directly to the vehicle's body. This configuration, which is known as the strapdown inertial navigation system (Welch and Foxlin, 2002), does not have the expensive moving parts but requires more extensive computation. Because the accelerations are expressed in the body-fixed reference frame, they cannot be integrated directly. The angular velocities from the gyroscopes must be continually integrated to obtain the orientation of the vehicle with respect to the ground-fixed reference frame. Matrix transformations must then be used to transform the accelerations from the body-fixed to ground-fixed reference frame before they can be integrated to obtain the vehicle's velocity and position. Because of its simplicity and compact size, the strapdown configuration built from miniaturized MEMS sensors has found applications in human motion measurement. But the use of the technology is customized to the specific requirements of the human movement as described below.

A set of three orthogonal gyroscopes and three orthogonal accelerometers on a body segment can measure its angular velocity and linear acceleration. The measurements are with respect to an inertial ground-fixed reference frame but the measured quantities are projected to the axes of the body-fixed reference frame (Figure 22.4). If the initial orientation of the body segment is known (from initial calibration), it can be used to transform the acceleration and angular velocity measurements from the body-fixed to ground-fixed reference frame. Then the global acceleration minus the gravity acceleration (see below description) and angular velocity can be numerically integrated to obtain the global position and orientation of the segment at the end of the first integration step. Because the global orientation of the segment is known at the start of the next integration step, the integration process can be repeated to track the global motion of the segment over time.

As mentioned earlier, the acceleration due to gravity must be subtracted from the measured accelerations before they can be integrated. Acceleration sensors measure the strain induced by a proof mass in a supporting structure such as a cantilever beam, which reflects the sum of two forces: the weight of the mass that results from gravity and the force due to changes in the velocity of the mass that is acceleration. The accelerometers are therefore sensitive to and measure an acceleration signal that is the sum of the gravity and motion accelerations. The gravity component of the acceleration that exists even when the segment does not move must be subtracted from the measured acceleration before it can be integrated to obtain the velocity and position of the body segment. The estimate of gravity effects must be accurate because even small errors can produce large integration drifts over time. For slow movements with very small movement acceleration, however, the accelerometers measure predominantly the constant gravity acceleration vector, which allows an accurate determination of the segment's inclination with respect to the gravity vector (Luinge and Veltink, 2004; Kemp et al., 1998) (Figure 22.5). Because

FIGURE 22.4 Inertial motion capture system. Motion of a body segment is tracked by an inertial sensing unit consisting of three orthogonal accelerometers and three orthogonal gyroscopes. 3D orientation is obtained by integrating the angular velocities from the gyroscopes and the 3D position from double integrating the linear accelerations from the accelerometers. Because inertial sensing unit can operate autonomously, it has been used widely in portable applications outside the laboratory.

many human movements such as sitting and standing are slow and the objective is to keep the body segments upright, the measurement of the body segment's deviations from the vertical direction has special utility in many applications.

The main advantage of inertial motion measurement is that it is not susceptible to signal distortion or sensor occlusion. The sensors can be made in small, wearable, and portable packages that operate independent of any external device such as cameras and transmitters. This is possible because solid-state MEMS sensors can be easily integrated with powerful microprocessors and even radio transmitters and packaged into small battery powered units. These standalone units require little power to operate and can be installed on one or more body segment as needed to measure their motion. These unique characteristics have enabled the measurement of motion in daily life activities for long periods at home and at outdoor environment (Godfrey et al., 2008). Inclination measurement by the accelerometers has also been used extensively because it provides the inclination of the body segment with little computation and can be implemented with as little as a single axis accelerometer (Luinge and Veltink, 2004; Godfrey et al., 2008).

Because of their unique capabilities, inertial sensors are finding applications in many areas of movement science, especially in measuring the motion of a limited number of body segments outside the laboratory. Many commercial devices based on inertial sensors

FIGURE 22.5 Components of the measured acceleration signal. The acceleration measured by an accelerometer (a_m) is the sum of the projections of movement (a_s) and gravity (g_s) accelerations on its sensitive axis (left). The gravity component of the acceleration must be accurately estimated and subtracted from the measured acceleration before it can be integrated to obtain position. Any small error in the estimation can result in large integration drifts over time. In slow movements where the movement acceleration is very small compared to the gravity acceleration, the accelerometer predominantly measures the projection of the constant gravity vector (right). This allows the determination of the segment's inclination with respect to the gravity vector, which is an informative motion variable for human movement.

have been developed and applied widely to monitor the type and intensity of physical activity (Godfrey et al., 2008; Yang and Hsu, 2010). The portable inertial sensor may be worn on a body segment relevant to the monitored activity such as the ankle for gait monitoring (Kuo et al., 2009) or on a body segment closest to the body's center of mass such as the waist to monitor the whole body movement and energetics (Karantonis et al., 2006). The measured quantities are then processed by a set of rules or more advanced statistical classification methods to identify the type of activity and estimate the energy expenditure (Godfrey et al., 2008; Yang and Hsu, 2010). Assessment and prevention of falls in the elderly has benefited from the inertial sensors' unique capability to measure inclination and dynamic accelerations. Maintaining balance depends on a limited number of motion variables such as sway distance, sway velocity, and sway acceleration of the body's center of mass that can be measured with a limited number of carefully placed inertial sensors (Sipp and Rowley, 2007). The desired values of these motion variables for maintaining stability can be obtained from simple rules or optimization (Davoodi and Loeb, 2006). Inertial sensor can then be used to detect falls by measuring whether the stability limits have been violated or train the users to avoid falls by alerting them when they are about to lose their balance (Conard et al., 2009; Maurice et al., 2010). Inertial sensors are also more practical because they can be used to monitor and prevent falls outside the laboratory environment (Sipp and Rowley, 2007). Other less common applications of inertial sensing in human motion measurement include the measurement of the upper extremity movements for rehabilitation (Zhang et al., 2008), assessment of spinal posture (Wong and Wong, 2008), measurement and analysis of the lower extremity biomechanics

(Fong and Chan, 2010), and feedback control of human movement in functional electrical stimulation (Tong et al., 2003).

The most important drawback of the inertial sensors is the integration drift and the need for initialization. Unlike optical and magnetic systems that measure absolute motion with respect to a ground-fixed reference frame, the inertial sensors are not aware of their absolute position and orientation. Inertial sensor is like a blind person in a car who knows whether the car is turning left or right but is unaware of the absolute direction with respect to the west, east, north, or south. The inertial sensors must therefore be initialized at the start of the session. Because inertial measurements must be integrated over time to obtain the position of the body segment, even small bias errors in the measurement or errors in the gravity compensation can accumulate resulting in large errors over time (Figure 22.6). Most accelerometers are known to suffer from fluctuating offset or bias error that are difficult to remove completely by calibration especially in clinical applications (Luinge and Veltink, 2004). The most effective method to minimize the effect of integration drift is to periodically reset the integrated motion variables by independent measurements (Figure 22.6). The main reason for building such hybrid systems is that the independent measurements are not always available or they can be made only at much slower rates than is required. A relatively successful example for human motion measurement is the hybrid

FIGURE 22.6 Integration drift caused by acceleration bias error. Unlike optical and magnetic systems that directly measure the position and orientation, inertial measurements must be integrated twice to obtain these quantities. Shown in the figure is the position of an imaginary point on the body obtained by double-integration of its acceleration (sinusoidal trajectory, 1 m/s^2 amplitude) with no bias error, with a typical bias error of 3 mg for industrial grade MEMS accelerometers, and with resetting of the integrated position or both position and velocity at the rate of 1 Hz . Over only 10 s of movement, the integrated position drifts by 1.5 m . Resetting the integrated position or both position and velocity with independent measurements reduces the max error within 10 s of integration to 0.26 m and 0.014 m , respectively.

inertial–magnetic system in which the integrations of the faster inertial measurements are periodically reset (reinitialized) by the slower measurements of the magnetic system. If the magnetic system senses the magnetic field generated by a small battery-powered transmitter (Roetenberg et al., 2007) or the earth’s magnetic field (Zhang et al., 2008), it can be packaged with inertial sensors in small portable units that can be used in ambulatory applications outside the laboratory. These are increasingly marketed as inexpensive “electronic compasses” or “digital compasses” for use in cell phones, video game controllers, and other portable, consumer electronic devices.

22.6 DISCUSSION

The growing applications in different areas of movement science, entertainment, and medicine are the motivating forces for the development of increasingly sophisticated human motion measurement systems. These often demand measurement systems that are cheaper, smaller, faster, and more accurate, and at the same time capable of measuring human motion in its natural environment reliably and without any encumbrance by markers, sensors, or wires. None of the existing measurement systems satisfy all of these requirements but they offer range of possibilities that must be carefully considered for a specific application.

For whole body motion measurement, optical systems are the gold standard. They are expensive but they can make accurate and reliable measurements when necessary. Because the markers are small and there are no wires, the movements can be made with little encumbrance in relatively large spaces. As the result, they have been used widely to capture the movement of actors for movies and video games and motion of patients with movement disorders. They can also be used in smaller scale measurements of the body segments if their expense can be justified. Magnetic systems have been less accurate and more limited in terms of their capture volume but they are faster and less expensive. Therefore, they have been used in smaller scale measurements of few body segments such as head and arms. They are especially suited for real-time interactive applications where the speed may be more important than the accuracy of the measurements. Magnetic systems are catching up and, with careful calibration, can achieve measurement accuracies that are comparable to the optical systems. But to achieve wider acceptance in character animation and biomechanics, the range of the system must be extended and the electromagnetic distortions must be minimized in a more reliable manner. The most distinguishing aspect of the inertial systems is that they can operate autonomously in indoor and outdoor environments and they do not suffer from the main sources of interference in other systems, that is, marker occlusion and electromagnetic interference. In addition, inertial sensors can directly measure acceleration and inclination of the body segments that are important aspects of many human movements. Inertial sensors have therefore been used more widely in portable applications to monitor physical activity in free-living environments. Inertial sensors can measure the complete 6D motion of body segments but integration drift has limited their use in this capacity. Hybrid inertial–magnetic systems have been built to minimize the integration drift but they need further development before they can be used in multi-segment motion measurement.

Measurement of human motion challenges even the most advanced measurement technologies. For example, inertial sensing is a mature and successful technology for tracking the motion of missiles and airplanes but its application to human motion has faced many

challenges (see Section 22.5). Some of the difficulties arise from the anatomical complexity and large variations of human movement that cannot be changed. But others arise from the limitations of the measurement technologies that are the subject of intense research and development. One of the main limitations and the cause of many errors is the requirement to attach the markers or sensors to the body segments. They are difficult to attach and calibrate consistently; they measure the skin motion on top of the skeletal motion; they suffer from occlusion and interference; they are tedious to attach and they encumber the natural motion of the human target. The goal of one of the promising technologies, markerless motion capture, is to extract the motion of the human target from the 2D images of one or more cameras. Markerless systems are very appealing because they allow the human targets to move freely in their natural environment without the encumbrance of the markers or sensors. They can be applied in areas that have traditionally used marker-based systems and they enable new areas of application such as surveillance where marker-based systems are impractical. But extracting accurate skeletal motion from the video images alone is a challenging task. Sophisticated algorithms must be used to separate the human target's body from the background in the image, identify individual segment's boundary and shape, infer the location of the joint centers, and deal with segment occlusion (Kehl and Gool, 2006; Mundermann et al., 2006). Markerless motion capture has its origin in computer vision research and has been applied mainly to applications with lower accuracy requirement such as surveillance (Mundermann et al., 2006; Aggarwal and Cai, 1999). But the use of more cameras and sophisticated feature extraction algorithms are enabling measurements that are approaching the accuracy requirements of some clinical applications (Corazza et al., 2010; Corazza et al., 2007).

ACKNOWLEDGMENT

The author would like to thank Dr. Gerald E. Loeb for his excellent comments.

23.1 INTRODUCTION

Fluid flow occurs throughout biomedical engineering in areas as different as airflow in the lungs, Fung (1990) and Primiano (1998), for diffusion of nutrients or wastes through membranes [Hampers et al. (1973), Neuman (1998), and Tedgui and Lever (1984)]. Flow-related problems can involve fluid media in the form of gas, liquid, or multiphase flows of liquids, and gas together or in combination with solid matter. Biomedical flows occur in both *in vivo*, Jin et al. (2003), and *in vitro*, Hochareon et al. (2004). They can involve relatively benign flows like that of saline through an intravenous tube to a biochemically active flow of a non-Newtonian fluid such as blood. Many biomedical or bioengineering processes require the quantification of some flow field that may be directly or indirectly related to the process. Such quantification can involve the measurement of volume or mass flow, the static and dynamic pressures, the local velocity of the fluid, the motion (speed and direction) of particles such as cells, the flow-related shear, or the diffusion of a chemical species.

Interest in understanding fluid flows, and attempts to measure flow-related phenomena has had a long history in the scientific and medical communities with early work by Newton, DaVinci, and others. Early studies often involved observations of flow-related phenomena that can be characterized as simple flow visualization or particle tracking (Merzkirch, 1974), or the estimation of a pressure by the displacement of a fluid. Rouse

and Ince (1957) provide a historical review of these early works. Throughout the years, flow measurement techniques have advanced significantly in capability (what is measured and how), versatility, and in many ways, complexity. Some techniques, such as photographic flow visualization, have changed little in over 100 years, whereas others are only possible because of advances in electronics, optics, and physics. Improved capability and versatility are evidenced through the increased ease of use in some systems, and the ability to measure more quantities with increased accuracy and resolution. However, this improved capability and versatility has, in some cases, come at the cost of increased complexity in system hardware, calibration requirements, and application complexity.

Measurement techniques can be characterized as invasive or noninvasive, and direct or indirect. Invasive measurement techniques require the insertion of a sensing or a sampling element directly into the flow field. As a result of this direct insertion, invasive probes may alter the flow field characteristics or induce bias errors associated with the presence of the probe in the flow field or by the operation of the probe (Latto et al., 1981; Lauchle et al., 1989). Invasive probes are often designed to minimize flow disturbance by miniaturizing the sensing elements or by displacing the sensing elements some distance from the hardware holding the probe in the flow, as illustrated in Figure 23.1. Invasive probes also require some type of closure at the penetration site through the boundary of the flow, which must be accounted for in the test design, and can be particularly important in *in vivo* applications to prevent fluid loss or infection. White et al. (1994) measured wall shear stress in the abdominal aorta of dogs with an invasive, flush-mounted hot-film probe. These authors describe how the probe tip is modified to provide an effective entry mechanism through the arterial wall with an adequate seal.

Noninvasive techniques do not involve direct insertion of a sensor into the flow but provide sensing capability through either access to the flow at the flow boundary or through the use of some form of electromagnetic radiation (EMR) transfer or propagation. Wall-mounted thermal sensors, static pressure taps, and transducers, or surface sampling probes are examples of noninvasive techniques that require access to the boundary of the flow field through a wall penetration (White et al., 1994). Ultrasound (Povey, 1997), magnetic resonance (MR), X-ray, and optical techniques are all examples of EMR that can be used to probe flow fields (Siedband, 1998). Unlike the wall-mounted, invasive probes described above, EMR-based measurement systems do not require physical penetration into the flow field or access through the flow field boundary. They do, however, require a “window” into the flow through the boundary enclosing the flow field of interest. This

FIGURE 23.1 Examples of invasive velocity measurement sensors with displaced sensing elements relative to their probe supports. (a) A boundary layer style hot-wire probe for thermal anemometry (Picture from TSI Inc. catalog, probe catalog #1261A) (b) Pitot static probe for velocity measurement.

“window” depends on the type of technique being used. Optical-based techniques require an optically clear window that may not be suitable for *in vivo* applications, whereas ultrasound and X-ray techniques require the material properties of the flow boundaries be transparent to these forms of EMR waves. For example, lead will shield X-ray penetration, and metal objects on a surface or in the flow may create local artifacts (noise or error) in MR measurements.

Direct and indirect measurements are defined by how quantities of interest are measured. The displacement of a particle or cell in a flow can be directly measured by photographing the movement of the particle over a finite time interval (Adrian, 1991). Most flow-related measurement systems, however, are indirect. In general, velocity or flow is indirectly calculated from the direct measurement of a quantity and the application of a calibration that relates the magnitude of the measured quantity to the parameter of interest. This calibration may involve not only a conversion of a measured quantity like a voltage to a physical quantity such as a pressure, but may also involve the application of a functional relationship (i.e., Bernoulli’s equation), which requires assumptions about the flow. For example, volume flow probes often assume a characteristic velocity profile at the location of the probe (Webster, 1998). Blood flow in the microcirculation can be estimated by indirectly measuring the cell velocity with a time-of-flight optical technique where the time a cell takes to move a known distance is measured and the cell velocity is calculated by the ratio of the distance divided by the transit time (Lipowski et al., 1989).

Indirect measurement can also impact the uncertainty in the estimated quantity. The measurement of velocity with a Pitot probe is one example of an indirect measurement (Shaughnessy et al., 2005). The Pitot probe measures the local dynamic and static pressures in the flow. These pressures are most often measured with a pressure transducer that provides a voltage output in response to an applied pressure. A calibration is then applied to the measured voltage to convert it to pressure. Velocity is indirectly calculated from the estimated pressures using the Bernoulli equation. The error in Pitot probe velocity measurements includes the pressure transducer calibration uncertainty, noise, and statistical uncertainty during the pressure measurement, electronic noise in the acquisition of the transducer output voltage, transducer drift, and potential bias caused by the physical size of the probe relative to the flow scales being measured. These errors are nonlinearly propagated into the estimate of the velocity uncertainty.

Measurement accuracy is also a function of the physical and operating characteristics of the probe itself. Many flows exhibit a range of spatial and temporal scales. The physical size and the frequency response of the sensing element must be taken into account when choosing a measurement system for a particular application. A large sensing element or an element with poor frequency response has the effect of low-pass filtering the measured signal (Bendat and Peirsol, 1986). This low-pass filtering will cause a bias in the measured quantity. The total measurement uncertainty must also take into account statistical errors associated with random processes, cycle-to-cycle variability in pulsatile systems, and noise. The reader is referred to the texts by Coleman and Steele (1999) and Montgomery (1991) for a detailed approach to experimental uncertainty analysis. The focus of this chapter will be on measurement techniques, their fundamentals of operation, their advantages and disadvantages, and examples of their use.

The name “Flow Measurement” is a broad term that can encompass the measurement of many different flow-related parameters. In this chapter, we will focus on the measurement of those parameters that are most often desired in a biomedical/bioengineering application, volume flow rate, and velocity. Imaging, Doppler echocardiography, and MR

techniques are addressed in other chapters within the encyclopedia and, thus, will only be briefly introduced in this chapter when applicable. This chapter is subdivided into sections that will address volume flow, and velocity separately, with a detailed presentation of systems that are available for the measurement of each. Although ultrasound and MR techniques are often used to measure flow-related parameters, a detailed discussion of the principles of operation will not be presented here as these topics are covered in depth in other chapters of this encyclopedia.

23.2 FLOW MEASUREMENT APPLICATIONS

23.2.1 Volume Flow Measurement

In both the clinical environment and the laboratory environment, the measurement of the volume flow rate of a fluid as a function of time can be an important parameter. In internal flow applications, which comprise most biomedical flows of interest, the volume flow of a fluid (Q) is related to the local fluid velocity (V) through the integration of the velocity over the crosssectional area of the duct or vessel (Shaughnessy et al., 2005; White, 1979)

$$Q = \int V dA \quad (23.1)$$

The flow rate Q , velocity V , and area A have dimensions of volume per time, length per time, and length squared, respectively. The SI units are typically used in the bioengineering field with mass units of grams or kilograms, length units of meters (millimeter and centimeter), and time units of seconds. The mass flow (M) is directly related to the flow volume through the fluid density, ρ , with units of mass/volume,

$$M = \rho \cdot Q \quad (23.2)$$

Fluid pressure and velocity are related through the Navier–Stokes equations, which govern the flow of fluids in internal and external flows (see White, 1979).

The volume flow rate of blood is often measured in many cardiovascular applications (Caro et al., 1978). For example, cardiac output (CO) is the integrated average of the instantaneous volume flow rate of blood (Q_b) exiting the aortic valve over one cardiac cycle (T_c):

$$CO = \left[\int Q_b dt \right] / T_c \quad (23.3)$$

The cardiac output has units of volume flow rate, volume per unit time. The following subsections will provide an overview of measurement techniques typically used for volume flow and velocity measurement in *in vivo*, and *in vitro* studies. This chapter will be limited to those flow measurement techniques most often used in the biomedical and bioengineering fields. Specialized measurement techniques, such as concentration or species measurement through laser-induced fluorescence (LIF) or mass spectrometry, will not be addressed.

23.2.1.1 Electromagnetic Flow Probes Carolina Medical, Inc. developed the first commercially available electromagnetic flow meter in 1955. The design provided scientists

and clinicians with a noninvasive tool that could directly measure the volume flow rate (Webster, 1998). Clinical probes were developed that could be attached to a vessel for extravascular measurement of blood flow without the need for cannulation of a surgically exposed vessel.

Electromagnetic flow meters are volumetric flow measuring devices designed to measure the flow of an electrically conducting liquid in a closed vessel or pipe. Commercial meters, used in both the biomedical and general engineering fields, come in a variety of sizes and designs that can measure flow rates from ~ 1 mL/min to $>100,000$ L/min. Reported uncertainties are typically on the order of a few percent but can be as low as 0.5% of reading in some specialized meter designs. Low uncertainties are dependent on proper use and installation of the meter. Improper use or installation (mounting the meter in a location with a complex flow profile) will increase measurement uncertainty. Most clinical quality meters that are mounted externally to a vessel exhibit uncertainties that can approach 15% in some applications, (Carolina Medical, Inc., product support literature). In cardiovascular applications, these meters may also be susceptible to electrical interference by the heart or by measurement anomalies caused by motion of the probe.

The principle governing the operation of an electromagnetic flow meter is Faraday's Law of Electromagnetic Induction. This law states that an induced electrode voltage is proportional to the velocity of flow of a conductor through a magnetic field of a known density. Mathematically, this is:

$$E_e = K[V \cdot B \cdot L_e] \quad (23.4)$$

Here, E_e is the induced voltage between two electrodes (with units of volts) separated by a known conductor length L_e (provided by the conducting fluid between the electrodes) in units of millimeters or centimeters, B is the magnetic field strength in units of Tesla's, and V the conducting fluid average velocity in units of length per time. The parameter K is a dimensionless constant. Meter output is linear and proportional to flow velocity.

Fluid properties such as viscosity and density are absent from Equation (23.4). Thus, the output of an electromagnetic flow meter is independent of these properties and its calibration is independent of the type of fluid, provided the fluid meets minimum conductivity levels. This meter can then be used for highly viscous fluids, Newtonian fluids, and non-Newtonian fluids such as blood. The requirement of an electrically conductive fluid can disqualify an electromagnetic meter in some applications. Typical meters require a minimum fluid conductivity of ~ 1 mS/cm. However, low conductivity designs are capable of operating with fluid conductivities as low as 0.1 mS/cm. The presence of gas bubbles in the fluid can cause erratic behavior in the meter output.

A typical meter design has electromagnetic coils mounted on opposing sides of an electrically insulated duct with two opposing electrodes mounted 90° relative to the electromagnets. The two electrodes are mounted such that they are in contact with the conducting fluid. Figure 23.2 illustrates the typical configuration.

The meter is designed to generate a magnetic field that is perpendicular to the axis of motion of the flowing fluid. A voltage is generated when the conducting fluid flows through the magnetic field. This voltage is sensed by the two opposing electrodes. The supporting material around the meter is made of a nonconducting material to prevent leakage of the voltage generated in the moving fluid into the surrounding material. In practice, the conductor length, L_e , is not the simple path illustrated, but is rather the integral of all possible path lengths between the two electrodes across the crosssection of the duct or vessel. The signal generated along each path length is proportional to the fluid

FIGURE 23.2 Illustration of the principle of operation of the electromagnetic flow meter. Note, the magnetic field, electrodes, and flow direction are all mutually perpendicular to one another.

velocity across that path. Thus, the two electrodes measure the integrated sum of all velocities across every possible path in the vessel crosssection. This signal is then directly proportional to the volume flow rate of the fluid passing through the magnetic field.

The magnetic field generated in commercial meters may be anything from a uniform field to a specifically designed field with prescribed characteristics. Meters with uniform magnetic fields can exhibit some sensitivity to the conducting liquid's velocity profile. Fluid flowing through a vessel does not have the same velocity at all locations across the vessel. The no-slip condition at the walls of the duct ensures that the fluid velocity at the wall is zero (Shaughnessy et al., 2005). Viscosity then generates a gradient between the flowing fluid in the vessel and the stationary fluid at the wall. In complex geometries, secondary flows may occur, and velocity gradients in other directions may also develop (Pedley et al., 1971; Mori and Nakayama, 1965). This variation in fluid velocity across the magnetic field coupled with variations in the conductor length generates a variation in the magnitude of the voltage measured across the duct. As a result, installation of these meters must be carefully performed to ensure that the velocity profile of the liquid in the tube is close to that used during calibration.

A number of commercial meters shape the magnetic field coils to generate a magnetic field that exhibits a field strength with a prescribed pattern across the duct. This field shaping compensates for some velocity variations in the duct, and provides a meter with a reduced sensitivity to flow profile. As a result, this type of meter is better able to measure in vessels with upstream and downstream characteristics, such as curvature and non-uniformity in the vessel crosssection, that generate asymmetric flow profiles with secondary flow velocity components.

Commercial meters generate magnetic fields with either an AC excitation or a pulsed DC excitation. The AC excitation generates a magnetic field with a strength that varies with the frequency of the applied AC voltage. This configuration produces a meter with a relatively high-frequency response but with the disadvantage that the output signal not only varies with the flow velocity but also with the magnitude of the alternating excitation

voltage. Thus, the output of the meter for a flow with constant velocity across the vessel will exhibit a sinusoidal pattern. In addition, zero flow will produce an offset output because of the presence of the nonmoving conductor in a moving magnetic field. Quadrature signal rejection techniques can be used to filter the unwanted signal generated by the AC excitation from the desired signal generated by the flowing liquid, but this correction requires careful compensation and zeroing of the meter in the flow field before data acquisition.

The pulsed DC excitation was developed to reduce or eliminate the zero shift encountered with AC excitation. This improvement has the cost of reduced frequency response, and increased sensitivity to the presence of particulates in a fluid. Particles that impact the electrodes in a pulsed DC-operated meter produce output fluctuations that can be characterized as noise. The accuracy in each system is comparable.

A low sensing voltage at the electrodes requires a signal-conditioning unit to provide a measurable output with a good signal-to-noise. Meter calibrations typically involve one of two calibration techniques. The meter and signal-conditioning unit are calibrated separately, or the meter and signal-conditioning unit are calibrated as a system. The latter provides the most accurate calibration with accuracies that can approach 0.5% of reading in certain applications. The reader is referred to literature by various manufacturers of electromagnetic flow meters for a more comprehensive discussion of the techniques, operation, and use for specific applications.

23.2.1.2 Ultrasound Techniques—Transit Time Volume Flow Meters Ultrasonic Transit Time flow meters provide a direct measure of volume flow by correlating the change in the transit time of sound waves across a pipe or vessel with the average velocity of the liquid flowing through the pipe (Webster, 1998; Drost, 1978; Lynnworth, 1979). Transit time ultrasonic flow meters are widely used in clinical cardiovascular applications. In recent years, a number of studies have been performed to evaluate and compare transit time ultrasonic flow measurement techniques with other techniques used clinically (Beldi et al., 2000). The typical configuration for an ultrasonic flow probe involves one or two ultrasonic transducers (transmitters/receivers) and possibly an ultrasonic reflector. Transducers and reflectors are positioned in opposing configurations across a tube or vessel as illustrated in Figure 23.3. The time it takes an ultrasound wave to propagate across a fluid depends on the distance of propagation and the acoustic velocity in the fluid. If the fluid is moving, the motion of the fluid will positively or

FIGURE 23.3 Illustration of principal of transit time ultrasonic flow probe operation.

negatively add a phase shift to the time of propagation (transit time) through the fluid, which can be written mathematically as:

$$T_t = D_p / [c \pm V \cdot \cos(\theta)] \quad (23.5)$$

Here, T_t is the measured transit time (s), D_p is the total propagation distance of the wave (length units), c is the acoustic speed of the fluid (units of length per time), V is the average velocity of the fluid (units of length per time) over the propagation length, and θ is the angle between the flow direction and the propagation direction of the wave. The configurations illustrated in Figure 23.3 have an inherent dependency of the measured transit time on the coupling of the transducer with the vessel. Acoustic impedance characteristics of the vessel wall, and mismatches in impedance at the vessel wall/transducer and wall/fluid interfaces will affect the accuracy of the flow rate measurement.

The approach to using Equation (23.5) in a metering device is to incorporate bidirectional wave propagation in opposing directions, as shown in Figure 23.4, which will produce two independent transit time measurements (T_{t1} and T_{t2}), one from each direction of propagation. The forward direction transit time T_{t1} is defined by Equation (23.5) with a plus sign before V and T_{t2} by the minus sign. The fluid velocity can then be obtained by taking the difference of the transit times ($T_{t1} - T_{t2}$). It can be shown that, for fluid velocities small relative to the acoustic velocity of the fluid ($V^2 \ll c^2$), this difference reduces to:

$$(T_{t1} - T_{t2}) = 2D_p(V \cdot \cos(\theta)) / c^2 \quad (23.6)$$

With the probe geometry defined (the propagation distance and propagation angle relative to the vessel or flow direction) and with the fluid properties known (acoustic speed of the fluid), the average speed of the fluid along the propagation path of a narrow beam can be calculated from the transit times. Wide beam illumination, where the beam width is wider than the vessel diameter, effectively integrates the measured transit time phase shift over the crosssection of the vessel. The wide beam transmission can be approximated by the summation of many infinitesimally narrow beams adjacent to one another. Thus, the measured wide beam phase shift is proportional to the sum of these narrow beams propagating through the vessel. As the phase shift encountered in a narrow beam transmission is proportional to the average fluid velocity times the beam path length, integrating or summing over all narrow beams across the vessel results in a measured total transit time phase shift

FIGURE 23.4 Bidirectional wave propagation.

that is proportional to the average fluid velocity times the area of the vessel sliced by the ultrasound beam, or the volume flow rate.

The popular Transonic Systems, Inc. flow meter uses bidirectional transmission with two transducers operating in transmit and receive modes, and a single reflector configured as illustrated in the left schematic of Figure 23.4. This approach increases the propagation length while effectively reducing sensitivity to wall coupling or misalignment of the probe with the wall. The increased path length improves uncertainty and provides a probe body with a relatively small footprint, an advantage in *in vivo* or surgical applications.

The basic operation of a bidirectional transit time meter involves the transmission of an ultrasound plane wave at a specific frequency. This wave propagates through the vessel wall and fluid where it is either received at the opposite wall or is reflected to another transducer operating as an acoustic receiver. This received signal is recorded, processed, and digitized before the transducer is reconfigured to transmit a second pulse in the opposite direction. The overall frequency response of such a probe is dependent on the pulse time, the time delay between the forward and reverse pulses, the acoustic speed through the medium, the propagation distance, and the signal-conditioning electronics, which can include analog signal acquisition, and filtering. The meter size governs the propagation distance and, thus, the size of the vessel that the meter can be mounted on.

The frequency response of commercial probes varies from approximately 100 Hz to more than 1 KHz, where the highest frequency responses are obtained in the smaller probes. As a result, commercial probes have sufficient frequency response for most clinically or biomedically relevant flow regimes. Velocity and flow resolution is governed, in part, by the propagation length over which the flow is integrated and the resolution of the transit time measurement. The reader is referred to the meter manufacturers for detailed information about the operating specifications of particular meters. Reported uncertainties in transit time meters can be better than 15%. Actual uncertainties will depend on meter use, the experience of the operator, the meter calibration, and the acoustic properties of the fluid measured and how these properties differ from those of the calibration fluid.

23.2.1.3 Ultrasound Techniques—Doppler Volume Flow Meters Flow can also be measured by ultrasound using the Doppler shift in a propagating sound wave generated by moving objects in a fluid flow (Webster, 1998; Weyman, 1994). The primary difference is in the principal of operation. Devices using the Doppler approach measure the Doppler frequency shift of the transmitted beam caused by the motion of particles encountered along the beam path, as illustrated in Figure 23.5. The Doppler shift caused by reflection of an incident wave by a moving particle is given by:

$$F_D = 2F_o V \cos(\theta) / c \quad (23.7)$$

The shift frequency F_D (units of 1/s) is linearly related to the component of the speed of a particle, V , in + the direction of the wave propagation, the initial transmission frequency of the wave, F_o , and the speed of sound in the fluid, c . The reader is referred elsewhere in this encyclopedic series, and to the text by Weyman (1994) for a detailed presentation of the Doppler technique.

The Doppler meter provides a direct measure of velocity that can be used to calculate the volume flow rate indirectly. Most biomedical applications involving volume flow measurement are performed on flow through a duct or vessel of given shape and size. Thus, the volume flow is the integral of the measured velocity profile across the vessel

FIGURE 23.5 Schematic of the operation of a Doppler ultrasound probe.

crosssectional area as defined in Equation (23.1). The integral in Equation (23.1) can be related to the average velocity \bar{U} across the duct multiplied by the crosssectional area of the duct (White, 1979). The Doppler technique then requires not only an estimate of the average velocity in the vessel but knowledge of the vessel area as well.

Commercially available Doppler volume flow meters, although not commonly used in biomedical applications, can be attached to a pipe or duct wall as with transit time meters. The commercial Doppler flow meters measure volume flow by integrating the measured Doppler shift frequency generated by particles throughout the flow. This integration is performed over a predefined path length in the flow and is dependent on the number, type of particles, their size, and distribution. The meter accuracy is also dependent on the velocity profile in the flow. Careful *in situ* calibrations are often needed to obtain accuracies of less than 10%. The Doppler meter has several disadvantages when compared with the transit time meter.

It requires a fluid that contains a sufficient concentration of suspended particles to act as scattering sites on the incident ultrasound wave. These particles must be large enough to scatter the incident beam with a high intensity level, but small enough to ensure that they follow the fluid flow (Crowe et al., 1998). As a result of their dependence on flow profile, Doppler flow meters are not well suited for measurement of flow in vessels with curvature or branching. Doppler flow meter measurements in blood rely on blood cells to act as scatterers. Clinical Doppler ultrasound machines, commonly used in echocardiography, can also be used to indirectly infer volume flow through the direct measure of the fluid velocity, and will be discussed later in the subsection on velocity measurements.

23.2.1.4 Invasive or Inline Volume Flow Measurement Invasive or inline flow meters must be installed inline as a part of the piping or vessel network and involve hardware that is in contact with the fluid. These meters often have a non-negligible pressure drop and may adversely interact with the flowing fluid. As a result, these meters are not often used in *in vivo* applications. Meters that fall in this category are: variable area rotameters, turbine/paddle wheel meters, and vortex shedding meters. The primary advantage of these meters is low cost and ease of use. However, these meters typically exhibit sensitivity

FIGURE 23.6 Schematic of a variable area flowmeter.

both to fluid properties, which can be dependent on temperature and pressure, and to flow profile (White, 1979).

Variable area rotameters are simple measurement devices that can be used with a variety of liquids and gases. The flow of fluid through the meter raises a float in a tapered tube, as shown in Figure 23.6. The higher the float is raised, the larger the diameter of the tapered tube, increasing the crosssectional area of the tube for passage of the fluid. As the flow rate increases, the float is elevated higher in the tube. The height of the float is directly proportional to the fluid flow rate. In liquid flow, the float is raised by the combination of the buoyancy of the liquid and the fluid drag on the float. Buoyancy is negligible in gaseous flows and the float moves in response to the drag by the gas flow. For constant flow, the float reaches a stable position in the tube when the upward force generated by the flowing fluid equals the downward force of gravity. The float will move to a new equilibrium position in response to a change in flow. These meters must be installed vertically to operate properly; however, spring-loaded meters have been designed to eliminate the need for gravity, and permit installation in other orientations.

Rotameters are designed and calibrated for the type of fluid (fluid properties such as viscosity and density) and flow range expected. They do not function properly in non-Newtonian fluids. Use of a meter with a fluid different from that which the meter was calibrated for, or with a fluid at a different temperature or pressure, requires a correction to the meter reading. Meter uncertainty and repeatability will vary with operation of the meter, but can approach a few percent with proper operation.

Turbine and paddle wheel meters measure volume flow rate through the rotation of a vaned rotor in contact with the flowing fluid. These meters are intrusive flow

measurement devices that produce higher pressure drops than others in the class of invasive flow probes. The turbine meter has a turbine mounted across the pipe or duct in full contact with the flow, whereas the paddle wheel meter has a vaned wheel mounted on the side of the duct with half of the wheel in contact with the flow. Accuracy and repeatability is best with the turbine meter, but the pressure drop is also higher. An AC voltage is induced in a magnetic pickup coil as the turbine or paddle wheel rotates. Each pulse in the AC signal represents the passage of one blade of the turbine. As the turbine fills the flow path, a pulse represents a distinct volume of fluid being displaced between two turbine blades. This design provides an accurate direct measure of the volume flow rate.

Flowmeter selection must take into account the type of fluid, the flow rate range under study, and the acceptable pressure drop for a given flow application. In general, these meters have a sensitivity to flow profile, and the pressure drop is dependent on the fluid properties. The meters incorporate moving parts within the flow and thus use bearings to ensure smooth operation. Bearing wear will affect the meter accuracy and must be monitored for the life of the meter. The paddle wheel meter operates in a similar manner as the turbine meter. The primary difference is that only part of the rotor is in contact with the fluid and, thus, although the paddle wheel meter is more sensitive to flow profile, it has a smaller pressure drop. Installation of these meters often involves a specified number of straight pipe sections upstream and downstream of the meter, and may also require installation of a flow straightener inline upstream of the meter.

Vortex meters operate on the principal of Strouhal shedding. Separating flow over an obstruction such as a cylinder or sharp-edged bar results in a pulsatile or oscillatory pattern as shown in Figure 23.7. The shedding frequency, ω (units of 1/s), is related to the fluid velocity by:

$$\omega = V \cdot S_t / L \quad (23.8)$$

where S_t is the Strouhal number, which is a nondimensional number that is a function of the flow Reynolds number and geometry of the obstruction, and L is a characteristic length scale (White, 1979). For a cylinder, L is the diameter of the cylinder. The Reynolds

FIGURE 23.7 Vortex shedding from a circular cylinder (Picture from White (1979), courtesy of the U.S. Naval Research Laboratory)

number is a dimensionless number that is the ratio of inertial to viscous forces in the flow and is defined as

$$Re = V \cdot L / \nu \quad (23.9)$$

Here, V and L are defined as in Equation (23.8), and ν is the kinematic viscosity of the fluid with units of length squared per time.

The vortex meter is an intrusive meter that has a "shedder bar" installed across the diameter of the duct. The flow separates off this bar and generates a shedding frequency that is transmitted through the bar to a piezoelectric sensor attached to the bar. The meter is sensitive to flow and fluid properties, and rated accuracy and pressure drop depend on application.

Volume flow rate can also be estimated through an indirect measure of the velocity profile in the flow and the use of Equation (23.1). A number of instruments are available that measure fluid velocity in biomedical engineering applications. Doppler ultrasound and MR phase velocity encoding are standard clinical techniques used to measure velocity of a flowing fluid noninvasively. *In vitro* systems that are commonly used to measure fluid velocity, in addition to Doppler and MR, are laser Doppler velocimetry (LDV), particle image velocimetry (PIV), and thermal anemometry. Besides an estimate of volume flow rate, fluid velocity measurement can provide quantification of flow profiles, fluid wall shear, pressure gradient, and flow mixing. The following section summarizes velocity measurement techniques commonly used in biomedical/bioengineering applications.

23.2.2 Velocity Measurements

23.2.2.1 Thermal Anemometry Thermal anemometry is an invasive technique used to measure fluid velocity or wall shear. A heated element is inserted into the flow and specialized electronic circuitry is used to measure the rate of change in heat input into the element in response to changes in the flow field (Comte-Bellot, 1976). Thermal anemometry, when used properly, is characterized by high accuracy, low noise, and high spatial, and temporal resolution. Its main disadvantages are sensitivity to changes in fluid temperature and properties, particulates and bubbles suspended in a fluid, nonlinear response to velocity, and its invasive characteristics (geometry, size, vibration, etc.).

Hot-film anemometry has been used to measure blood velocity and wall shear in biomedical and bioengineering applications both *in vitro* and *in vivo*. Arterial blood flow velocity measurements were performed by Nerem et al. 1976, 1974 in horses and by Falsetti et al. (1983) in dogs. Tarbell et al. (Baldwin et al., 1988) used flush-mounted hot films to measure wall shear in the abdominal aorta of a dog. *In vitro* applications of hot-film anemometry include the measurement of wall shear in an LVAD device (Baldwin et al., 1988) and the *in vitro* measurement of flow in rigid models of arterial bifurcations by Batten and Nerem (1982). Although rarely used in biomedical applications now, we will briefly present hot-film anemometry here for completeness. The reader is referred to the text by Brunn (1995) and the symposium proceedings by Stock (1993) for a detailed presentation of thermal anemometry.

Thermal anemometry operates on the principal of convective cooling of a heated element. A thin wire or coated quartz element, mounted between supports, is heated and exposed to a fluid flow, as shown in Figure 23.8. The element is heated by passing a current through the wire or element. The amount of heat generated is proportional to the

FIGURE 23.8 Illustration of a hot wire or film element.

current, I (measured in units of amps), and the resistance of the element, R (ohms), by I^2R . The element is convectively cooled by flow until an equilibrium state is reached between electrical heating of the element and flow-induced convective cooling; $DE/Dt = W + H$, where E is the thermal energy stored in the element, W is the heat added by Joule heating, and H is the heat loss to the environment by cooling. At equilibrium, $DE/Dt = 0$ and $W = H$.

Changes in flow velocity will increase or decrease the amount of convective cooling and produce changes in the equilibrium state of the element or the temperature of the element. Commercial anemometers employ a four-arm electronic bridge circuit to maintain constant element temperature, current, or voltage in response to changes in convective cooling. As convective cooling changes, the anemometer output, current, or voltage changes in response to maintaining the desired set condition. This equilibrium condition assumes that radiation losses are small, conduction to supports is small, temperature is uniform over the length of the sensor, velocity impinges normally on the sensor, velocity is uniform over the sensor length and is small compared with the sonic speed, and, finally, the fluid temperature and density are constant.

An energy balance between convective heat cooling and Joule heating can be performed to derive a set of governing equations that relate input current, I , to convective velocity, V . The “King’s Law” is the classic result of this energy balance:

$$I^2 R^2 = V_o^2 = (T_w - T_a)(A + B \cdot V^n) \quad (23.10)$$

where V_o is the measured voltage drop in response to a velocity, V , and T_w and T_a are the wire and ambient fluid temperatures (degrees Centigrade), respectively. The coefficients, A and B , and power, n , are determined through careful calibration over the velocity and temperature range that will be observed experimentally. In the event of a three-component flow, the probe must be calibrated for yaw and pitch angles between the probe and the flow velocity vector, and the velocity, V , in Equation (23.10) must be replaced by a term related to the velocity vector magnitude. Bridge-type circuits are also prone to stable and unstable performance under unsteady operation. Thus, the overall calibration of a

hot-wire/film system must involve the element and electronics as a system, and must also involve dynamic calibrations to characterize the frequency response of the system.

Hot-wire/film probes come in a variety of sizes, shapes, and configurations. Probes are manufactured from platinum, gold-plated tungsten, or nickel-plated quartz, and comes in single-or multi-element configurations for measurement in a variety of flow conditions. The reader is referred to the hot-wire/film manufacturers for a complete summary of probe types and conditions for use. In general, wire probes are used when possible because of lower cost, improved frequency response, and ease of repair. However, wire probes are more fragile when compared with film-type probes and are usually restricted to airflows. Film probes are used in rough environments, such as liquid flows.

The following considerations should be addressed to ensure accurate measurements when using thermal anemometry. The type of flow should be assessed for velocity range, flow scales, and fluid properties (clean gas or particle contaminated liquid, etc.). The flow characteristics will define the right probe, anemometer configuration, and A/D setup to use. Appropriate calibrations with complete hardware setup should be performed. Perform the experiment and post calibrations to ensure that the anemometer/probe calibration has not changed.

23.2.2.2 Doppler Ultrasound and Magnetic Resonance Flow Mapping The focus of this subsection is to introduce the concept of Doppler ultrasound and MR flow mapping for local velocity measurement. Flow measurement with clinical Doppler can suffer from the same limitations as the small Doppler meter, but has several advantages over these small meters. Most ultrasound machines can operate in continuous wave or pulsed Doppler modes of operation; see Weyman (1994) for a more detailed discussion of the modes of operation.

Pulsed Doppler ultrasound offers the advantage of localizing a velocity measurement within a flow and can be used to measure the velocity profile across a vessel or lesion. This information coupled with echocardiographic imaging of the geometry can be used to calculate the flow rate from Equation (23.1). Unfortunately, the implementation of this technique is not straightforward because of limitations in resolution, velocity aliasing, and the need to know the relative angle between the transmitted ultrasound beam and the local flow.

Velocity aliasing in pulsed-mode Doppler occurs because the signal can only be sampled once per pulse transmission (e.g., the pulse repetition frequency). Frequency aliasing, or the ambiguous characterization of a waveform, occurs in signal processing when a waveform is sampled at less than one half of its fundamental frequency, referred to as the Nyquist condition in signal processing. In a pulsed Doppler system, velocity aliasing will occur when the Doppler shift of the moving particles exceeds half of the pulse repetition frequency. As the pulse repetition frequency is a function of the depth at which a sample is measured, the alias velocity will vary with imaging depth. Increasing the imaging depth will lower the velocity at which aliasing will occur. Continuous wave Doppler signals are typically digitized at higher sampling frequencies, limited by the Nyquist frequency associated with the frequency of the transmission wave. Velocities observed clinically produce Doppler shifts that are generally lower than sampling frequencies used in continuous wave Doppler. As a result, velocity alias is not usually observed with continuous mode Doppler in clinical applications.

Aliased signals that are processed by the measuring system are not directly proportional to the Doppler shift generated by the velocity of the particle but can be related to

the Doppler shift. Undersampling a wave under estimates the frequency and produces a phase shift. Most clinical Doppler machines use the frequency and phase of the sampled wave to infer both velocity magnitude and direction. Velocity alias will produce a lower velocity magnitude with increasing Doppler shift above the alias limit. As frequency is by definition positive and Doppler machines use the signal phase to determine direction, the measured frequency is usually reported as a negative velocity above the alias limit, which is often displayed as an increasing positive velocity magnitude with increasing Doppler shift up to the alias limit. Further increases in the Doppler shift (particle velocity) result in a sign change at the velocity magnitude of the alias velocity with a continued decrease in velocity with increasing Doppler shift. Velocity alias can be reduced or eliminated by frequency unwrapping and baseline shifting, or through the careful selection of machine settings during data acquisition.

Frequency unwrapping is simply correcting the reported aliased velocity by a factor that is related to the alias velocity limit and the magnitude of the reported negative velocity. This correction is, roughly speaking, adding the relative difference in magnitude between the measured aliased velocity and the velocity alias limit to the velocity alias limit. This method of addressing velocity alias is often accomplished by baseline shifting in commercial Doppler machines. In baseline shifting, the phase angle at which a negative velocity is defined is shifted with the effect of a relative shift in the reported alias velocity. Baseline shifting or frequency unwrapping does not eliminate velocity alias but provides a correction to extend the measurement to higher frequencies.

Velocity alias can be "eliminated" by reducing the Doppler frequency of moving particles and thereby shifting the measurable range below the alias limit, which can be accomplished by reducing the carrier frequency of the ultrasound wave, which will in turn reduce the Doppler frequency shift induced by a moving particle and increase the maximum velocity that can be recorded before reaching the Nyquist limit. Alternatively, the Doppler shift frequency can be reduced by increasing the angle between the propagation of the ultrasound wave and the velocity vector, which reduces the magnitude of the Doppler shift frequency by the cosine of this included angle. Angle correction has limitations in that the flow direction must be known and the uncertainty in the correction increases with increasing included angle. As color flow mappers operate in the pulsed Doppler mode, they are subject to velocity alias. Color flow mappers indicate velocity direction by a color series (for example, shades of red or blue). Velocity alias is displayed as a change in a color series from red-to-blue or blue-to-red.

The clinical measurement of many velocity ensembles across a vessel and the integration across the vessel geometry can be time-consuming and problematic in pulsatile flow through a compliant duct. Furthermore, lesions are often complex in shape and cannot be adequately defined by echo. Doppler echocardiographers and scientists have exploited the physics of fluid flow to develop diagnostic tools that complement these capabilities of commercial Doppler systems. The text by Otto (1997) provides an excellent review of these diagnostic tools. Techniques, such as the PISA (proximal isovelocity surface area) or proximal flow convergence, use the capability of color Doppler flow mapping machines to estimate volume flow through an orifice, such as a heart valve. Figure 23.9 illustrates the concept of the proximal flow convergence method.

The flow accelerating toward a small circular orifice will increase in velocity V_a , until a maximum velocity at the orifice V_j is reached. This acceleration occurs in a symmetric pattern around the orifice and is characterized by hemispheres of constant velocity. As the

FIGURE 23.9 Illustration of the proximal isovelocity surface area (PISA) concept.

orifice is approached, the velocity increases and the radius of the hemisphere decreases. The regurgitant flow through the orifice can then be calculated as:

$$Q = (2\pi r^2)V_a \quad (23.11)$$

The combined imaging and Doppler characteristics of color Doppler flow mapping are exploited in the PISA approach. The location of the alias velocity in the flow map provides a measure of V_a , which is then coupled with a measure of the radial location from the orifice using the imaging capability of color flow mapping. As flow is velocity times area, the hemispheric assumption provides a shell with a surface area of $2\pi r^2$ that velocity V_a is passing through. Figure 23.10 illustrates the concept of PISA with a color Doppler flow image of valvular regurgitation in a patient.

The PISA approach assumes a round orifice with a hemispherical acceleration zone. In clinical applications, orifices are rarely round and the acceleration zone is not

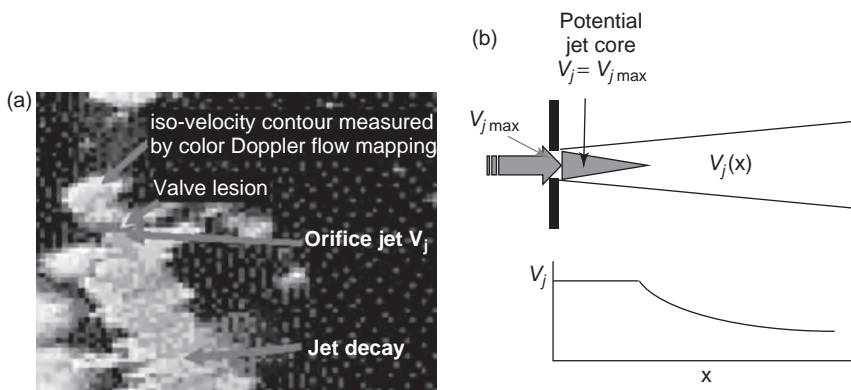

FIGURE 23.10 (a) Color Doppler flow map image of the proximal isovelocity surface area (PISA) in valvular regurgitation. (b) Illustration of the jet decay downstream of an orifice. V is the Jet velocity and x is measured from the orifice.

hemispherical with the result of under or over estimation of the flow rate depending on what radial velocity contour is used in Equation (23.11). The semielliptic method is one approach at considering nonhemispheric geometries in an attempt to correct for errors associated with the PISA technique.

The combination of continuous wave and pulsed Doppler ultrasound is exploited in the turbulent jet decay method of measuring flow through a stenotic lesion or a regurgitant valve. Although continuous wave Doppler does not suffer from velocity alias as does pulsed Doppler, it cannot provide spatial localization of the velocity. The turbulent jet decay method uses continuous wave Doppler to measure the high velocity at the lesion orifice and then uses pulsed.

Doppler to measure the velocity decay at specified location downstream of the orifice. Turbulent jet theory can be used to relate the flow rate of the turbulent jet to the decay of the jet velocity downstream of the orifice, as in Equation (23.12):

$$Q = (\pi V_m^2 x^2) / 160 V_j \quad (23.12)$$

The velocity V_m is measured by pulsed Doppler at location x measured from the jet orifice, whereas the orifice velocity, V_j , is measured by continuous wave Doppler, Figure 23.10b illustrates this decay phenomenon. This equation is valid for round jets and has been extended to jets with other geometries by Cape et al. (1993) with the resulting change to Equation (23.12):

$$Q = (V_m^2 H x) / 5.78 V_j \quad (23.13)$$

where H is the width of the jet measured by color Doppler.

Doppler velocity measurements are also used to estimate pressure gradients in various cardiovascular applications. The Bernoulli equation can be used to estimate the pressure drop across a stenotic lesion or through a valve by measuring the velocity upstream and downstream of the lesion or valve. The Bernoulli equation is

$$\Delta P = (P_1 - P_2) = 1/2 \cdot \rho (V_2^2 - V_1^2) \quad (23.14)$$

where position 1 is often measured upstream of the lesion and position 2 is at the lesion or downstream. In this equation, the pressure drop ΔP has units of Pascals's (Pa). A Pascal is a Newton (N) per square meter, where a Newton has units of mass (kg) times length (m) per time squared. Bioengineering and biomedical applications often use the units of millimeters of mercury (mmHg) in defining a pressure value. A mmHg is related to Pa by the conversion $1 \text{ mmHg} = 133.32 \text{ Pa}$.

Magnetic resonance flow mapping has the advantage over Doppler that it can measure the full three component velocity field over a volume region (Hahn, 1960; Ku et al., 1990; Pettigrew, 1993), which eliminates the uncertainty in flow direction and enables the use of standard fluid dynamic control volume analysis. The advantages of MR flow mapping come at the cost of long imaging times and increased sensitivity to motion artifacts in *in vivo* applications, where phase locking to the heart rate or breathing cycle can increase complexity.

The velocity of moving tissue can be detected by a time of flight technique (Singer and Crooks, 1983) and by phase velocity encoding (Moran et al., 1985; Bryant et al., 1984).

The time-of-flight method tracks a selected number of protons in a plane and measures the displacement of the protons over a time interval defined by the imaging rate. *In vivo* (Matsuda et al., 1987), and phantom (Edelman et al., 1989) studies have shown that the time-of-flight technique is capable of accurate velocity measurement up to velocities at least as high as 0.5 m/s. However, the time-of-flight method requires a straight length of vessel on the order of several centimeters for accurate velocity estimation. This requirement reduces its usability in most *in vivo* applications. The phase velocity encoding method has become the preferred technique in most clinical applications.

Phase velocity encoding directly relates the local velocity of nuclei to the induced phase shift in an imaging voxel. Properly defined bipolar magnetic field gradients are produced in the direction of interest for velocity measurement. The velocity of hydrogen nuclei is then encoded into the phase of the detected signal (Moran, 1982). Chatzimavroudis et al. (2001) and Firmin et al. (1990) provide a discussion of the phase encoding technique with an assessment of its accuracy and limitations for flow measurement.

The technique uses two image acquisitions to provide velocity compensation and velocity encoding. Velocity information in each voxel is obtained by a voxel-by-voxel subtraction of the two images with respect to the phase of the signal. Like Doppler ultrasound, phase velocity encoding can suffer from aliasing effects, alignment error, and limits in spatial and temporal resolution. Velocity estimation using phase shift measurement is limited to a maximum range of phase of 2π radians without ambiguity or aliasing. However, the estimation of the phase shift using phase subtraction between two images reduces that sensitivity to this problem. Studies have been conducted that show MR phase velocity encoding can measure velocities covering the complete physiologic range up to several meters per second (Zhang et al., 2004). Misalignment of the flow direction with the encoding direction will produce a negative bias in the measured flow where the measured velocity will be lower than the true velocity. Like Doppler, this bias follows a cosine behavior where $V_{\text{meas}} = V_{\text{act}} \cos(\theta)$, where V_{meas} is the measured velocity, V_{act} is the actual velocity, and θ is the misalignment angle. This error is typically less than 1% in most applications.

The size of a voxel and the sampling capabilities of the hardware characterize the spatial and temporal resolution of the system. Spatial resolution affects the size of a flow structure that can be measured without spatially filtering or averaging the structure or velocity measurement. Spatial velocity gradients that are small relative to the voxel size will not be adequately resolved and will be averaged over the voxel volume (Kraft et al., 1992). In addition, rapidly varying velocity fluctuations in time will produce a similar low-pass frequency filtering effect if these fluctuations occur with a time scale that is much smaller than the imaging time scale of the measurements. Turbulent flow can produce spatial and temporal scales that could be small relative to the imaging characteristics and can result in what is referred to as signal loss in the image (Suzuki et al., 1990). Stenotic lesions and valvular regurgitation are clinical examples where turbulent flow can occur with spatial and temporal scales that could compromise measurement accuracy.

Phase velocity encoding has the drawback of fairly long imaging or magnet residence times, which is particularly true for three-component velocity mapping. Although long imaging times acceptable for *in vitro* testing with flow loop phantoms, it can present problems and concerns with clinical measurements. Patients can be exposed to long time intervals in the magnetic with the associated problems of patient comfort and care. *In vivo* velocity measurements are often phase-locked with cardiac cycle or breathing rhythm.

Long imaging times can increase potential for measurement error caused by patient movement and variability in the cardiac cycle or breathing rhythm, which can cause noise in the phase-averaged, three-component velocity measurements. Research, in recent years, has focused on hardware and software improvements to increase spatial resolution and reduce imaging time, for example, Zhang et al. (2002).

Magnetic resonance phase velocity encoding provides coupled 3D geometric imaging using traditional MR imaging methods with three-component velocity information. This coupled database provides a powerful diagnostic tool for blood flow analysis and has been used extensively in *in vitro* and clinical applications. Jin et al. (2003) used this coupled imaging flow-mapping capability to study the effects of wall motion and compliance on flow patterns in the ascending aorta. Standard imaging was used to measure aortic wall movement and the range of lumen area and diameter change over the cardiac cycle. This aortic wall motion was phase-matched with phase velocity encoded axial velocity distributions in the ascending aorta. Similar to the PISA approach in Doppler ultrasound, a control volume approach using phase velocity encoded MR velocities can be applied to the assessment of valvular regurgitation (Walker et al., 1995; Chatzimavroudis et al., 1998). The control volume approach is illustrated in Figure 23.11.

23.2.2.3 Laser Doppler Velocimetry The Doppler shift of laser light scattered by particles or cells in a fluid is the basis of laser Doppler velocimetry. Detailed presentations of the LDV technique are provided in the works by Adrian (1983), Drain (1980), and Durst et al. (1976). The scattered radiation, from a laser beam directed at moving particles in a fluid, has a Doppler-shifted frequency defined as

$$f_D \sim (1 - V/C_1)f' \quad (23.15)$$

where C_1 is the speed of light in a vacuum, V is the particle velocity, and f' incident light frequency. The Doppler-shifted frequency is very small relative to the frequency of

FIGURE 23.11 Illustration of the control volume method in MR phase velocity assessment of valvular regurgitation. The control volume (CV) is the heavy dotted line box around the mitral regurgitant orifice. The box edges are usually selected to correspond with rows and columns in the MR image. V_i represents the 3-component velocities measured with MR through the i faces of the box. Faces 4 and 5 are in the plane of the image at $\pm Z$ offsets from the plane of the image. The regurgitant flow Q_r is the sum of the $V_i A_i$ on each face.

FIGURE 23.12 Illustration of the dual-beam or fringe mode LDV setup.

light and, thus, dual-beam or fringe mode LDV is the system configuration of choice. The dual-beam mode of operation is schematically shown in Figure 23.12. In fringe mode LDV, two coherent laser beams of the same wavelength or frequency are focused to a common point (control volume) in the flow field. The scattered light from a particle moving through the control volume is received by a photodetector.

The crossing of two, coherent, collimated laser beams forms interference fringes as the propagating light waves constructively and destructively interfere with one another. This interference creates a series of light and dark bands with spacing, d_f , of:

$$d_f = \lambda / 2\sin(\kappa) \quad (23.16)$$

The number of fringes, N_{FR} , in the measurement volume is given by:

$$N_{FR} = 1.27d/D_e^{-2} \quad (23.17)$$

where d is the spacing between the two parallel laser beams before the focusing lens and D_e^{-2} is the beam diameter before the lens. Figure 23.13 illustrates the probe geometry generated by the intersection of two focused coherent laser beams with a common wavelength.

FIGURE 23.13 Illustration of the measurement volume generated in fringe mode LDV.

The spatial resolution of a dual-beam system is affected by the distribution of the light intensity at the intersection of the two focused beams, referred to as the probe or measurement volume. When the laser is operating in the TEM₀₀ mode, the laser cavity sustains a purely longitudinal standing wave oscillation along its axis with no transverse modes. The laser output has an axisymmetric intensity profile that is approximately a Gaussian function of radial distance from the axis. In the far field, the beam divergence is small enough to appear as a spherical wave from a point source located at the front of the lens. A lens is used to focus the beam into a converging spherical wave. The radius of this wave decreases until the focal point of the lens is reached. At the focal point, the beam has almost a constant radius and planar behavior. The beam is focused to its minimum diameter or focal waist, d_e^{-2} and is defined as:

$$d_e^{-2} = (4\lambda f) / (\pi D_e^{-2}) \quad (23.18)$$

where λ is the wavelength of the laser beam and f is the focal length of the lens. A single pair of laser beams generates an ellipsoidal geometry having dimensions of major axis l_m and minor axis d_m given by:

$$l_m = d_e^{-2} / \sin(\kappa) \quad \text{and} \quad d_m = d_e^{-2} / \cos(\kappa) \quad (23.19)$$

where κ is the half angle between the two laser beams, as illustrated in Figure 23.13.

The particle velocity is calculated by the fluctuating light intensity collected by the receiver as the particle passes through the measurement volume and scatters light from the fringes. The intensity change of the scattered light from the light and dark fringes is converted into an electrical signal by a photomultiplier tube (PMT). The electrical signal represents an amplitude-modulated sine wave, with frequency proportional to the Doppler frequency shift (f_D) of the particle traveling through the measurement volume. The particle velocity is then equal to the Doppler frequency multiplied by the fringe spacing. In a two-beam LDV system, the measured velocity component is in the plane of the two laser beams and in the direction perpendicular to the long axis of the measurement volume.

Coherent laser beams with the same frequency produce stationary fringes. A particle moving in either direction across the fringes will produce the same frequency independent of sign, such that a stationary fringe system can only determine the magnitude of the velocity, not the direction. To avoid this directional ambiguity, one of the laser beams of a beam pair is shifted to a different frequency, using a Bragg cell, to provide a moving fringe pattern. One laser beam from each beam pair passes through a transparent medium such as glass, in which acoustic waves, generated by a piezoelectric transducer, are traveling. If the angle between the laser beam and the acoustic waves satisfies the Bragg condition, reflections from successive acoustic wave fronts reinforce the laser beam. The beam exits at a higher frequency and a prism directs the beam to its original direction. The Bragg shift causes the fringes in the probe volume to move at a constant speed in either the positive or negative direction relative to the flow. The measured frequency by the PMT and processor is then the sum or difference of the Bragg cell frequency (typically 40 MHz) and the Doppler shift frequency. This measured frequency is then downmixed with a frequency that is a percent of the Bragg frequency (called the shift frequency) producing a frequency that has a zero shifted to a higher baseline frequency (usually on the order of several mega hertz). This zero shift eliminates directional ambiguity in LDV signal processing.

Laser Doppler velocimetry has excellent spatial and temporal frequency response compared with most other measurement systems. It is considered a gold standard measurement technique in biomedical applications and is the noninvasive measurement system of choice for turbulence measurements. Two disadvantages of LDV worth noting are: (1) LDV noise and (2) velocity bias. The LDV is noisy when compared with other turbulence measurement systems, such as thermal anemometry, because of the use of photomultiplier tubes. These optical detectors, used for their sensitivity and high-frequency response, suffer from higher noise floors than other photo detectors.

Velocity bias is a result of the random sampling characteristics of LDV. As a velocity ensemble is randomly recorded when a particle passes through a probe volume, the statistics of the measured velocity ensembles are not independent of the particle velocity. A greater number of higher speed particles will cross the measurement volume over a specified time than will slower speed particles. Standard ensemble averaging will produce mean velocity estimates that are biased toward higher velocities. This velocity bias can have a significant impact on the velocity statistics, particularly in turbulent flow. In addition to velocity bias, two other biases may occur, fringe bias and gradient bias.

Fringe bias is an error that is minimized by frequency shifting. This type of bias is created by not having enough fringe crossings to satisfy processor validation criteria when calculating a velocity, which occurs when a particle crosses the edge of the probe volume or if the particle velocity is nearly parallel to the fringes. Thus, velocity ensemble averages weight velocities from particles traveling near the center of the measurement volume or those particles that cross more fringes than others. By frequency shifting with a fringe velocity at least two times greater than the flow velocity, particles moving parallel to the fringes can cross the minimum number of fringes for validation by a processor.

Gradient bias results from a non-negligible mean gradient across the probe volume. This bias depends on the fluid flow and the measurement volume dimensions. The mean velocity and the odd order moments are the only statistics affected by gradient bias. In general, LDV transmitting optics are chosen to provide as small a measurement volume as possible to increase spatial resolution and reduce gradient bias. As the LDV measurement volume is longer than it is wide, experiments should be designed to ensure that the LDV optical setup is oriented to position the measurement volume diameter in the direction of the maximum gradients in the flow.

Several postprocessing techniques have been developed to reduce velocity bias. The recommended technique is to use a transit time weighting when computing the velocity statistics. This transit time weighting approximates the ensemble average as a time average. The reader is referred to the reference by Edwards (1987) for a detailed discussion of the transit time technique and its implementation in LDV data processing.

Multiple pairs of laser beams with different wavelength (color) or polarization can be used to produce a multicomponent velocity measuring system. Two or three laser beam pairs can be focused to the same point in the flow. Each beam pair can then be used to independently measure a different component of the velocity vector. As more than one particle can pass through a measurement volume at one time, it is possible to get valid velocity component estimates from different particles. The ellipsoidal geometry of the measurement volumes exaggerates this problem. As a result, LDV data are often processed in one of two modes, random and coincident.

Random mode processing records every valid velocity ensemble as it arrives at the measurement volume, which can generate uneven sample distributions in the different velocity components or LDV channels being measured. Random mode processing has a

negligible impact on mean velocity statistics but can be detrimental to turbulence estimates. Coincident mode processing uses hardware and or software filters to ensure that each velocity component ensemble is measured from the same particle. Filters are used to ensure that the Doppler bursts measured on the different LDV channels overlap in time. Bursts generated by one particle should be measured on each channel with perfect overlap. Time window filters are used to reject bursts that do not occur within a window defined by a percentage of the burst length. The effect of coincident mode processing is usually a reduction in the overall data rate by a factor of at least two, but provides the necessary data quality for turbulence measurements.

Laser Doppler velocimetry is primarily an *in vitro* tool, although systems have been developed for blood flow measurement (Webster, 1998; Tomonaga et al., 1981). Blood is a multiphase fluid composed of a carrier liquid, plasma, and a variety of cells and other biochemical components. Plasma is optically clear to the wavelengths of light used in LDV. The optical opacity of blood is caused by the high concentration of cells, in particular red cells. On the microscopic level, however, blood can transmit light over a short distance because of the plasma carrier fluid. Clinical style probes have been developed to measure the velocity of blood cells in blood using catheter type insertion into vessels of suitable size or through transcutaneous measurement of capillary flow below the skin. These *in vivo* systems are designed with very short focal length transmitting lenses providing a small measurement volume located a very short distance from the transmitting lens. Laser light is propagated through the plasma and focused a few millimeters from the probe tip. Blood cells act as particles in the fluid and scatter light that is collected by the transmitting lens and directed to a PMT system for recording of the Doppler bursts. Manning et al. (2005) and Ellis et al. (1996) have used LDV to measure the velocity fields around mechanical heart valves in *in vitro* studies. Figure 23.14 shows the measured velocity distributions associated with impact of a Bjork–Shiley monostrut valve (Manning et al., 2005).

23.2.2.4 Particle Image Velocimetry and Particle Tracking Velocimetry Particle image velocimetry (PIV) and particle tracking velocimetry (PTV) have been applied in fluid flow applications for over a decade. They are noninvasive experimental techniques that provide a quantitative, instantaneous velocity vector field with good spatial resolution; an appealing feature when studying complex, time-dependent fluid flows that can occur in biomedical applications. The methods allow the quantitative visualization of instantaneous flow structures over a spatial region, as opposed to a point measurement like LDV, which can provide insight into the flow physics. The two techniques, PIV and PTV, differ in the way particle displacements are measured. Particle tracking follows and tracks the motion of individual particles, whereas PIV measures the displacement of groups of particles within the flow. PTV, although not commonly used, is a subset of the more common PIV technique and is still used in specific applications of PIV. Raffel et al. (1998) provides a comprehensive discussion of the PIV and PTV techniques with a detailed presentation of the physics, processing tools, capabilities, and errors.

The instantaneous velocity field is computed by measuring an instantaneous particle displacement field over a specified, finite time interval. Laser-based PIV and PTV are non-invasive velocity measurement tools that require good optical access to the flow field. As a result, they are essentially *in vitro* tools (Hochareon et al., 2004; Oley et al., 2005) that are of limited use *in vivo*. Figure 23.15 shows an example of the use of PIV in a bioengineering application of flow through one chamber of an artificial heart (Hochareon, 2003). X-ray-based PTV systems are being developed and will be capable of *in vivo* use. In this

(b) Illustration of measurement plane and vortex flow pattern. (c) Flow field schematic during valve closure determined from multi-component LDV measurements (Manning et al., 2005).

section, we will focus on PIV; however, system concepts (seeding, acquisition, processing, noise, and errors) would be applicable to some degree to systems like X-ray PTV (Lee and Kim, 2003).

Particle image velocimetry uses a double-pulsed light source, usually a laser, to illuminate a thin sheet in the flow field. Particles suspended in the fluid scatter light during each pulse, and this scattered light is recorded on a digital camera. The optimal setup has the recording device located 90° to the illumination sheet. Figure 23.16 illustrates the typical PIV setup.

Two lasers with coincident beam paths are used to illuminate a desired plane of the flow by incorporating optics to produce thin laser sheets. During image acquisition, the two lasers are pulsed with the specified time separation (typically $1\text{--}1000\ \mu\text{s}$). A trigger system, referred to as a synchronizer, controls the firing of the two lasers relative to the shuttering

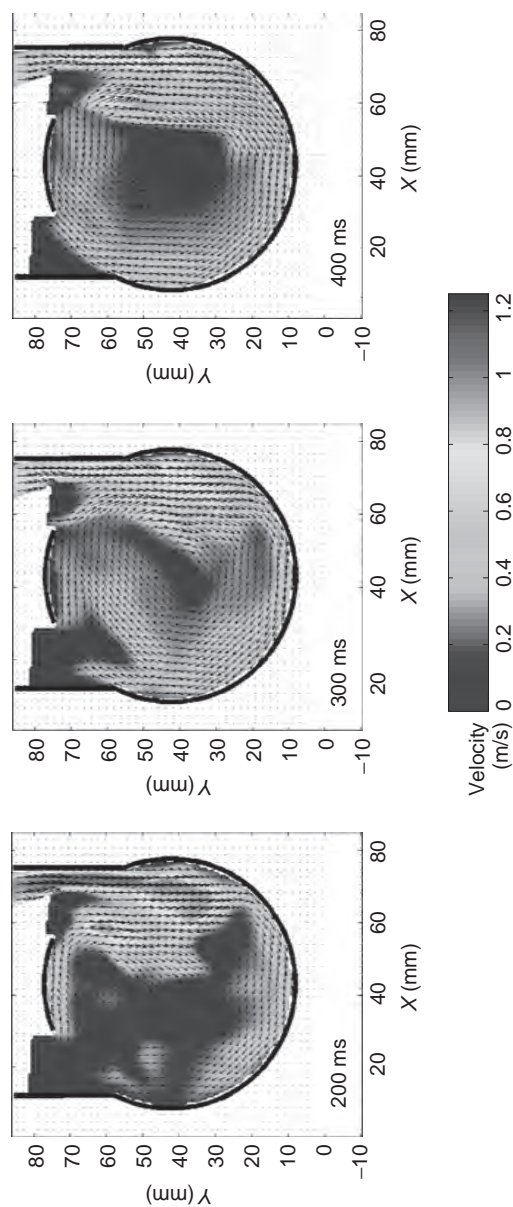

FIGURE 23.15 Phase-average velocity maps from mid to late diastole for a prototype artificial heart ventricular chamber (time reference is from the onset of diastole, 4.7 L/min CO, 75 bpm) (Hochareon, 2003).

FIGURE 23.16 Schematic of a PIV setup. (Raffel et al., 1998; Chapter 1, p. 4, Fig. 1.4., with kind permission of Springer Science and Business Media.)

of a CCD camera. The camera, usually placed orthogonal to the laser sheet, collects the light scattered by tracer particles in the flow and records an image. The synchronizer, used in crosscorrelation-based PIV systems, delays the firing of the first laser such that the camera shutter is centered between the firing of the two lasers. This synchronization technique is called frame straddling and produces two sequential images of each laser beam pulse.

Although the time between successive camera frames may be much larger than the time duration between laser pulses, the two images of the particle field created are separated by the specified time interval between the two laser pulses.

A discussion of PIV must begin with a brief introduction of the terminology commonly used. Figure 23.17 provides a schematic representation of geometric imaging. The “light plane” is the “volume” of the fluid illuminated by the light sheet. The “image plane” is the image from the light plane captured on the CCD sensor. It is important to note that the light plane is a 3D space or “volume,” whereas the image plane is a 2D space or “surface.” The subvolume selected from the light plane for cross correlation is called the “interrogation subvolume.” The corresponding location of this interrogation volume captured on the image plane is called the “interrogation subregion.” Please note that the displacement vectors in an interrogation volume are three-component vectors, whereas those in an interrogation area are two-component vectors. “Particle” is the physical particle suspended in the fluid volume. “Particle image” is the image of each particle in the image plane. Particle density, intensity, and pair refer to particle properties, whereas image density, intensity, and pair refer to particle image properties.

Most commercial systems use a crosscorrelation-based image processing technique to compute the particle displacement. Images are subdivided into small “interrogation regions,” typically a fraction of the overall image size, and the same two subregions are crosscorrelated between the two images to obtain the average displacement of the particles within that subregion. From this displacement and the known time delay, the velocities within the interrogation region are obtained.

FIGURE 23.17 Schematic representation of geometric imaging. (Raffel et al., 1998; Chapter 3, p. 62, Fig. 3.1., with kind permission of Springer Science and Business Media.)

Statistical PIV assumes all particles in an interrogation subregion move a similar distance and direction. The processing algorithm then computes the mean displacement vector for the particles in the interrogation volume. Therefore, the local particle distribution pattern captured on each exposure should be similar; but the group of local particles is displaced from image to image. Statistical PIV is then “pattern recognition” of the particle distribution within an interrogation subregion, instead of the averaged particle displacements. Sophisticated pattern recognition schemes have been developed by a number of researchers; however, the crosscorrelation tends to be the algorithm of choice. The use of a crosscorrelation as opposed to an autocorrelation eliminates directional ambiguity in the velocity measurement. Most commercial systems use advanced crosscorrelation algorithms, such as the Hart correlation, developed to improve signal to noise in the correlation estimate and enhance resolution (Hart, 1999, 2000).

The crosscorrelation function for two interrogation subregions of frames A and B is defined by:

$$R_{II}(s, \Gamma, D) = \langle I(x, \Gamma) I'(x + s, \Gamma' D) \rangle \quad (23.20)$$

where s is the shifting vector of the second interrogation window, Γ is the series of location vectors for each particle in the interrogation volume, D is the displacement vector for each particle, x is the spatial domain vector within the interrogation area, I is the intensity matrix for the interrogation area from frame A, and I' is the intensity matrix for the interrogation area from frame B. A detailed mathematical derivation of the crosscorrelation for (group) particle tracking is beyond the scope of this presentation. The location of the maximum value of crosscorrelation function represents the mean particle displacement

FIGURE 23.18 Representative crosscorrelation map between frames A and B.

for the interrogation image. Figure 23.18 is an example of a crosscorrelation function between two images.

The location of the crosscorrelation peak should be determined with subpixel accuracy. Several curve fitting algorithms have been developed to identify the peak in the crosscorrelation. Gaussian, Parabolic, and Centroid are three common methods in commercial software, although others exist. A Gaussian peak fit is most commonly used because the crosscorrelation function of two Gaussian functions also yields a Gaussian function, which means if the intensities of individual particle images in the interrogation area fit a Gaussian shape, the crosscorrelation function can be accurately approximated by the Gaussian function, which occurs only under the condition of low displacement gradient, so that the particle distribution pattern is preserved in windows A and B. The crosscorrelation function in distorted, particle image intensity distribution patterns are less accurately approximated by a Gaussian distribution. A three-point estimator for Gaussian fit works better with a narrow and symmetric peak. Centroid peak finding should be considered when the crosscorrelation peak is expected to have asymmetric and irregular patterns. Such cases occur for particle images larger than 2–3 pixels in diameter, for a low intensity ratio of particle image to background noise, or for a high gradient displacement field. For “correlation-based correction,” the centroid peak finding might be more suitable than Gaussian because the multiplications could distort the crosscorrelation peak.

The use of a digital CCD camera presents an error source known as “peak locking.” This error impacts the accuracy of the subpixel estimation in the correlation peak and thus impacts the velocity measurement. This error will be discussed later.

Like LDV and Doppler, PIV and PTV require that the fluid be seeded with tracer particles that follow the fluid motion. The particle density, the number of particles per unit volume of fluid, determines what technique should be used, PIV or PTV. Flows with a low particle density are more suited to PTV, whereas PIV works best in high particle density flows. It is assumed that the tracer particles follow the flow accurately to give an exact representation of the flow field at various times and locations. The particle density, however, should be sufficiently low to preserve the original flow dynamics. Such a dilute condition is expressed by the inequality:

$$(\rho_p \pi d_p^4 v_r) / (18 \mu \delta_p^3) < 1 \quad (23.21)$$

where d_p and ρ_p are the particle diameter and density, respectively, μ is fluid viscosity, v_r is the averaged particle velocity relative to neighboring particles, and δ_p is the average distance between the particles.

Particles must be small enough to follow the fluid flow but large enough to be seen. The particle relaxation time, τ_s , should be small relative to the flow time scales.

$$\tau_s = d_p^2 (\rho_p / 18 \mu) \quad (23.22)$$

In practice, τ_s is made small by using very small particles. The Stokes number for PIV experiments, St_{PIV} , can be defined as τ_s / τ_{PIV} , where τ_{PIV} is the small finite separation time between two observations (pulse separation time). St_{PIV} should be much less than 1 to assure negligible particle-fluid velocity differences over the pulse separation. However, particles must be large enough to scatter sufficient light energy to be visualized on the recording device (e.g., a CCD camera) with the goal that a particle image is at least several pixels in size. Increasing the light source energy can improve visibility, but a saturation point is reached where increasing light source energy does not help. Furthermore, high energy can damage windows and plastic test models.

The time separation of the two laser pulses must be small enough to minimize particle loss through too large a particle displacement between the first and second frames of the interrogation window. However, the time separation must be long enough to permit adequate displacement of particles at the lowest measurable velocities in each velocity component and to minimize the impact of pixel peak locking (Christensen, 2004). Complex and highly 3D flows can be biased in a 2D PIV system. PIV can provide very high spatial resolution, but suffers from low temporal resolution. Furthermore, high magnification imaging used in high resolution PIV introduces additional constraints and limitations that must be overcome to achieve high-quality vector maps.

The challenge for PIV is to correctly track particle motion. Figure 23.19 shows an example of a PIV particle image. The statistical crosscorrelation approach is used to track the displacement of a “group” of particles within an indicated small volume or subregion. The location of a velocity vector is at the center of the subregion spot. The spatial resolution for a “velocity vector” in PIV is the size of the interrogation subregion. Overlapping adjacent interrogation subregions is commonly used to reduce the distance between adjacent vectors and provide additional vectors in the overall vector map. However, this does not increase the spatial resolution of the velocity field, which is limited to the size of the interrogation subregion.

Commercial PIV systems use a multigrid recursive method to reduce interrogation subregion size. In the hierarchical approach, a PIV measurement with large interrogation

FIGURE 23.19 Example of a PIV particle image.

subregions is first computed. Subsequently, the initial interrogation area is evenly divided into smaller areas for processing. Each smaller interrogation area is offset by the displacement obtained from its parent interrogation area. This process is repeated until the smallest possible interrogation size is reached (for example, $128 \times 128 \rightarrow 64 \times 64 \rightarrow 32 \times 32 \rightarrow 16 \times 16$) for the given flow field. An iterative method can be applied at the final grid level. Similar to the multigrid method, the iterative method uses the obtained displacement from the first crosscorrelation to offset the second window for the next crosscorrelation. The difference is that it does not break down the interrogation areas into smaller windows. This process is repeated until the difference between the displacements from successive crosscorrelations is less than one pixel. If the window B is shifted by the converged displacement, windows A and B should be virtually the same, as long as the gradient is sufficiently low. Iterative crosscorrelation is another way to increase accuracy.

A minimum number of particle pairs (on the order of 10) are required in PIV processing. The particle density in the flow will determine the minimum size subregion that can be used to obtain adequate vector maps. Thus, the spatial resolution is governed by the particle density. In near-solid surfaces, the particle density is often lower in flows with strong wall gradients. Reducing the interrogation window size increases spatial resolution. However, an overly small window causes in-plane particle loss because of particles moving out of the interrogation spot. Several techniques exist to capture the particles moving out of the window without enlarging the interrogation spot. The first is simply to enlarge the second window to cover the expected displaced particle. The original interrogation window (frame A) is enlarged to the same size as window B and zero-padded at the extended part. The second technique is to offset the second window to the location of anticipated displacement.

Errors in PIV processing can occur from several sources. The spatial resolution for a velocity vector is the dimension of the interrogation volume. If the particles are evenly
