distributed, the center of an interrogation volume can be used as the vector location. The accuracy of the displacement depends on both the subpixel accuracy of the peak finding algorithm and the image quality. A one-tenth pixel is the best accuracy (Raffel et al., 1998). Time resolution for the velocity is the separation time between two pulses, as the information during this period is not recorded. The velocity error is composed of systematic and residual error. Systematic errors come from the algorithm and experiment setting or image quality, which can be minimized and uncertainty in the time separation. Residual errors are inherent in the processing, such as errors caused by the peak finding algorithm. The residual errors are usually not a function of Δt . Therefore, a too small separation time increases the velocity error as this error is proportional to $1/\Delta t$.

The following discussion is relevant to the effect of image quality on PIV accuracy. Large particle images can result in wide crosscorrelation peaks, which can reduce the accuracy of the peak finding algorithm. In addition, large particles require larger interrogation spots to contain an appropriate number of particles, which leads to a reduction in spatial resolution. Particle images smaller than two pixels in diameter, or particle displacements that are less than two pixels, can introduce a displacement bias, called "peak locking." The displacement peaks tend to be biased toward integer values. Peak locking presents itself as a "staircased" velocity pattern, in a region with a velocity gradient where the velocity distribution should be smooth. The calculation of spatial derivatives of this vector map then produces a mosaic pattern in the gradient map. Figure 23.20 illustrates these patterns. Techniques, such as multigrid or continuous window-shifting or iterative image deformation, have been proposed to overcome peak locking. Image preconditioning, such as filtering, or defocusing can optimize the image diameter. The resolution of the CCD sensor, therefore, also limits the use of smaller particles to increase the velocity resolution.

The methods developed to increase displacement accuracy rely on the assumption of low displacement gradient. High gradient tends to bias the displacement toward low values because the particles with smaller displacements are more likely to remain in the interrogation volume longer than those with higher displacements. This bias can be minimized by reducing the size of the interrogation volume and separation time. For high distortion of the particle pattern in a high gradient spot, the centroid peak finding algorithm is more suitable than the Gaussian. However, PTV, as it follows an individual particle, is not affected by high gradient. Several research groups use the displacement results from PIV to guide the local search areas for PTV in a coupled PIV/PTV processing algorithm. These coupled techniques relieve the gradient limit in PIV and increases resolution of both velocity vectors and velocity fields.

The motion across the light sheet in highly 3D flows can bias the local velocity estimation caused by perspective projection, if the particle has not left the light sheet. The effect of perspective projection velocity bias, illustrated in Figure 23.21, is usually more severe at the edges of the image, where the projection angle increases. At high image magnification, the focal length becomes shorter and the projection angle increases, which worsens the perspective projection. Strong perspective projection could vary the magnification factor through the image plane resulting in an image distortion.

In general, the light sheet thickness is smaller than the depth of focus, δ_z . The light sheet thickness, therefore, determines the thickness of the effective interrogation volume: All illuminated particles are well focused. Most commercial systems using standard-grade Yag lasers with appropriate optics can generate light sheets that have a thickness on the order of one to two hundred microns, although light sheets can be as thick as a 1 mm.

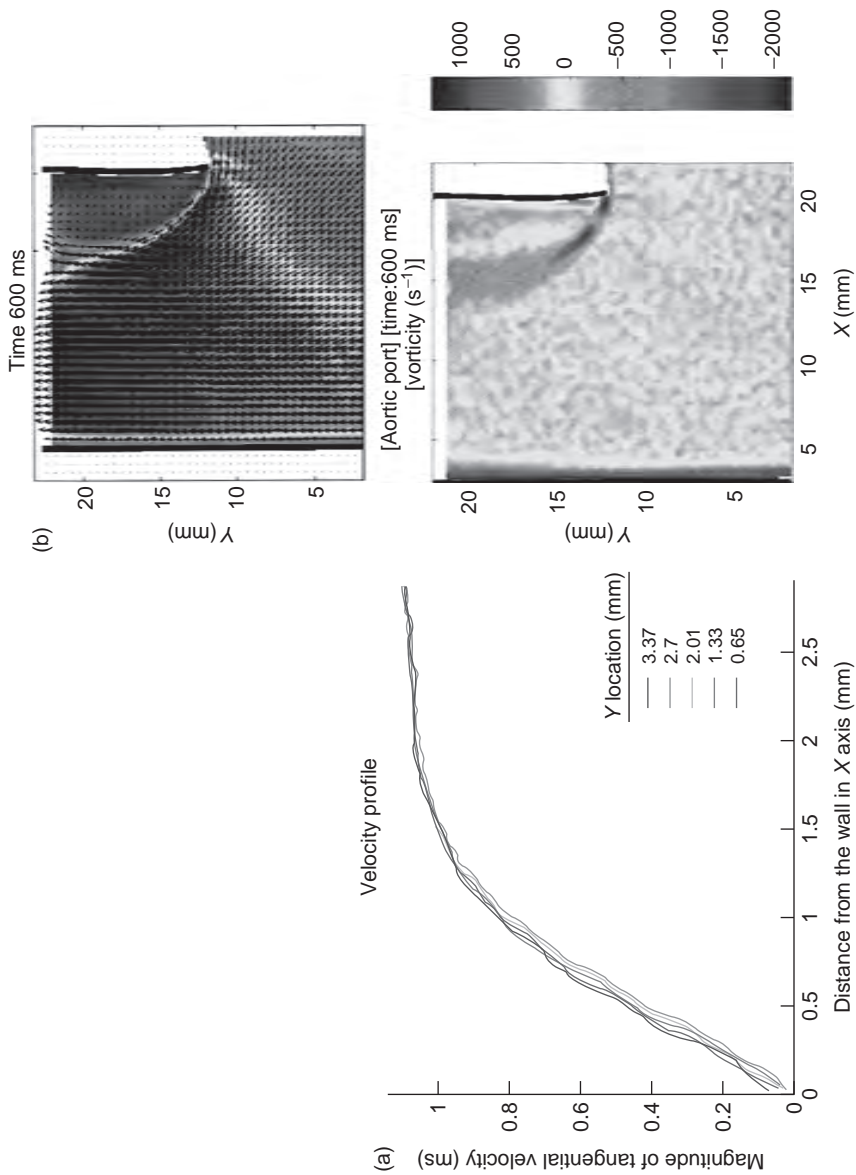

FIGURE 23.20 (a) Staircased pattern in a velocity profile at a wall. (b) Gradient field calculation (bottom image) of a measured velocity field (top image) showing mosaic pattern (Hochareon, 2003).

FIGURE 23.21 Illustration of the perspective projection; red arrow is the vector obtained from perspective projection; blue is the correct projection of displacement vector on the XY plane (Hochareon, 2003).

In high magnification imaging, the depth of focus can become smaller than the light sheet thickness. The thickness of the effective interrogation volume is then constrained to the depth of focus. In this case, particles located beyond the focal plane but within the illuminated plane are out-of-focus and appear as highly nonuniform background image noise, and can affect the crosscorrelation. In addition, the thickness of the effective interrogation volume determines the tolerance to out-of-plane motion. A smaller effective volume thickness increases the probability for out-of-plane particle loss. In general, the estimated maximum out-of-plane motion should be less than one fourth of the effective volume thickness.

Data validation is another source of uncertainty in PIV. Bad velocity vectors will ultimately appear within a vector map because of noise in the displacement estimation. Several filtering algorithms have been developed to remove these bad vectors. These filter routines operate on thresholding velocity at a particular location and using the magnitude of the velocity estimate; the mean, the median, or the rms within a predefined subregion; or other more complicated thresholds to low-pass filter the estimates. Improper application of a validation scheme can over filter the velocity map and throw away good data. For example, rms validation techniques should be carefully used in turbulent shear layers where high rms values are normally encountered. It is possible to inadvertently filter good

instantaneous turbulent velocity ensembles with a tight rms filter setting. In general, some knowledge of the flow under study is needed to accurately perform vector validation.

Commercial PIV systems can be two-component or three-component, planar or volume systems. A two-component, planar PIV system provides information on two components of the velocity vector. In two-component PIV, the measured displacement vector is the projection of the three-component velocity vector on the 2D plane of the light sheet. Flow information for highly three-component flows can be inaccurately represented by planar PIV images. Stereographic and holographic PIV systems have been developed for three-component measurement in a plane or volume, respectively. Although the instantaneous velocity field obtained by PIV is an advantage over LDV (or Doppler), two-exposure PIV only provides information on the particle motion during the two exposures and also suffers from poor temporal frequency response in the measurement of adjacent vector maps in time. Particle acceleration cannot be measured by direct two-exposure PIV. Four-exposure systems have been developed to permit calculation of the particle acceleration by Hassan and Phillip (1997) and Lui and Katz (2004), although the temporal resolution for the acceleration is not yet comparable to that of LDV.

24.1 MEASUREMENTS AND QUALITY CONTROL

The metric and English measuring systems are the two measuring systems commonly used throughout the world. The metric system is universally used in most scientific applications but, for manufacturing in the United States, has been limited to a few specialties, mostly items that are related in some way to products manufactured abroad.

24.2 DIMENSION AND TOLERANCE

In dimensioning a drawing, the numbers placed in the dimension lines are only approximate and do not represent any degree of accuracy unless so stated by the designer.

To specify the degree of accuracy, it is necessary to add tolerance figures to the dimension. Tolerance is the amount of variation permitted in the part or the total variation allowed in a given dimension.

Dimensions given close tolerances mean that the part must fit properly with some other part. Both must be given tolerances in keeping with the allowance desired, the manufacturing processes available, and the minimum cost of production and assembly that will maximize profit. In general, the cost of a part is increased as the tolerance is decreased.

Allowance, which is sometimes confused with tolerance, has an altogether different meaning. It is the minimum clearance space intended between mating parts and represents the condition of tightest permissible fit.

24.3 QUALITY CONTROL

When parts must be inspected in large numbers, 100% inspection of each part is not only slow and costly but does not eliminate all of the defective pieces. Mass inspection tends to be careless; operators become fatigued; and inspection gages become worn out or out of adjustment more frequently. The risk of passing defective parts is variable and of unknown magnitude, whereas, in a planned sampling procedure, the risk can be calculated. Many products, such as bulbs, cannot be 100% inspected, since any final test made on one results in the destruction of the product. Inspection is costly, and nothing is added to a product that has been produced to specifications.

Quality control enables an inspector to sample the parts being produced in a mathematical manner and to determine whether the entire stream of production is acceptable, provided that the company is willing to allow up to a certain known number of defective parts. This number of acceptable defectives is usually taken as 3 out of 1000 parts produced. Other values might be used.

24.3.1 \bar{X} , R , and σ Charts

To use quality techniques in inspection, the following steps must be taken (Table 24.1):

- 1. sample the stream of products by taking m samples, each of size n ;
- 2. measure the desired dimension in the sample, mainly the central tendency;
- 3. calculate the deviations of the dimensions;
- 4. construct a control chart;
- 5. plot succeeding data on the control chart.

TABLE 24.1 Computational Format for Determining \bar{X} , R , and σ

Sample Number	Sample Values	Mean \bar{X}	Range R	Standard Deviation σ'
1	$X_{11}, X_{12}, \dots, X_{1n}$	\bar{X}_1	R_1	σ'_1
2	$X_{21}, X_{22}, \dots, X_{2n}$	\bar{X}_2	R_2	σ'_2
.	\dots	.	.	.
.	\dots	.	.	.
.	\dots	.	.	.
m	$X_{m1}, X_{m2}, \dots, X_{mn}$	\bar{X}_m	R_m	σ'_m

The arithmetic mean of the set of n units is the main measure of central tendency. The symbol \bar{X} is used to designate the arithmetic mean of the sample and may be expressed in algebraic terms as

$$\bar{X}_i = (X_1 + X_2 + X_3 + \cdots + X_n)/n \quad (24.1)$$

where X_1, X_2, X_3 , and so on represent the specific dimensions in question. The most useful measure of dispersion of a set of numbers is the standard deviation σ . It is defined as the root-mean-square deviation of the observed numbers from their arithmetic mean. The standard deviation σ is expressed in algebraic terms as

$$\sigma_i = \sqrt{\frac{(X_1 - \bar{X})^2 + (X_2 - \bar{X})^2 + \cdots + (X_n - \bar{X})^2}{n}} \quad (24.2)$$

Another important measure of dispersion, used particularly in control charts, is the range R . The range is the difference between the largest and the smallest observed values in a specific sample

$$R = X_i(\max) - X_i(\min) \quad (24.3)$$

Even though the distribution of the X values in the universe can be of any shape, the distribution of the \bar{X} values tends to be close to the normal distribution. The larger the sample size and the more nearly normal the universe is, the closer will the frequency distribution of the average \bar{X} 's approach the normal curve, as in Figure 24.1.

According to the statistical theory (the Central Limit Theory), in the long run, the average of the \bar{X} values will be the same as μ , the average of the universe. And in the long run, the standard deviation of the frequency distribution \bar{X} values, $\sigma_{\bar{X}}$, will be given by

$$\sigma_{\bar{X}} = \frac{\sigma}{\sqrt{n}} \quad (24.4)$$

FIGURE 24.1 Normal distribution and percentage of parts that will fall within σ limits.

where σ is the standard deviation of the universe. To construct the control limits, the following steps are taken:

1. calculate the average of the average $\bar{\bar{X}}$ as follows

$$\bar{\bar{X}} = \sum_1^m \bar{X}_i / m \quad i = 1, 2, \dots, m \quad (24.5)$$

2. calculate the average deviation, $\bar{\sigma}$, where

$$\bar{\sigma} = \sum_1^m \sigma'_i / m \quad i = 1, 2, \dots, m \quad (24.6)$$

Statistical theory predicts the relationship between $\bar{\sigma}$ and $\sigma_{\bar{X}}$. The relationship for the $3\sigma_{\bar{X}}$ limits or the 99.73% limits is

$$A_1 \bar{\sigma} = 3\sigma_{\bar{X}} \quad (24.7)$$

This means that control limits are set so that only 0.27% of the produced units will fall outside the limits. The value of $3\sigma_{\bar{X}}$ is an arbitrary limit that has found acceptance in industry.

The value of A_1 calculated by probability theory is dependent on the sample size and is given in Table 24.2. The formula for 3σ control limits using this factor is

$$CL(\bar{X}) = \bar{\bar{X}} \pm A_1 \bar{\sigma} \quad (24.8)$$

Once the control chart (Figure 24.2) has been established, data (\bar{X}_i 's) that result from samples of the same size n are recorded on it. It becomes a record of the

FIGURE 24.2 Control chart \bar{X} .

TABLE 24.2 Factors for \bar{X} , R , σ , and X Control Charts

variation of the inspected dimensions over a period of time. The data plotted should fall in random fashion between the control limits 99.73% of the time if a stable pattern of variation exists.

So long as the points fall between the control lines, no adjustments or changes in the process are necessary. If five to seven consecutive points fall on one side of the mean, the process should be checked. When points fall outside of the control lines, the reason must be located and corrected immediately.

Statistical theory also gives the expected relationship between $\bar{R}(\Sigma R_i/m)$ and $\sigma_{\bar{X}}$. The relationship for the $3\sigma_{\bar{X}}$ limits is

$$A_2 \bar{R} = 3\sigma_{\bar{X}} \quad (24.9)$$

The values for A_2 calculated by probability theory, for different sample sizes, are given in Table 24.2.

The formula for 3σ control limits using this factor is

$$CL(\bar{X}) = \bar{\bar{X}} \pm A_2 \bar{R} \quad (24.10)$$

In control chart work, the ease of calculating R is usually much more important than any slight theoretical advantage that might come from the use of σ . However, in some cases where the measurements are costly, and it is necessary that the inferences from a limited number of tests be as reliable as possible, the extra cost of calculating σ is justified. It should be noted that, because Figure 24.2 shows the averages rather than individual values, it would have been misleading to indicate the tolerance limits on this chart. It is the individual article that has to meet the tolerances, not the average of a sample. Tolerance limits should be compared with the machine capability limits. Capability limits are the limits on a single unit and can be calculated by

$$\begin{aligned}\text{Capability limits} &= \bar{\bar{X}} \pm 3\sigma \\ \sigma &= \bar{R}/d_2\end{aligned}\tag{24.11}$$

Since $\sigma' = \sqrt{n} \sigma_{\bar{x}}$, the capability limits can be given by

$$\text{Capability limits } (X) = \bar{\bar{X}} \pm 3\sqrt{n} \sigma_{\bar{x}}\tag{24.12}$$

$$= \bar{\bar{X}} \pm E_1 \bar{\sigma}\tag{24.13}$$

$$= \bar{\bar{X}} \pm E_2 \bar{R}\tag{24.14}$$

The values for d_2 , E_1 , and E_2 calculated by probability theory, for different sample sizes, are given in Table 24.2.

Figure 24.3 shows the relationships among the control limits, the capability limits, and assumed tolerance limits for a machine that is capable of producing the product with this specified tolerance. Capability limits indicate that the production facility can produce 99.73% of its products within these limits. If the specified tolerance limits are greater than the capability limits, the production facility is capable of meeting the production requirement. If the specified tolerance limits are tighter than the capability limits, a certain percentage of the production will not be usable and 100% inspection will be required to detect the products outside the tolerance limits.

To detect changes in the dispersion of the process, the R and σ charts are often employed with \bar{X} and X charts.

The upper and lower control limits for the R chart are specified as

$$\text{UCL } (R) = D_4 \bar{R}\tag{24.15}$$

$$\text{LCL } (R) = D_3 \bar{R}\tag{24.16}$$

Figure 24.4 shows the \bar{R} chart for samples of size 5.

The upper and lower control for the T chart are specified as

$$\text{UCL } (\sigma) = B_4 \bar{\sigma}\tag{24.17}$$

$$\text{LCL } (\sigma) = B_3 \bar{\sigma}\tag{24.18}$$

The values for D_3 , D_4 , B_3 , and B_4 calculated by probability theory, for different sample sizes, are given in Table 24.2.

FIGURE 24.3 Control, capability, and tolerance (specification limits).

FIGURE 24.4 R Chart for samples of five each.

24.4 INTERRELATIONSHIP OF TOLERANCES OF ASSEMBLED PRODUCTS

Mathematical statistics states that the dimension on an assembled product may be the sum of the dimensions of the several parts that make up the product. It states also that the standard deviation of the sum of any number of independent variables is the square root of the sum of the squares of the standard deviations of the independent variables. So if

$$X = X_1 \pm X_2 \pm \cdots \pm X_n \quad (24.19)$$

$$\bar{X} = \bar{X}_1 \pm \bar{X}_2 \pm \cdots \pm \bar{X}_n \quad (24.20)$$

$$\sigma(X) = \sqrt{(\sigma_1)^2 + (\sigma_2)^2 + \cdots + (\sigma_n)^2} \quad (24.21)$$

Whenever it is reasonable to assume that the tolerance ranges of the parts are proportional to their respective σ' values, such tolerance ranges may be combined by taking the square root of the sum of the squares

$$T = \sqrt{T_1^2 + T_2^2 + T_3^2 + \cdots + T_n^2} \quad (24.22)$$

24.5 OPERATION CHARACTERISTIC (OC) CURVE

Control charts detect changes in a pattern of variation. If the chart indicates that a change has occurred when it has not, Type I error occurs. If three-sigma limits are used, the probability of making a Type I error is approximately 0.0027.

The probability of the chart indicating no change, when in fact it has, is the probability of making a Type II error. The operation characteristic curves are designed to indicate the probability of making a Type II error. An OC curve for an \bar{X} chart of three-sigma limits is illustrated in Figure 24.5.

24.6 CONTROL CHARTS FOR ATTRIBUTES

Testing may yield only one of two defined classes: within or outside certain limits, acceptable or defective, working or idle. In such a classification system, the proportion of units falling in one class may be monitored with a p chart.

In other cases, observation may yield a multivalued, but still discrete, classification system. In such case, the number of discrete observations, such as events, objects, states, or occurrences, may be monitored by a c chart.

24.6.1 The p and np Charts

When sampled items are tested and placed into one of two defined classes, the proportion of units falling into one class p is described by the binomial distribution. The mean and standard deviation are given as

$$\begin{aligned} \mu &= np \\ \sigma &= \sqrt{np(1-p)} \end{aligned}$$

FIGURE 24.5 Operating characteristic curve for 3σ limit.

Dividing by the sample size n , the parameters are expressing as proportions. These statistics can be expressed as

$$\bar{p} = \frac{\text{Total number in the class}}{\text{Total number of observations}} \quad (24.23)$$

$$s_p = \sqrt{\frac{\bar{p}(1 - \bar{p})}{n}} \quad (24.24)$$

The control limits are set either at two-sigma limits with Type I error as 0.0456 or at three-sigma limits with Type I error as 0.0027. The control limits for the p chart with two-sigma limits (Figure 24.6) are defined as

$$CL(p) = \bar{p} \pm 2S_p \quad (24.25)$$

FIGURE 24.6 P charts.

However, if subgroup size is constant, the chart for actual numbers of rejects np or pn may be used. The appropriate model for three-sigma control limits on an np chart is

$$CL(np) = n\bar{p} \pm 3\sqrt{n\bar{p}(1-\bar{p})} \quad (24.26)$$

24.6.2 The c and u Charts

The random variable process that provides numerical data that are recorded as a number c rather than a proportion p is described by the Poisson distribution. The mean and the variance of the Poisson distribution are equal and expressed as $\mu = \sigma^2 = np$. The Poisson distribution is applicable in any situation when n and p cannot be determined separately, but their product np can be established. The mean and variable can be estimated as

$$\bar{c} = S_c^2 = \frac{\sum_l^m C_i}{m} = \frac{\sum_1^m (np)_i}{m} \quad (24.27)$$

The control limits (Figure 24.7) are defined as

$$CL(c) = \bar{C} \pm 3S_c \quad (24.28)$$

If there is change in the area of opportunity for occurrence of a nonconformity from subgroup to subgroup, such as number of units inspected or the lengths of wires checked, the conventional c chart showing only the total number of nonconformities is not applicable. To create some standard measure of the area of opportunity, the

FIGURE 24.7 C charts.

nonconformities per unit (c/n) or u is used as the control statistic. The control limits are

$$CL(u)\bar{u} \pm 3 \frac{\sqrt{\bar{u}}}{\sqrt{n_i}} \quad (24.29)$$

where

$$\bar{u} = \frac{\sum C_i}{\sum n_i} = \frac{\text{Total nonconformities found}}{\text{Total units inspected}}$$

$c = nu$ is Poisson-distributed, u is not

24.7 ACCEPTANCE SAMPLING

The objective of acceptance sampling is to determine whether a quantity of the output of a process is acceptable according to some criterion of quality. A sample from the lot is inspected, and the lot is accepted or rejected in accordance with the findings of the sample.

Acceptance sampling plans call for the random selection of sample of size n from a lot containing N items. The lot is accepted if the number of defectives found in the sample are $\leq c$, the acceptance number. A rejected lot can either be returned to the producer, non-rectifying inspections, or it can be retained and subjected to a 100% screening process, rectifying inspection plan improves the outgoing quality. A second attribute-inspection

plan might use two samples before requiring the acceptance or rejection of a lot. A third plan might use multiple samples or a sequential sampling process in evaluating a lot. Under rectifying inspection programs, the average outgoing quality level (AOQ), the average inspection lot (I), and the average outgoing quality limit (AOQL) can be predicted for varying levels of incoming fraction defective p .

Assuming that all lots arriving contain the same proportion of defectives p , and that rejected lots will be subjected to 100% inspection, AOQ and I are given below:

$$\text{AOQ} = \frac{P_a p (N - n)}{N - pn - (1 - P_a)p(Nn)} \quad (24.30)$$

$$I = n + (1 - P_a)(N - n) \quad (24.31)$$

The average outgoing quality (AOQ) increases as the proportion defective in the incoming lots increases until it reaches a maximum value and then starts to decrease. This maximum value is referred to as the average outgoing quality limit. The hypergeometric distribution is the appropriate distribution to calculate the probability of acceptance P_a ; however, the Poisson distribution is used as an approximation.

Nonrectifying inspection program does not significantly improve the quality level of the lots inspected.

24.7.1 Double Sampling

Double sampling involves the possibility of putting off the decision on the lot until a second sample has been taken. A lot may be accepted at once if the first sample is good enough or rejected at once if the first sample is bad enough. If the first sample is neither, the decision is based on the evidence of the first and second samples combined.

The symbols used in double sampling are

N = lot size

n_1 = first sample

c_1 = acceptance number for first sample

n_2 = second sample

c_2 = acceptance number of the two samples combined.

Computer programs are used to calculate the OC curves: acceptance after the first sample, rejection after the first sample, acceptance after the second sample, and rejection after the second sample. The average sample number (ASN) in double sampling is given by

$$\text{ASN} = [P_a(n_1) + P_r(n_1)]n_1 + [P_a(n_2) + P_r(n_2)](n_1 + n_2) \quad (24.32)$$

24.7.2 Multiple and Sequential Sampling

In multiple sampling, three or more samples of a stated size are permitted, and the decision on acceptance or rejection is revealed after a stated number of samples. In sequential sampling, item-by-item inspection, a decision is possible after each item has been inspected, and when there is no specified limit on the total number of units to be

inspected. OC curves are developed through computer programs. The advantage of using double sampling, multiple sampling, or sequential sampling is to reach the appropriate decision with fewer items inspected.

24.8 DEFENSE DEPARTMENT ACCEPTANCE SAMPLING BY VARIABLES

MIL-STD-105 A, B, C, D, and then ABC-STD-105 are based on the acceptance quality level (AQL) concept. The plans contain single, double, or multiple sampling depending on the lot size and AQL and the probability of acceptance at this level P_a . Criteria for shifting to tightened inspection, requalification for normal inspection, and reduced inspection are listed in the tables associated with plan.

MIL-STD-414 plans were developed to reduce inspection lots by using sample sizes compared with MIL-STD-105. They are similar, as both procedures and tables are based on the concept of AQL; lot-by-lot acceptance inspection; both provide for normal, tightened, or reduced inspection; sample sizes are greatly influenced by lot size; several inspection levels are available; and all plans are identified by sample size code letter. MIL-STD-414 could be applied either with a single specification limit, L or U , or with two specification limits. Known-sigma plans included in the standard were designated as having "variability known." Unknown-sigma plans were designated as having "variability unknown." In the latter-type plans, it was possible to use either the standard deviation method or the range method in estimating the lot variability.

Predicting project success is difficult and often unreliable (Prabhakar, 2009; Raz et al., 2002; Shenhar et al., 2002; Thamhain and Skelton, 2007). The long list of prominent project failures, ranging from computers to pharmaceutical and supersonic transport, reminds us of this reality (Cicmil et al., 2006; Lemon et al., 2002). Many projects do not live up to their expectations or outright fail even before their technical completion (El Emam & Koru, 2008). The ability to evaluate project proposals, assessing future success and organizational value, is critical to overall business performance for most enterprises.

25.1 MANAGEMENT PERSPECTIVE

Project success is multifaceted. Typically, it includes not only technical but also financial; marketing; and social, legal, and ethical dimensions. For most projects, the DNA of

success is highly complex, and outcomes are difficult to predict (Shenhar & Dvir, 2007). Evaluating and selecting projects is both an art and a science that, for most cases, has to go beyond a simple cost–benefit analysis. To be sure, few decisions have more impact on business performance than the resource allocations for new projects. Virtually, every organization selects and implements projects, ranging from product developments to organizational improvements, and from customer contracts to R&D activities and bid proposals. Pursuing the “wrong” project not only wastes company resources but also causes the enterprise to (i) miss critical alternatives, (ii) operate less flexible and responsive in the market place, and (iii) miss opportunities for leveraging core competencies. Project opportunities must be analyzed relative to their potential value, strength, and importance to the enterprise. *Four major dimensions* should be considered: (1) added value of the new project, (2) cost of the project, (3) readiness of the enterprise to execute the project, and (4) managerial desire. A well-organized *project evaluation and selection process* provides the framework for systematic data gathering and informed decision-making toward resource allocation (Bstieler, 2005; Ciemil & Marshall, 2005). Typically, these decisions can be broken into four principal categories:

1. *Deciding Initial Feasibility*: screening and filtering, quick decision on the viability of an emerging project for further evaluation;
2. *Deciding Strategic Value to Enterprise*: identifying alternatives and options to proposed project;
3. *Deciding Detailed Feasibility*: determining the chances of success for a proposed project;
4. *Deciding Project Go/No-Go*: committing resources for a project implementation.

While making these decisions looks simple, logical, and straightforward, developing meaningful support data is a complex undertaking. It is also expensive, time-consuming, and often highly eclectic. Typically, decision-making requires the following inputs:

1. specific resource requirements;
2. specific implementation risks;
3. specific benefits (economics, technology, markets, etc.);
4. benchmarking and comparative analysis;
5. strategic perspective, including long- and short-term value assessment.

Although it is challenging to estimate costs, schedules, risks, and benefits, such as those shown in Table 25.1, these measures are relatively straightforward in comparison to *predicting project success*. The difficulty is in defining a meaningful *aggregate indicator for project value and success*. Methods for determining success range from purely intuitive to highly analytical. No method is seen as truly reliable in predicting success, especially for more complex and technologically intensive types of projects. Yet, some companies have a better track record in selecting “winning” projects than others. They seem to have the ability to create a more integrated picture of the potential benefits, costs, and risks for the proposed project relative to the company’s strength and strategic objectives. Producing such a composite is both a science and an art. Traditionally, the management literature suggested by-and-large *rational selection processes* to support project selections (Remer, 1993). However, purely rational-analytical processes apply only to a limited number of

TABLE 25.1 Typical Criteria and Measures used for Project Evaluation

The criteria relevant to the evaluation and selection of a particular project depend on the specific project type and business situation such as for a particular product development, custom project, process development, industry, or market. Typically, evaluation procedures include the following criteria and measures

- Development cost
- Development time
- Technical complexity and feasibility
- Risk
- Return on investment
- Cost–benefit
- Product life cycle
- Sales volume
- Market share
- Project business follow-on
- Organizational readiness and strength
- Consistency with business plan
- Resource availability
- Cash flow, revenue, and profit
- Impact on other business activities

Note: Each criteria is based on a complex set of parameters and variables.

business situations. Many of today's technologically complex business scenarios require the integration of both analytical and judgmental techniques to evaluate projects in a meaningful way (Kavadias and Loch, 2004; Khorramshahgol et al., 1998), predicting success and making the *best choice*.

Yet, in spite of the dynamics involved in the selection process, systematic information gathering and standardized methods are at the heart of any project evaluation process, and provide the best assurance for reliably predicting project outcome and repeatability of the decision process. Approaches to project evaluation and selection fall into one of three principal classes:

1. primarily *quantitative* and *rational* approaches;
2. primarily *qualitative* and *intuitive* approaches;
3. *mixed approaches*, combining both quantitative and qualitative methods.

Because of the interdisciplinary complexities involved, analyzing a new project opportunity is a highly interactive effort among the various resource groups of the enterprise and its partners (Thamhain, 2005). Often, many meetings are needed before (i) a clear picture emerges of potential benefits, costs, and risks involved in the project, and (ii) data emerge that is useful for the project evaluation and selection process, regardless of its quantitative, qualitative, or combined nature.

25.2 QUANTITATIVE APPROACHES

Quantitative approaches are often favored to support project evaluation and selections if the decisions require economic justification. They are also commonly used to support judgment-based project selections. One of the features of quantitative approaches

is the generation of numeric measures for simple and effective comparison, ranking, and selection (Mantel et al., 2011; Remer et al., 1993). These approaches also help to establish quantifiable norms and standards, and lead to repeatable processes. Yet, the ultimate usefulness of these methods depends on the assumption that the decision parameters, such as cash flow; risks; and the underlying economic, social, political, and market factors can actually be quantified and reliably estimated over the project life cycle. Therefore, quantitative techniques are effective and powerful decision support tools, if meaningful estimates of cost-benefits, such as capital expenditures and future revenues, can be obtained, and converted into net present values for comparison. Because of their importance, quantitative methods have been discussed in the literature extensively, ranging from simple return on investment (ROI) calculations to elaborate simulations of project scenarios. Many companies eventually develop their own project evaluation/selection models, customized to their specific needs. However, the backbone for most of these customized models is a set of economic/financial measures that tries to determine the cost–benefit of the proposed venture, usually for some point in the future. Specifically, four measures are especially popular:

1. net present value (NPV),
2. return on investment (ROI),
3. cost–benefit (CB),
4. payback period (PBP).

The calculation and application of these measures to project evaluation/selection will be illustrated by case examples. Specifically, four project proposals (described in Table 25.2) are evaluated in this chapter, using the above measures. The results are summarized in Table 25.3.

25.2.1 Net Present Value (NPV) Comparison

This method uses discounted cash flow as the basis for comparing the relative merit of alternative project opportunities. It assumes that all investment costs and revenues are known and that economic analysis is a valid basis for project selection.

We can determine the *Net Present Value (NPV)* of a single revenue, or stream of future revenues, or costs expected in the future. Two types of presentations are common: (1) present worth and (2) net present value.

TABLE 25.2 Description of Four Project Proposals

<i>Project option P1:</i> Management does not accept any new project proposal. Hence, no investment capital is required, nor is any revenue generated
<i>Project option P2:</i> This opportunity requires a \$1000 investment at the beginning of the first year and generates a \$200 revenue at the end of <i>each</i> of the following 5 years
<i>Project option P3:</i> This opportunity requires a \$2000 investment at the beginning of the first year and generates a variable stream of net revenues at the end of <i>each</i> of the next 5 years as follows \$1500, \$1000, \$800, \$900, and \$1200
<i>Project option P4:</i> This opportunity requires a \$5000 investment at the beginning of the first year and generates a variable stream of net revenues at the end of <i>each</i> of the next 5 years as follows \$1000, \$1500, \$2000, \$3000, and \$4000

TABLE 25.3 Cash Flow and Net Value Calculations of Four Project Options or Proposals, Assuming a MARR of $i = 10\%$

End of Year N	Do-Nothing Option P1	Project Option P2	Project Option P3	Project Option P4
<i>Given cash flow</i>				
0	0	−1,000	−2,000	−5,000
1	0	200	1,500	1,000
2	0	200	1,000	1,500
3	0	200	800	2,000
4	0	200	900	3,000
5	0	200	1,200	4,000
<i>Calculations</i>				
Net cash flow (ΣP)	0	0	+3,400	+6,500
Net present value at the end of year 5 ($NPV _{N=5}$)	0	−242	+2,153	+3,192
Net present value for revenue to continue to ∞ ($NPV _{N=\infty}$)	0	+1,000	+9,904	+28,030
Average annual ROI ($ROI _{N=5}$)	0	20%	54%	46%
Cost–benefit ($CB = ROI_{NPV N=5}$)	0	76%	108%	164%
Payback period for MARR = 10% ($N_{PBP} _{i=10}$)	0	8	1.8	3.8
Payback period for MARR = 0% ($N_{PBP} _{i=0}$)	0	5	1.5	3.3

Note: Given for all four project proposals: (1) a single investment is being made at the beginning of the project life cycle (e.g., at the end of year 0) and (2) the internal rate of return, IRR, or the minimum attractive rate of return, MARR, is 10%.

Present Worth (PW): This is the single revenue or cost (also called annuity A) which occurs at the end of a period n , subject to the *prevailing interest rate* i . Depending on the management philosophy and enterprise policies, this interest rate can be (i) the *internal rate of return (IRR)* realized by the company on similar investments and (ii) the *minimum attractive rate of return (MARR)* acceptable to company management, or the prevailing discount rate. The present worth is calculated as

$$PW(A|i, n) = PW_n = A \frac{1}{(1+i)^n}$$

For the examples used in this chapter, we consider the *internal rate of return, IRR* (defined as the average return realized on similar investments), to be the prevailing interest rate.

Net Present Value (NPV): The *net present value* is defined as a series of revenues or costs, A_n , over N periods of time, at a prevailing interest rate i :

$$NPV(A_n|i, N) = \sum_{n=1}^N A_n \frac{1}{(1+i)^n} = \sum_{n=1}^N PW_n$$

Three special cases exist for the net present value calculation: (1) *for a uniform series of revenues or costs over N periods*: $\text{NPV}(A_n|i, N) = A[(1+i)^N - 1]/i(1+i)^N$; (2) *for an annuity or interest rate i approaching zero*: $\text{NPV} = A \times N$; and (3) *for the revenue or cost series to continue forever*: $\text{NPV} = A/i$.

Table 25.3 applies these formulas to the four project alternatives described in Table 25.2, showing the most favorable 5-year net present value of \$3192 for project option P3.

25.2.2 Return on Investment (ROI) Comparison

Perhaps, one of the most popular measures for project evaluation is the *return on investment, ROI*:

$$\text{ROI} = \frac{\text{Revenue}(R) - \text{Cost}(C)}{\text{Investment}(I)}$$

ROI calculates the ratio of net revenue over investment. In its simplest form, the stream of cash flow is *not* discounted. One can look at the revenue on a year-by-year basis, relative to the initial investment. For example, project option 1 in Table 25.3 would produce a 20% ROI each year, whereas project option 2 would produce a 75% ROI during the first year, 50% during the second year, and so on. In a somewhat more sophisticated way, we can calculate the *average ROI per year* over a given revenue cycle as shown in Table 25.3

$$\overline{\text{ROI}}(A_n, I_n|N) = \left[\sum_{n=1}^N \frac{(\text{Revenue } R)_n - (\text{Cost } C)_n}{(\text{Investment } I)_n} \right] / [N]$$

We can then *compare the average ROI to the minimum attractive rate of return, MARR*. Given a MARR of 10% for our project environment, all three project options P1, P2, and P3 compare favorable, with project P3 yielding the highest average return on investment of 54%. Although this is a popular measure, it does not permit a meaningful comparative analysis of alternative projects with fluctuating costs and revenues. Furthermore, it does not consider the time-value of money.

25.2.3 Cost–Benefit (CB)

Alternatively, we can calculate the *net present value* of the total ROI over the project life cycle. This measure, known as *Cost–Benefit, CB*, is calculated as the present-value stream of net-revenues divided by the present-value stream of investments. It is an effective measure for comparing project alternatives with fluctuating cash flows:

$$\text{CB} = \text{ROI}_{\text{NPV}}(A_n, I_n|i, N) = \left[\sum_{n=1}^N \text{NPV}(A_n|i, N) \right] / \left[\sum_{n=1}^N \text{NPV}(I_n|i, N) \right]$$

In our example of four project options (Table 25.3), project proposal P4 produces the highest cost–benefit of 164% under the given assumption of $i = \text{MARR} = 10\%$.

25.2.4 Payback Period (PBP) Comparison

Another popular figure of merit for comparing project alternatives is the *Payback Period (PBP)*. It indicates the time period of net revenues required to return the capital investment made on the project. For simplicity, *undiscounted* cash flows are often used to calculate a quick figure for comparison, which is quite meaningful if we deal with an initial investment and a steady stream of net revenue. However, for fluctuating revenue and/or cost streams, the net present value must be *calculated for each period individually* and cumulatively added up to the “break-even point” in time, N_{PBP} , when the net present value of revenue equals the investment. Mathematically,

$$N_{\text{PBP}} \text{ occurs when } \sum_{n=1}^N \text{NPV}(A_n|i) \geq \sum_{n=1}^N \text{NPV}(I_n|i)$$

In our example of four project options (Table 25.3), project proposal P3 produces the shortest, most favorable payback period of 1.8 years under the given assumption of $i = \text{MARR} = 10\%$.

25.2.5 Pacifico and Sobelman Project Ratings

The previously discussed methods of evaluating projects rely heavily on the assumption that technical and commercial success is assured, and all costs and revenues are predictable. Because these assumptions do not always hold, many companies have developed their own special procedures and formulas for comparing project alternatives. Two examples illustrate this special category of project evaluation metrics.

The Project Rating Factor (PR): This measure was originally developed by Carl Pacifico for assessing chemical products and predicting commercial success:

$$\text{PR} = \frac{\text{pT} \times \text{pC} \times R}{\text{TC}}$$

Pacifico’s formula is in essence an ROI calculation adjusted for risk. It includes probability of technical success ($0.1 < \text{pT} < 1.0$), probability of commercial success ($0.1 < \text{pC} < 1.0$), total net revenue over project life cycle [R], and total capital investment for product development, manufacturing setup, marketing, and related overheads (TC).

Product Development Figure of Merit: The formula developed by Sobelman

$$z = (P \times T_{\text{LC}}) - (C \times T_{\text{D}})$$

represents a modified cost-benefit measure that takes into account both the development time and the commercial life cycle of the product. It also includes average profit per year (P), estimated product life cycle (T_{LC}), average development cost per year (C), and years of development (T_{D}).

25.2.6 Going Beyond Simple Formulas

While quantitative methods of project evaluation have the benefit of producing relatively quickly a measure of merit for simple comparison and ranking, they also have many

TABLE 25.4 Comparison of Quantitative and Qualitative Approaches to Project Evaluation

Quantitative Methods	Qualitative Methods
<i>Benefits</i> Clear and simple comparison, ranking, selection Repeatable process Encourages data gathering and measurability Benchmarking opportunities Programmable Useful input to sensitivity analysis and simulation Connectable to many analytical and statistical models	<i>Benefits</i> Search for meaningful evaluation metrics Broad-based organizational involvement Understanding of problems, benefits, opportunities Problem solving as part of selection process Broadly distributed knowledge base Multiple solutions and alternatives Multifunctional involvement leading to buy-in and risk sharing
<i>Limitations</i> Many success factors are not quantifiable Probabilities and weights may change True measures do not exist Analyses and conclusions are often misleading Masking of hidden problems and opportunities Stifle innovative decision making Lack people involvement, buy-in, commitment Ineffective in dealing with multifunctional issues, nonlinearities and dynamic situations May mask hidden costs and benefits Temptation for acting too quickly and prematurely	<i>Limitations</i> Complex, time-consuming process Biases introduced via organizational power and politics Difficult to procedurelize or repeat Conflict and disagreement over decision/outcome Does not fit conventional decision processes Intuition and emotion may obscure facts Used for justifying “wants” Lead to more fact-finding than decision making Temptation for unnecessary expansion of fact-finding Process requires effective managerial leadership

limitations, as summarized in Table 25.4. Yet, in spite of the limitations inherent to quantitative evaluation and the increased use of qualitative approaches, *virtually every organization supports its project selections with some form of quantitative measures*—most popular ROI, cost-benefit, and payback period. However, driven by the growing complexity of the business environment, and managers are getting increasingly concerned about these limitations and explore alternatives. They often augment quantitative methods with additional measures for determining the long-range cost-benefits of a project proposal to the enterprise. Many of these contemporary decision-making methods rely to a large degree on *qualitative, judgmental decision-making*. These data gathering methods cast a wide net and consider a broad spectrum of factors that are often difficult to describe or quantify, but are effective in gaining strategic perspective and a more comprehensive picture on potential benefits, risks, and challenges of the proposed project.

25.3 QUALITATIVE APPROACHES

While quantitative methods provide an important toolset for project evaluation and selection, there is also a growing sense of frustration, especially among managers of complex and technologically advanced undertakings, that reliance on strictly quantitative methods, does not always produce the most useful or reliable inputs for decision-making, nor are all methods equally suited for all situations (Kulkarni et al., 2004;

Kumar, 2006). Therefore, it is not surprising that for project evaluations involving complex sets of business criteria, narrowly focused quantitative methods are often supplemented with broad-scanning, intuitive processes and collective, multifunctional decision-making such as *Delphi*, *nominal group technology*, *brainstorming*, *focus groups*, *sensitivity analysis*, and *benchmarking*. Each of these techniques can either be used by itself to determine the “*best, most successful, or most valuable*” option, or integrated into a comprehensive analytical framework for *collective multifunctional decision-making*, which is being discussed in the following section.

25.3.1 Collective Multifunctional Evaluations

This process relies on subject experts from various functional areas for collectively defining and evaluating broad project success criteria, employing both quantitative and qualitative methods (Kumar, 2006). *The first step* is to define the specific organizational areas critical to project success and to assign expert evaluators. For a typical product development project, these organizations may include R&D, engineering, testing, manufacturing, marketing, product assurance, and customer/field services. These function-experts should be given the time necessary for the evaluation. They also should have the commitment from senior management for full organizational support. Ideally, these evaluators should be members of the core team ultimately responsible for project implementation.

Evaluation Factors: Early in the evaluation process, the team defines the factors that appear critical to the ultimate success of the projects under evaluation and arranges them into a list, which includes both quantitative and qualitative factors. A mutually acceptable scale must be worked out for scoring the evaluation criteria. Studies of collective multifunctional assessment practices show that simple scales are most effective for leading to actionable team decisions. The four most popular and robust scales for judging situational outcomes are as follows:

1. *Ten-Point Judgment Scale:* from +5 (most favorable) to –5 (most unfavorable);
2. *Three-Point Judgment Scale:* +1 (favorable), 0 (neutral or cannot judge), and –1 (unfavorable);
3. *Five-Point Judgment Scale:* A (highly favorable), B (favorable), C (marginally favorable), D (most likely unfavorable), and F (definitely unfavorable);
4. *Five-Point Likert Scale:* 1 (strongly agree), 2 (agree), 3 (neutral), 4 (disagree), and 5 (strongly disagree).

Weighing of criteria is not recommended for most applications as it complicates and often distorts the collective evaluation.

The Evaluation Process: Evaluators first assess and then score all of the success factors they feel qualified to judge. Then collective discussions follow. Initial discussions of project alternatives, their markets, business opportunities, and technologies involved, are usually beneficial but not necessary for the first round of the evaluation process. The objective of this first round of expert judgments is to get calibrated on the opportunities and challenges presented. Further, each evaluator has the opportunity to recommend (1) actions that could improve the quality and accuracy of the project evaluation, (2) additional data needed, and (3) suggestions for increasing project success. Before meeting at the next group session, agreed-on action items and activities for improving the decision process should be completed. The evaluation

process is enhanced with each iteration by producing more accurate, refined and comprehensive data. Typically, between three and five iterations are required before a go/no-go decision can be reached for a given project.

25.4 RECOMMENDATIONS

Effective evaluation and selection of project opportunities involves many variables of the organizational and technological environment, reaching often far beyond cost and revenue measures. While economic models provide an important dimension of the project selection process, most situations are too complex to use simple quantitative methods as the sole basis for decision-making. Many of today's project evaluation procedures include a broad spectrum of variables and rely on a combination of rational and intuitive processes for defining the value of a new project venture to the enterprise. The better an organization understands its business processes, markets, customers, and technologies, the better it will be able to evaluate the value, risks, and challenges of a new project venture. Further, manageability of the evaluation process is critical to its results, especially in complex situations. The process must have a certain degree of structure, discipline, and measurability to be conducive to the intricate multivariable analysis. One method of achieving structure and manageability calls for grouping the evaluation variables into four categories: (1) consistency and strength of the project with the business mission, strategy, and plan; (2) multifunctional ability to produce the project deliverables and objectives, including technical, cost, and time factors; (3) success in the customer environment; and (4) economics, including profitability. Modern phase management, such as stage-gate[®] processes provide managers with the tools for organizing and conducting project evaluations in a systematic way. The following section summarizes suggestions that can help managers in effectively evaluating and selecting projects toward successful implementation:

Seek-Out Relevant Information: Meaningful project evaluations require relevant quality information. The four sets of variables, related to the strategy, results, customer and economics, as identified above, can provide a framework for establishing the proper metrics and detailed data gathering.

Ensure Competence and Relevancy: Ensure that the right people become involved in the data collection and judgmental processes.

Take Top-Down Look first, Detail Comes Later: Detail is less important than information relevancy and evaluator expertise. Do not get hung-up on missing data during the early phases of the project evaluation. Evaluation processes should be iterative. It does not make sense to spend a lot of time and resources on gathering perfect data, to justify a "no-go" decision.

Select and Match the Right People: Whether the project evaluation consists of a simple economic analysis or a complex multifunctional assessment, competent people from functions critical to the overall success of the project should be involved.

Define Success Criteria: Whether deciding on a single project or choosing among alternatives, evaluation criteria must be defined. They can be quantitative, such as ROI, or qualitative, such as the chances of winning a contract. In either case, these evaluation criteria should cover the true spectrum of factors affecting success and failure of the project(s). The success criteria should be identified by seasoned

enterprise personnel. In addition, people from outside of the company, such as vendors, subcontractors, and customers, are often included in this expert group and critical to the development of meaningful success criteria.

Strictly Quantitative Criteria can be Misleading: Be aware of evaluation procedures based on quantitative criteria only (ROI, cost, market share, MARR, etc.). The input data used to calculate these criteria are likely based on rough estimates and are often unreliable. Furthermore, a reliance on strictly quantitative data, considers only a narrow spectrum of factors affecting project success or failure, thus ignoring many other important factors, especially those that influence project success in a dynamic or nonlinear way, typical for many complex technologically sophisticated undertakings. Evaluations based on predominately quantitative criteria should at least be augmented with some expert judgment as a “sanity check.”

Condense Criteria List: Combine evaluation criteria, especially among the judgmental categories, to keep the list manageable. As a goal, try to stay within 12 criteria for each category.

Gain Broad Perspective: The inputs to the project selection process should include the broadest possible spectrum of data from the business environment that affect success, failure, and limitations of the new project opportunity. Assumptions should be carefully examined.

Communicate Across the Enterprise: Facilitate communications among evaluators and functional support groups. Define the process for organizing the team and conducting the evaluation and selection process.

Ensure Cross-Functional Representation and Cooperation: People on the evaluation team must share a strategic vision across organizational lines. They also must have the desire to support the project if selected for implementation. The purpose, goals, objectives, and relationships of the project to the business mission should be clear to all parties involved in the evaluation/selection process.

Do not Lose the Big Picture: As discussions go into detail during the evaluation, the team should maintain a broad perspective. Two global judgment factors can help to focus on the big picture of project success: (1) overall cost-benefit perspective and (2) overall risk of failure assessment. These factors can be recorded on a 10-point scale, -5 to $+5$. This also leads to an effective two-dimensional graphic display for comparing competing project proposals.

Do Your Homework between Iterations: Project evaluations are usually conducted progressively in iterative cycles. Therefore, the need for more information, clarification, and further analysis surfaces between each cycle. Necessary action items should be properly assigned and followed up to enhance the evaluation quality with each consecutive iteration.

Take a Project-Oriented Approach: Plan, organize, and manage your project evaluation/selection process as a *project*. Proposal evaluation and selection processes require valuable resources that must be justified and carefully managed.

Resource Availability and Timing: Do not forget to include in your selection criteria the availability and timing of resources. Many otherwise successful projects fail because they cannot be completed within a required time period.

Use Red-Team Reviews: Set up a special review team of senior personnel. This is especially useful for large and complex projects with major impact on overall

business performance. This review team examines the decision parameters, qualitative measures, and assumption used in the evaluation process. Limitations, biases, and misinterpretations that may otherwise remain hidden can often be identified and dealt with.

Stimulate Creativity and Candor: Senior management should foster an innovative risk-shared ambience for the evaluation team. Especially, the evaluation of complex project situations involves intricate sets of variables. Criteria for success and failure are linked among many subsystems, such as organization, technology and business, associated with a great deal of risks, and uncertainty. Innovative approaches are required to evaluate the true potential of success for these projects. Risk-sharing by senior management, recognition, visibility and a favorable image in terms of high priority, interesting work, and importance of the project to the organization, have been found strong drivers toward attracting and holding quality people on the evaluation team, and toward gaining their active and innovative participation in the process.

Manage and Lead: The evaluation team should be chaired by someone who has the trust, respect, and leadership credibility with the team members. Senior management can positively influence the work environment and the process by providing guidelines, charters, visibility, resources, and active support to the project evaluation team.

In summary, effective project evaluation and selection requires a broad-scanning process across all segments of the enterprise, and its environment to deal with the risks, uncertainties, ambiguities, and imperfections of data available for assessing the value of a new project venture relative to other opportunities. No single set of broad guidelines exist that guarantees the selection of successful projects. However, the process is not random! A better understanding of the organizational dynamics that affects project performance, and the factors that drive cost, revenue, and other benefits, can help in gaining a better, more meaningful insight into the future value of a prospective new project. Seeking out both quantitative and qualitative measures incorporated into a combined rational-judgmental evaluation process often yield the most reliable predictor of future project value and desirability. As equally important, the process requires managerial leadership and skills in planning, organizing, and communicating. Above all, the leader of the project evaluation team must be a social architect, who can unify the multi-functional process and its people. The leader must be able to foster an environment professionally stimulating and conducive to risk sharing. It also must be effectively linked to the functional support groups needed for project implementation. Finally, organizational strategy must be aligned and integrated with the evaluation/selection process, early and throughout its evaluation cycle. Senior management has an important role in unifying the evaluation team behind the mission objectives and in facilitating the linkages to the stakeholders and ultimate user community. Senior management should further help in providing overall leadership, and in building mutual trust, respect and credibility among the members of the proposal evaluation team, all critical drivers toward a strong partnership of all team members and the basis for an effective enterprise-wide decision-making system. Taken together, this is the environment conducive to cross-functional communication, cooperation, and integration of the intricate variables needed for effective engineering project evaluation and selection.

Terms

Cross-Functional: Actions that span organizational boundaries.

Phase Management: Projects are broken into natural implementation phases, such as development, production and marketing, as a basis for project planning, integration, and control. Phase management also provides the framework for *concurrent engineering* and *stage-gate processes*.

Project Success: A comprehensive measure, defined in both quantitative and qualitative terms, that includes economic, market, and strategic objectives.

Stage-Gate Process: Framework originally developed by R Cooper and S Edgett for executing projects within predefined stages (See also *Phase Management*) with measurable deliverables (*at gates*) at the end of each stage. These gates also provide the review metrics for ensuring successful transition and integration of the project into the next stage.

Weighing of Criteria: A multiplier associated with specific evaluation criteria.

VARIABLES AND ABBREVIATIONS

<i>A</i>	<i>Annuity</i> is the present worth of a revenue or cost at the end of a period n
CB	<i>Cost–benefit</i> , net present value of all ROIs in dollars
i	Prevailing <i>interest rate</i>
I	<i>Investment</i>
IRR	<i>Internal rate of return</i> , the average return on investment realized by a firm on its investment capital
MARR	<i>Minimum attractive rate of return</i> on new investments acceptable to an organization
NPV	<i>Net present value</i> of a stream of future revenues or costs
PBP	<i>Payback period</i> , the time period needed to recover the original investment
PR	<i>Project rating factor</i> , a measure developed by Carlo Pacifico for predicting project success
PW	<i>Present worth</i> (also called annuity), the present value of a revenue or cost at the end of a period n
ROI	<i>Return on investment</i>
z	<i>Project rating factor</i> , a measure developed by Sobelman for predicting project success.

26.1 INTRODUCTION

Environmentally conscious manufacturing (ECM) is the production of products using processes and techniques selected to have the least impact on the environment while still being economically viable. Process selection criteria include minimum waste, minimum use of hazardous materials, and minimum use of energy in addition to the production goals. Products produced in this manner are often more competitive in the marketplace because these criteria result in cost reduction, cost avoidance, and increased appeal to the consumer.

This chapter discusses several techniques for assessing and evaluating environmentally conscious manufacturing performance of manufacturing systems. These techniques begin with an analysis of the paperwork/data followed by a visit of the plant floor and

conducting interviews. This provides the basis for making evaluations of improvement areas and performing the tasks necessary to formulate improvement projects. The emphasis here is on improving the manufacturing systems; however, the benefits occur in production.

This chapter focuses on very practical and fundamental issues in manufacturing. As a result, it is not readily applicable to a firm seeking ISO 14001 accreditation. Nor is it meant to be. Whereas ISO 14001 is an environmental management system, this chapter is about manufacturing systems and their evaluation. Ghisellinia and Thurston identified several decision traps that ISO 14001 imposes “the ‘management’ nature of the standard, failure to identify a rigorous environmental baseline, misconception of pollution prevention, inordinate emphasis on short-term goals, focusing on regulatory compliance, and diversion of EMS resources to the documentation system (Ghisellinia and Thurston, 2005).” The processes here seek to avoid these traps. Therefore, there will be little reference to ISO 14001 or life cycle assessment (LCA) in the following sections.

Manufacturing systems are the planning, communications, coordination, monitoring, and management aspects of manufacturing. Industrial engineers often perform these tasks within the overall manufacturing system. The goal of this chapter is to provide guidance to assist the industrial engineer in finding better methods and techniques to make the overall manufacturing system more responsive to the goals of environmentally conscious manufacturing.

26.2 COMPONENTS OF ENVIRONMENTALLY CONSCIOUS MANUFACTURING

Although one can reduce ECM in a number of specific details, all of which seem independent of each other, the engineer would do well to remember three major points:

1. reduce waste,
2. reduce hazardous materials and processes,
3. reduce energy.

Almost every other ECM detail relates to these simple three objectives.

Waste is probably the single most important element. *Wastes are expenditures of resources that are not incorporated into the product.* Resources used in manufacturing are time, money, capital, labor, and materials. Wastes are characterized by emissions, machining offal, cutting fluids, person hours expended in waiting, buffering of items waiting for the next process, and machine downtime due to change over or maintenance, for example. When waste occurs, the product is more expensive.

A major division of manufacturing processes results in material separations. It is important to realize that it may be necessary to have waste in order to produce a product (Figure 26.1). However, the material lost should be minimized. A systematic approach to identifying and eliminating wastes results in increased ECM while also increasing profitability. Often trade-offs must be made. For example, to be economically viable, a process may require the use of a more wasteful material than one where material waste can essentially be eliminated but at a cost that prevents economic production of the product. Although this is an extreme example that is rarely encountered, effective ECM requires

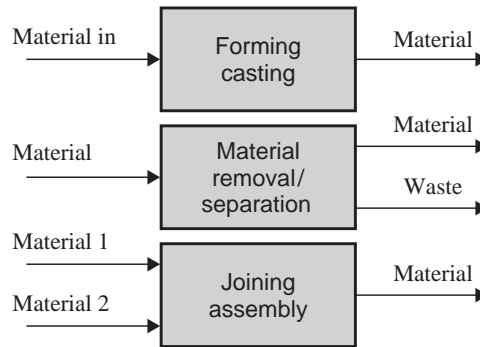

FIGURE 26.1 Classification of manufacturing processes.

that several objectives be met while producing a product that can be marketed successfully.

The greatest waste occurs when a product was produced in quantity that failed to meet market requirements. Thus, it is important to identify wastes and know exactly where wastes are occurring, but it is even more important to know how to reduce waste without incurring greater costs.

Hazardous materials are defined as materials that by their nature, chemistry, or conversion, result in reduced health of those exposed to them, degraded safety, or environmental risks produced by their uncontrolled release. These include toxic, mutagenic, radioactive, inflammable, and explosive substances. In addition to substances, hazards can include such things as noise, compressed fluids, and dusts. In many cases, specific controls and permissible levels are associated to these substances imposed by governments. Because of the additional controls and the additional increased handling awareness, use of these materials increases manufacturing costs.

Every industrial engineer in a manufacturing plant is intimately familiar with the cost of energy. However, they are not necessarily familiar with the environmental damage that energy production creates. Regardless of the form of energy or the source of energy, all energy has associated with environmental damage. For example, direct solar conversion, which many vaunt as clean energy, requires the use of cadmium, selenium, and tellurium—all of which are harmful to the environment. Therefore, the reduction of energy requirements not only reduces manufacturing costs but also reduces environmental damage. Thus, reduction of energy is also an objective of ECM.

26.3 MANUFACTURING SYSTEMS

Systems are required to produce products. A system is an organized whole consisting of subsystems that receive inputs from the external environment, transforming the inputs to outputs (Olson, 2006). Many manufacturing activities required well-defined systematic approaches to ensure efficiency. Manufacturing requires close coordination of labor, tools, materials, and information. If the systems that ensure this coordination are missing or flawed in their performance, waste is produced. These systems must start with the initial concept of the product and extend through the warranty of the product after it is in use. In some cases, this also includes the disposition of the product after the usage phase.

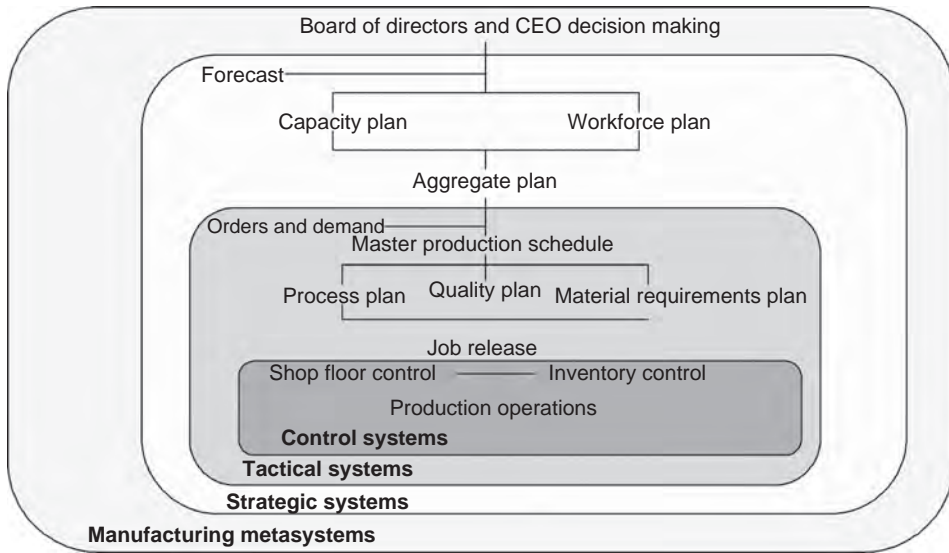

FIGURE 26.2 Manufacturing system levels.

26.3.1 Levels of Manufacturing Systems

Manufacturing systems can be considered at four different levels of refinement (Figure 26.2). At the top level, loosely called the *metasystem*, are decisions about the organization, the subcomponents, and the interactions of the components within the overall manufacturing systems. Factors that influence the metasystem are the top decisions as to what the foci of the businesses are whether to produce to order or produce to stock, the complexity of the product, and the economic responsiveness needed. These will determine the components of the manufacturing system and establish the outputs of the components. The planning horizon for these decisions is the expected life of the corporation. It ranges from years to decades.

At the *strategic* level, forecasting and capacity planning (including facility planning and workforce planning) are the major subsystems. They are taken together with an output of the aggregate plan. The aggregate plan is based on the capacity of the manufacturing firm and includes the labor policies to drive the resources at the firm level. Aggregate planning horizons typically range from 3 months to five years, depending on the size of the firm, the product complexity, and the commitment levels of resources needed. Since it might take 2 years or more to bring a new factory on-line, aggregate plans need to incorporate the long-term economic outlook of the corporation and be consonant with the corporation strategic plan. In fact, one could argue that the aggregate plan is the operational statement of the strategic plan.

The next level down is the *tactical* level of systems. Here, process plans, quality plans, and production scheduling need to be developed. Actual customer orders enter through a demand management system. Depending on decisions made at the metasystem level, orders are met from stock or by introduction of new production orders to the operations. Critical decisions at the tactical level determine what tools, what level of quality, and what response times are needed to meet the aggregate plan. The major output of the tactical

FIGURE 26.3 Plan, do, check, and act cycle.

systems is the production master schedule. At the tactical level, planning horizons range from 1 week to more than a year.

At the lowest system level are *control* systems. Shop floor control, inventory control, quality control, and maintenance control systems are the major components. These controls are driven by the production master schedule and direct and monitor resources to meet the production master schedule. Planning horizons may involve activities of a few seconds up to 3 months.

Decisions that have the most far-reaching effects occur at the metasystem level. As decisions are made at lower levels, they decrease in scope and reach but become more detailed. Thus, decisions at high levels involve more movement of resources and have greater potential for waste reduction than do decisions at the lowest levels.

Although various forms of manufacturing systems may have different names for the systems above and stipulate set of interactions between the systems, any complete manufacturing system will have subsystems performing the functions just described. Essentially, these systems relate real-world factors to models that can be used to direct future manufacturing activities. In this context, it is essential that all systems implement a *plan, do, check, and act (PDCA) cycle*. This is illustrated in Figure 26.3.

26.3.2 The Plan, Do, Check, and Act Cycle

The PDCA cycle, sometimes called the Deming cycle, expresses a relationship between planning, operations/production, evaluations of outcome, and management that are essential in a well-organized and profitable manufacturing system. The “Plan” phase of the cycle prepares the system to meet its operational objectives and goals. In this phase, the events necessary for performance of the system are organized, and the resources needed for production are scheduled. Planning is fed by the action phase that expresses management intent. The “Do” phase is the expression of the system performance. In most cases, the system is named after the “Do” phase as this is where the system produces its product and outputs. The “Check” phase is the assessment and evaluation of the do and plan phases. In the “Check” phase, it important to observe “what went right” as well as “what went wrong.” This is often the role of quality control within the system. Finally, the “Act”

phase is the role of management in the system. Leaders and managers set goals and objectives based on the reports from the check phase and their observations of the do and plan phases. Furthermore, they provide the directive action to correct and improve the system for the next cycle of PDCA.

Within manufacturing systems, most methods to detect system wastes are based on measuring the system variability. In general, if a system is highly variable, the system is not performing well. The major causes of system variability are insufficient resources to perform the assigned tasks, insufficient capacity to handle the workload and insufficient time for planning and execution. Often times, these problems are exacerbated by failure of higher-level systems that provide inputs to the system in question. For example, aggregate plan changes frequently raises havoc with production scheduling and material ordering systems in the attempt to keep the master production schedule responsive. As results, long lead-time materials may be ordered, labor hired, and plant resources designated that are either too much (hence, wasteful) or too little (again, wasteful of time) when actual production is executed.

Overall, the manufacturing systems organize production in an orderly way from high-level goals to the very detailed and mundane activities. Inefficient manufacturing systems results in inefficient production operations. Thus, observations of inefficiency at the operational level must be tracked to the level of system where the inefficiency first was manifested. This process reveals improvement opportunities. Thus far, these systems have been considered independently of environmentally conscious manufacturing. In the next section, it will be shown how these systems affect ECM.

26.4 SYSTEM EFFECTS ON ECM

Manufacturing systems are used to plan manufacturing, develop all of the subsystems, and then control the activities of manufacturing. They have a great impact on ECM. In fact, it is doubtful that ECM could be accomplished without active manufacturing-system participation. At the metasystem levels, there must be an overt commitment to ECM. A company is driven by risk reduction, corporate image, and economic objectives. The leaders of the corporation must understand and accept that ECM can reduce risk, improve corporate image, and improve the economics of the firm. Without such an understanding at the top decision-making levels, ECM stands little chance of being fully implemented. A company pursuing ECM should state that ECM is part of the core business structure. This has the influence of directing the subordinate-level activities toward choices that support ECM.

In addition, the *make to order* and the *make to stock* decisions influence the amount of material that a firm must hold to support its operations. Because of external constraints on certain materials and lead times for certain components, there will be differences in what manufacturing strategy a corporation will take. However, anytime that a company must store raw materials, components, or finished product, there is an increased opportunity for waste to occur. If these materials also include hazardous materials, handling awareness also increases costs.

At the strategic level, ECM is most affected by capacity and facility planning. Facilities determine the processes available to the firm. They also determine the capacity. Process selection for a facility has the greatest influence on whether ECM can be achieved in

a given facility. Any process that requires auxiliary materials to achieve an objective is subject for consideration for improvement under ECM. For example, a process that requires hydrochloric acid to clean a metal surface of rust and preservatives must be carefully examined. There are alternative processes that do not require the acid. However, once the process is selected and built into a facility, cost of replacement, space limitations, and a host of other factors may render it impossible to replace the process and therefore limit the effectiveness of subsequent ECM attempts.

Additionally, at the strategic level, choices are made on the layout of a given facility. Traditionally, these are transfer line, cell or flexible machine layouts, colony or job shop process layout, and (in the most extreme case) stationary product layout. This choice must satisfy the given production requirements that include product, quality, and process flow. Choice of the wrong layout strategy results in increased energy consumption, increased work in progress, increased internal plant transportation, and increased waste.

The second greatest influence on ECM occurs at the tactical level in process planning. Process planning is the conversion of the engineering design to definition of the detailed processes that will enable creation of the product. Process planning can be considered at two levels:

1. The *macro level* where decisions are made as to what process of the facility will be used, in what order.
2. The *micro level* where all of the details of machines, individual tools, and instructions are created.

Because of the influence of process planning on the individual details of creating a product, choices here directly influence waste, use of hazardous materials, and energy consumption. As the old cliché goes, “The devil is in the details!” Process planners intimate with the facility can greatly reduce waste and energy consumption by choice of energy saving and near net shape processes. An additional benefit for this process is that the cost of production is also less.

Another tactical decision that can have an influence on ECM is production scheduling. Long batch-run schedules tend to waste less and consume less energy. Process setups and changeovers are notoriously wasteful and costly. In addition, much of the quality control wastage occurs during the early part of new batch runs. However, the same benefits can often be achieved through planning the facility for flexibility at the strategic level.

At the lowest levels, controls have the least impact on ECM, although significant improvements are still possible. For example, early detection of a faulty process can prevent excess material and energy use. This is even more critical if the process in question is near the beginning of the product’s manufacturing.

The controls are often the best indicators of inadequate ECM decisions made at higher levels, even though they have the least impact. For example, while monitoring the production process, shop floor foremen should be aware of places where waste collects and should report this to the process planners and process engineers. Machine maintenance is often an indicator: frequent stoppages and unplanned maintenance are an indication of an improper process and of waste. Thus, assessment activities focus on data and observations at these levels. But where problems exist, often the improvement will be in a higher-level system.

This section discussed illustrations of systematic effects on ECM. The next sections focuses on assessment and evaluation and improvement methods for achieving ECM.

26.5 ASSESSMENT

Assessment as used here is the examination and evaluation of the effectiveness of a manufacturing facility and its systems in meeting the objectives of ECM. Assessment is properly the *check* phase of PDCA. In assessment, we examine the processes that are occurring and determine how well they function. The purpose of assessment is to benchmark the current state of operations against an ideal state of operations. Plants will have both exemplary operations and operations that do not meet desired standards. It is essential to recognize the exemplary operations for several purposes: exemplary practices should be copied where feasible across the corporation. In addition, recognition of what is being performed right is important to encouraging and rewarding the plant management for making improvements.

There are three parts to assessment: data collection, evaluation, and reporting. During data collection, information is gathered and analyzed to determine how the plant is performing over an extended period, usually a year or more. The evaluation is conducted on-site and is a snapshot of where the plant is at the time of assessment. Reporting is essential in documenting the assessment procedures, the assessment recommendations, and the plant exemplary practices so that they can be communicated appropriately.

26.5.1 Assessment Planning

The time and effort required for assessment will vary, depending on the size of the organization being evaluated. Typically, an assessment team will consist of a team leader and three to five team members. The team leader should have familiarity with the plant and its operations. However, the team leader and its members must be independent of the plant in the corporation organization. It is most common to select members of an industrial staff from another plant to perform the assessment if no formal organization exists in the corporate structure. For small firms with only one plant, these requirements cannot be met; however, assessments can still be performed using either outside resources or by subdividing the plant and limiting the assessments to subunits. An excellent program to assist small companies can be referenced at <http://www1.eere.energy.gov/industry/best-practices/iacs.html> (U.S. Department of Energy Industrial Assessment Program). Often the team leader is a senior industrial engineer. The team members are normally engineers and planners for the organization.

A typical assessment will require about a week to perform, provided the team is trained and has performed previous assessments. This will be far less for small plants and firms having only one plant, but the proportion of time planned will be approximately the same. The first 3 days of the assessment concentrates on data collection and analysis. The fourth day is the on-site plant visit. The fifth day is the on-site evaluation and report writing.

It is not uncommon and in some cases is desired that the first 3 days be separated from the plant visit by a time period of up to a month. This is to allow more time for analysis and to ensure that the correct data have been provided. It is desirable to have actual data, not summaries. However, the manufacturing unit will often try to provide summary only: this must be resisted. The actual data will have timing information and anomalies that are usually absent from summarized data. Where summaries have been furnished, time will

be needed to make requests for the actual data and to receive it in time for the analysis to be completed before the site visit.

The first part of the assessment is analysis of the documentation of a plant. Depending on the plant, this may be performed at the plant location or at another corporate location. Off-site evaluation is preferred to on-site evaluation to reduce potential interference with plant operations, reduce assessment cost, and provide the team with the most time to analyze the data. On-site visits are usually less productive because of the need for the plant management to perform briefings, setup work areas and preinterview team members from the concerned staff. During the first 2 h of the first day, the team leader assigns team members to analyze specific data. One team member should focus on plant processes, quality, and scheduling. Another team member should focus on plant purchases and inventory. Yet, another team member should concentrate on plant emissions and hazardous substances. A team member should be assigned to studying energy, water, and solid wastes for the plant. This analysis will focus on specific manufacturing systems improvement opportunities.

At the end of the third day, the team meets for approximately 2 h to discuss findings, compare notes, and establish what areas are of concern for the on-site visit. Team members should report what they have analyzed, what were the results, and any major omissions that may have occurred. The team leader may ask certain team members to concentrate on certain parts of the facility, based on these findings.

In addition to accessing documents, data collection also includes visiting the processes or facilities being assessed and interviewing managers and employees. The visit is organized by arrival on the site at the beginning of the workday. A management briefing on the plant will review the layout, processes, and safety requirements for the plant. This is usually followed by a management-guided walkthrough of the plant. The management briefings and the management-guided walkthrough should be performed in approximately 2 h. The team leader then assigns members areas of closer inspections and interviews in areas of interest.

At midday, the team should meet in a private location for the midday meal and should discuss any significant findings. Following this meal, the team leader may make additional assignments. The next 3 h should be used to complete the site inspection and to perform any more interviews needed. In multishift operations, assessment team members may be required to attend those shifts for interviews and inspections. Often in a multishift operation, certain operations are only performed in the night shift, or the graveyard shift.

The first hour of the fifth day should be used to formulate any major findings that will be in the team report. At the end of this hour, the plant management is presented with these findings for their further comments. After hearing the plant management, the next 2 h are used to discuss the formulation of recommended improvement projects. The remainder of the fifth day is used to formalize the team report. The formal report should be completed within 2 weeks of the site visit.

26.5.2 Data Collection

During the data collection phase of assessment, an attempt is made to collect all of the documents relevant to the operating state. Usually, a year's worth of consecutive data is needed. Information needed relates to operations, material storage and use, identified hazardous materials, and energy usage. This would include production data in units of production, aggregate plans, production schedules, downtime reports, material safety data sheets (MSDS), quality defect reports (QDR), purchase orders for materials, shipping orders, inventory turnover reports, emission reports, and energy bills. In some cases, the

records will be too voluminous to copy, and the data may have to be examined at the plant location for the usage of the data. Most facilities now keep electronic data rather than paper records. If not, this may be a big area for improving ECM. In addition, if previous assessment reports exist, these should be incorporated into the data analysis and used for comparative purposes.

When electronic records exist, usually the ability to perform statistical analysis is much easier. Basic statistics such as means and variances should be computed and compared to benchmarking statistics if available. In addition, trend analysis may be useful to find processes that may be approaching a critical situation. Special care should be given to data that seem unusual when taken in the context of the complete data stream. Outliers are often improper measurements; however, they may also flag conditions that require further action.

Production schedules indicate how often the production is being changed. In addition, they will indicate by the plan date how much lead time is given to changing the schedule. Short planning lead times are an indicator of poor planning and waste. Downtime reports will provide information on the reliability of a process. Planned schedules should be compared with actual performance to find discrepancies. Where these exist, they should be investigated to determine the reason. QDRs are particularly important, as these will highlight problematic areas with the production line. Most firms today use some form of statistical quality control. If this is not in use, this will flag a very important area for improvement. Excessive QDRs often highlight process planning problems.

Material purchase orders are measures of the inputs that the system is actually consuming. This needs to be compared with shipping orders to determine whether the material ordered is being converted into product. It is particularly important in the collecting and analyzing of purchase orders and shipping orders to observe waste collection volume, type, and frequency. Inventory turnover reports will indicate materials that are stagnant within the system. A high percentage of nonrotating stockages indicates poor production scheduling, poor material planning, or an inability of managers to release one-time stocks once acquired. The result is waste in time, storage, and capital to support maintenance of this inventory.

MSDS will indicate the hazardous materials in use, as well as the handling requirements. The person(s) doing the assessment should observe in the site visit where the materials are and how they are being handled. The emission reports from the facility indicate what substances are being released into the atmosphere. Because of the cost of licensing and compliance, any savings here can have a big impact on ECM.

The energy bills will indicate how energy is used and what types of loads are being billed against. Computation of power (the ratio of real power to total power) and load factors (overall percentage use of electrical equipment) should be performed and graphed. Power factors below 95% should be flagged as opportunities for improvement for reducing energy costs. Load factors below 70% indicate that equipment is not being used near its peak operating requirements. When these data are taken in their entirety, a picture will form of the state of current operations. In addition, inappropriate load factors will be highlighted that are out of place and will become opportunities for improvements. More extensive energy auditing information is located at the Energy Star Web site, <http://www.energystar.gov/>, or the more specific link, <http://www.energystar.gov/index.cfm?c=industry> bus industry plant energy auditing (U.S. Energy Star).

26.5.3 Site Visit and Inspection

The site visit begins with a plant management briefing and plant management-guided walk through. During the management briefing, often in the question and answer period

after the formal briefing, the assessment team should relate any significant findings that may have been noticed in the data and should ask questions regarding these. This discussion will prepare the management staff for the interviews to follow later in the day so they can gather the relevant information.

Information that was found in the documentation should be confirmed on the floor of the facility wherever it possible. During the visit, carefully note the state of the operations. Is the facility adequately lighted? Is the facility operating in an orderly manner? Are the floors and the machines clean? What smells exist, and from where do they originate? Is work in progress entering the areas reserved for transportation and passage? Are you receiving the same messages from the employees and the managers when you interview them and discuss their operations?

In addition, the assessment team member should walk the outside of the facility. It is often surprising what is found on the perimeter of the property of a plant. The team member might spot excess materials, defective product, liquid wastes, and other indicators of ECM defects. In the past, these were often unreported, and they hid errors. These need to be investigated and cleaned up.

26.5.4 Reporting and Project Formulation

The report is formulated in the following outline:

1. Title page
 - a. Name of the plant assessed
 - b. Name and contact details of who the report was prepared for
 - c. Assessment report number
 - d. Date of the report
 - e. Name and contact details of the assessment team leader
2. Executive summary
3. Assessment recommendations
 - a. Title
 - b. Observed problem
 - c. Recommendation
 - d. Estimated costs and benefits
4. Exemplary plant practices
 - a. Title
 - b. Observed practice
 - c. Estimated benefits
 - d. Contact information for more details
5. Synopsis of assessment
 - a. Plant background
 - b. General plant information
 - c. Plant leadership
 - d. Plant processes
 - e. Description of wastes
 - f. Description of energy usage
 - g. Hazardous materials in use

6. Data analysis—synopsis only (details are in appendices)
7. Site visit observations
 - a. What was observed
 - b. Who observed it
 - c. When was it observed
 - d. Why is it significant
 - e. Corrective action or plant response, if any
8. Findings and conclusions
9. Appendices as needed

The most important parts of the assessment report are the assessment recommendations and the exemplary plant practices. Each assessment recommendation (AR) should be itemized. The ARs provide the foundation for creating an improvement project. To do this, an AR should be titled in an active manner, starting with an action verb. An example is “Meter water use to reduce sewage charges.” This then should be followed by a description of anticipated benefits and savings by performing the action. Where possible, this should cite both dollars in savings, as well as fundamental units such as kWh/year or pounds CO₂. This is followed by who observed the operation and what exactly was observed. The team member should take or obtain pictures to illustrate the process recommended for change. Cost of the improvement project should be estimated if possible, with a short financial analysis of payback.

A key component of assessment is two-way communication between the assessment team and the plant management. In the process, there are ample opportunities for this to occur. On the fourth day, the plant management team provides information to the team and may wish certain areas to be emphasized in the study and may make certain recommendations for improvements. The team has discussed with the management staff the findings from the documentation. On the fifth day, the team reports its significant findings to the plant management team for comments.

Exemplary plant practices—or *best practices*, as they often titled—have a similar format. The title should indicate an action: “XYZ Plant uses ultrasonic tank cleaning.” Benefits achieved are itemized. Then the report should give short description of the practice, followed by a contact person in the plant who can provide more information.

The final report must be timely. The report should be ready within 2 weeks of the site visit and should be provided to the plant management team and the corporate vice president for the division. This may result in an order for a follow-up assessment to ensure that the assessment recommendations are being implemented and corrective actions were taken where needed.

26.6 SUMMARY

Manufacturing system evaluation for environmentally conscious manufacturing is based on three overriding goals:

1. reduce waste,
2. reduce hazardous materials and processes,
3. reduce energy.

These goals not only improve the responsiveness of the manufacturing unit to the environment, but they also result in significant cost savings and a better product when performed properly. Evaluation of manufacturing systems for environmentally conscious design begins with an assessment that highlights significant opportunities for improvement. Although the assessment focuses on actual operations, the solutions must be applied to the systems that created, support, and monitor the operations. Whereas ISO 14001 is a worthy goal to pursue and may be essential to the business practices of the firm, it is largely a paperwork exercise that does not solve common problems in manufacturing and does not necessarily lead to continuous improvement of the plant, the product, or the manufacturing systems. The evaluation process described in this chapter has been applied to several hundred different plants in the United States by a large number of auditors and assessors and has been shown to lead to real results in a timely fashion. It can also assist the ISO 14001 aspirations of the firm, if used properly.

27.1 INTRODUCTION

Engineers are often involved in the design of direct fired process heaters and other types of equipment for processing a variety of liquid, gaseous, or solid feed materials. The petroleum refining and chemical process industries make use of such processing to produce a variety of products, each product material being more useful and valuable than the feed material. In the case of direct fired heaters the design may require relatively simple processing, involving only heat transfer, and consists of raising the temperature of the given feed stream from a low to higher temperature, as in the conversion of crude oil to produce gasoline, diesel fuel, and fuel oil for home heating. In many cases, more complex processing may be required; however, such processing involves heating a process, consisting of a gaseous or vaporized hydrocarbon liquid, to a relatively high temperature, so that thermal decomposition of the feed occurs, producing a mixture of

lower molecular weight components at the heater outlet. The latter process is known as thermal cracking and is used to produce materials such as ethylene used in the manufacture of plastics and other products. Other types of complex processing are used, which involve chemically reacting two or more components at high temperature, to again create a product that is more valuable than the feed material. One such process, steam-gas reforming, converts a gaseous feed material, such as methane, natural gas or a vaporized liquid material such as naphtha, to a product consisting of a mixture of hydrogen and carbon monoxide, known as syngas. With further processing, the syngas is converted into valuable products such as hydrogen, which can be used as a nonpolluting fuel for automobiles, or into ammonia for fertilizer use.

A typical direct fired heater will consist of a multiplicity of tubular heat transfer elements containing the flow of pressurized feed to be processed. The elements are surrounded by a refractory-lined containment structure, which is also provided with a multiplicity of burners, distributed uniformly, and oriented so as to avoid overheating of the heat transfer surfaces.

Because of the many processing factors involved in the latter type of service and because heating of the process streams is accomplished through use of high temperature combustion products, generated by burners, continuous monitoring and controlling of the various processing variables responsible for proper heater performance and extended life of its mechanical components is necessary. The variables to be considered are production rate; product quality; overall thermal efficiency; concentration of undesirable emissions in the combustion product effluent; process stream temperature, pressure and flow rate; fuel composition used for burner firing; fuel temperature, pressure, and flow rate; combustion air pressure, temperature, and flow rate; tubular heating component temperature and pressure; and refractory temperature.

There are other types of equipment used in chemical processing that do not necessarily require the complex process variable monitoring required of fired heating. Some of the equipments used in the processing of solids are crushers and grinders. This type of equipment does, however, require monitoring of a different sort, namely, periodic examination of the feed materials processed, to determine size distribution, physical, and mechanical properties. The latter information allows for the determination of performance, in terms of numerical data, including product size distribution, production rate, and driving motor horsepower. Equations will be provided, as necessary, to indicate the relationship between pertinent variables, as will the manner in which pertinent instrumentation elements are used to measure and control process variables.

27.2 DIRECT FIRED HEATER MEASUREMENT AND PROCESS CONTROL INSTRUMENTATION

Figure 27.1 indicates the arrangement of the measurement and control instruments used for a direct fired tubular heater, processing a hydrocarbon feed at a high temperature, a temperature high enough so that it would be expected that fouling of the internal heat transfer surfaces with coke would occur and eventually progress to a point in time, varying from months to years, to an end of run condition. At this time, production would have to be curtailed or completely halted to avoid tube damage. Coke deposits would then be removed, so that the heating surfaces might be restored to their start of run condition. With reference to Figure 27.1, the components for a typical direct fired

Item No.	Description
4	Decoking system: Oxidation products and coke particles, generated by the decoking reaction, are disposed by the decoking system.
5	Radiant section outlet process product is conveyed to downstream equipment for further processing.
6	The burner fuel transfer line transports a controlled flow of pressurized burner fuel to the burners. The fuel may be gas or oil, and the control system used for this purpose is different for each. The control system for gaseous fuel is indicated.
7	Burner air transfer line conveys a controlled flow of combustion air to the burners.
8	Two or more burner combustion air manifolds allow use of single entry point for a relatively large number of burners.
9	Direct gas fired heater burners.
10	Refractory lined radiant section enclosure of fired heater.
11	Horizontal tube radiant section tubes: Tubes located at the walls of the enclosure and fired on only one side or centrally located between the refractory walls and fired from both sides may be used. Because of the high temperature combustion products at this location, heat is transferred from combustion products to tubes by radiation. The tubes are arranged so as to provide for four parallel streams in both the radiant and convection sections.
12	Refractory lined convection section enclosure of fired heater.
13	Horizontal convection section tubes: These are closely spaced, on two diameter centers, so that combustion products move at relatively high velocity between tubes, transferring heat from combustion products to tubes by convection.
14	Stack discharging combustion products to atmosphere or to equipment designed to separate carbon dioxide from the other combustion products and store or sequester the carbon dioxide underground in an effort to lessen global warming.
15	Stack combustion products flow control damper operator. This device actuated by a controller, automatically positions the stack damper to maintain a negative pressure between the radiant and convection section enclosure, a point corresponding to minimum negative pressure in the enclosure. Pressure at this location must be maintained at a level low enough to prevent an outflow of hot combustion products that would otherwise result in damage to various external heater components and pose a safety threat, as well. Pressure must also be controlled at a level such that excessive cold air infiltration does not occur, as this would result in a significant overall reduction in heater thermal efficiency.
16	Pressure indicator–controller, an instrument that senses pressure at the location previously described and maintains the desired pressure level at this location by appropriate positioning of the stack damper.
17	Oxygen analyzer, an instrument that samples combustion products, at a point above the radiant section, senses oxygen concentration at this point, and controls the flow of combustion air to maintain an excess air concentration of 10–20% in excess of that required for complete combustion by providing a set point signal to a temperature flow indicator—controller, item 18.
18	Combustion airflow indicator–controller, an instrument that senses the burner combustion airflow rate by means of a venturi tube, or orifice meter, which generates a differential pressure, or a comparable device which generates an electrical signal that is proportional to the airflow. The controller maintains the airflow at the proper level required, based on a set point signal from oxygen analyzer, item 17, and positions air stack damper, item 21, accordingly.
19	Burner fuel gas pressure indicator–controller controls pressure at a constant predetermined level, by properly positioning control valve (item 28), thereby allowing proper functioning of item 20.

Item No.	Description
20	Burner fuel gas flow controller–recorder senses flow rate of burner fuel by means of a venturi tube or like flow measuring device, receives an outlet set point signal from item 22 indicating any temperature deviation from that required, and actuates control valve (item 28) to modify fuel flow rate. The recording function permits determination of heater thermal performance for a finite time period.
21	Burner combustion airflow control damper actuator is properly positioned by means of appropriate signal from item 18.
22	Process product outlet temperature sensor–controller provides set point signal that allows flow controller item 20 to maintain burner heat input at a level coinciding with desired product outlet temperature.
23	Outlet tube steam–air decoking temperature indicator allows operator modulation of decoking air–steam ratio so as to maintain decoking temperature at a level, coinciding with a rapid decoking rate, yet one that will not cause damage to the tubular heating heat transfer elements.
24	Decoking airflow indicator–controller assists decoking operator in maintaining a proper decoking temperature.
25	Decoking steam flow indicator–controller also assists in maintaining an effective decoking procedure.
26	Process feed flow recorder–controller operates in conjunction with item 27 to maintain a desired feed inlet temperature. A recording feature permits analysis of overall heater performance for a lengthy period of time.
27	Process feed flow temperature sensor–controller provides set point signal for item 26. Temperature sensors usually consist of thermocouples contained in a protective metal sheath.
28	Process feed flow control valve modulates feed flow by means of signal generated by item 26.
29	Stack combustion product temperature, in conjunction with data from item 20, permits determination of overall heater thermal efficiency.
30	Burner feed gas sample withdrawal connection permits determination of fuel gas composition, which can then be used to obtain overall heat input and thermal efficiency.
31	Process inlet feed flow pressure indicator.
32	Process outlet product flow pressure indicator, at the location shown and at several other intermediate locations, can be used in conjunction with tube metal temperature measurements to determine the adequacy of existing tube wall thicknesses, or to predict tube life.
33	Radiant section outlet tube metal temperature, sensed by a thermocouple welded to this tube and to each of the other three parallel streams, in order to determine whether decoking operations need be commenced, because of tube metal temperatures that exceed the design temperature. Several such thermocouples, uniformly spaced, are also to be located at tubes located at the midpoint of the coil, for all of the four parallel streams.
34	Radiant section refractory temperature measurement is useful in determining whether refractory damage is likely to occur when the heater is operated at through-puts in excess of that for which the heater was designed.
35	Burner combustion air temperature data are required to determine overall heater thermal efficiency.

27.3 CRUSHING AND GRINDING EQUIPMENT MEASUREMENTS

Selection and evaluation of crushing and grinding equipment, as with many other types of processing equipment, is very often made the responsibility of the manufacturer. Thus, the would-be user will supply such information as the type of feed to be processed, the feed to product size reduction ratio, and the desired feed flow rate. The manufacturer, will on the

basis of their experience with similar material and the calculation procedures at their disposal, will then be able to select equipment that will most likely perform in accordance with the user's specifications. In addition, the manufacturer will want to perform tests on the type of equipment that is to be provided, ideally using the same type and size of feed material that is to be processed, so as to demonstrate that the equipment will perform as specified. This procedure, although costly and time consuming, will usually result in equipment that will, in service, perform as intended.

An alternate selection procedure would be one in which the user assumes a greater role in equipment selection, in conjunction with the manufacturer, and would involve having the manufacturer provide sufficient mechanical design data regarding the equipment, and the user having a working knowledge of how one might go about calculating what the performance would be on the basis of the mechanical design of the equipment and the mechanical and physical properties of the feed material. It is the alternate selection procedure, which is the subject of this document. The advantages of having as full an understanding as possible, regarding the workings of the equipment being purchased, usually at great cost, is perhaps obvious, but would, for example, allow for determination of the effects on operational variables such as power requirements, product flow rate capability, and feed/product size reduction ratio when such feed mechanical and physical properties, as feed material size, crush strength, tensile strength, bulk density, and true density are varied.

27.3.1 Basic Selection Considerations

Initial selection will depend upon the initial size of the feed, the final size of the product, and the characteristics of the feed material. For a relatively high strength brittle material such as coal, it must be reduced from a very large size (12 in. or greater) to a very small size (-200 mesh or 0.0029 in.), for use in pulverized coal-fired power boilers, it is not uncommon for processing such a feed in three stages; Thus, for Stage 1, a jaw crusher, as depicted in Figure 27.2 (Perry and Green, 1984) could be used. For Stage 2, a hammer mill, as depicted in Figure 27.3 (Perry and Green, 1997), could be used, and for Stage 3, a

FIGURE 27.2 Primary crusher.

FIGURE 27.3 Hammer mill.

ball pulverizer, or the equivalent, as depicted in Figure 27.4, could be used (Perry and Green, 1984). Realizing that there are many different types, capacities, and operational characteristics of size reduction equipment to choose from, the procedure described herein is just but one of many that can be chosen for purposes of illustrating the selection and calculation procedures that can be used for overall performance evaluation. However,

FIGURE 27.4 Ball crusher.

Bulk density, Lbs/cubic ft	Not specified	47
True density, Lbs/cubic ft	Not specified	95

only three commonly used types of equipment, as referred to above, will be considered herein. Similar methods can nevertheless be used for other types of equipment, feed materials, feed mechanical properties, and feed/product size ranges that may be required.

27.3.2 Jaw Crusher Performance

For illustrative purposes a Nordberg Jaw Crusher Model Number C-80, as depicted generically in Figure 27.2, has been selected for preliminary Stage 1 feed size reduction. Design data are as shown in Table 27.1 considering coal as the feed material.

Assuming coal, the feed material, has a crush strength of 4000 PSI, a tensile strength of 350 PSI, corresponding to about 10% of its crushing strength, and negligible elongation in tension, one may calculate crusher HP as follows:

$$\text{HP} = (\text{Pc})(\text{Acr})(\text{e}) \text{ per rev.} (\text{RPM}) / (33,000)(\text{Eff.}) \quad (27.1)$$

$$(\text{e}) \text{ per rev.} = (\text{Sc})(\text{Ec})(L_{\text{avg.}}) \quad (27.2)$$

where (Acr) is the crusher blade face area, square inches; (RPM) the crusher drive rotational speed, revolutions per minute; (e) per rev. the average compressive deformation of feed particles, feet/rev.; (Sc) the compressive strength, PSI; (Ec) the feed modulus of elasticity, million PSI; ($L_{\text{avg.}}$) the arithmetic average of feed thickness between crusher blades, inches; and (Eff.) the fractional overall mechanical efficiency of crusher.

Maximum coal feed rate is calculated as follows:

$$W_{\text{product}} = \left(\frac{L_{\text{cw}}}{L_{\text{product}}} \right) \left(\frac{L_{\text{product}}^3}{1728} \right) (\text{Dens.}) (\text{RPM}) \left(\frac{60}{2000} \right) \quad (27.3)$$

where (W_{product}) is the product flow rate, Tons/h, noting that downward flow of solids occurs when blades are open and stops when blades are closed; (L_{cw}) the crusher blade width, inches; (L_{product}) the cubical product size, inches; (Dens.) the true density of product, Lbs/cubic foot; and (RPM) the crusher operating speed, revolutions per minute.

Observation of particles of brittle material, such as coal, undergoing compression reveal that the force generated by compression causes the faces of the particles to bulge outward, resulting in multipoint cracking at the faces of the feed particles and ending with fragmentation of the initial particles to produce many smaller size particles. It is concluded that when particles subjected to compression fragment, the fragmentation is actually due to tensile failure of the material, at the many small cracks that form at the faces of the material, which then propagate to the central portions of the material. The reduction in particle size may therefore be predictable from knowledge of the compressive force acting on the material and the mechanical properties of the material. In the case of a jaw crusher, feed size reduction occurs with each forward movement of the crusher blades. In other types of size reduction equipment components of a different type perform the same function. The following mass balance provides a relationship between feed particle size and product particle size, assuming the particles to be cubical in shape.

$$(L_p)^3(N_p)(\text{Dens.}) = (L_f)^3(\text{Dens.}) \text{ and } (N_p) = (L_f)^3/(L_p)^3 \quad (27.4)$$

Furthermore, the compressive force on the feed articles must be equal to the force required to fragment the particles by tensile failure, or;

$$(S_c)(L_f)^2 = (N_p)(S_t)(6)(L_p)^2 \quad (27.5)$$

where (S_c) is the compressive strength of particles, PSI; (L_f) the feed particle size, assumed cubical in shape, inches; (N_p) the number of particles; (S_t) the tensile strength of particles, PSI; (6) the number of particle surface faces; and (L_p) the product particle size, also assumed cubical in shape, inches.

The number of forward crusher blade movements required to reach the desired final particle size is calculated as follows:

$$N_{\text{comp.}} = L_1 + L_2 + L_3 + \cdots + L_n = L_{\text{crusher blade}} \quad (27.6)$$

where (N_{comp}) is the number of compressions required by one forward movement of the crusher blade, with the resultant conversion the feed to product size; $(L_{\text{crusher blade}})$ the total crusher blade height, equals 48 in.; and (L_1) , (L_2) , (L_3) , \dots , (L_n) the sum of the particle lengths from initial to final size, as determined from Equation (27.5), inches.

27.3.3 Hammer Mill Performance

For illustrative purpose, a Meadows Hammermill, Model 90, as depicted generically in Figure 27.3, was selected for Stage 2 size reduction. Design data are as shown in Table 27.2.

The hammer mill is to be of the bottom discharge type wherein the feed free falls from the top of the mill and encounters the rotating hammers. These hammers initially impact and fracture the feed particles, followed by outward and downward flow of the particles at the walls of the mill enclosure, where secondary impact of the particles occurs. The initial impact reduces the particles from their initial size to an intermediate size. The secondary impact reduces the particles from their intermediate size to a final product size. A screen below the hammers, perforated with openings equal to the final product size desired is provided, so that the particles from the first and second impact, which are larger than these openings, are impacted again by the hammers. Thus, the final product collected does not contain oversize material. For much finer product sizes, the mill is provided with

TABLE 27.2 Meadows Hammer Mill, Model 90

	Specified Data	Calculated Data
Horsepower	75–200	204
Operating rotational speed RPM	3,600	3,600
Grinding capacity, pounds per hour	6,000–12,000	12,000
Screen size, width × length, inches	30 × 37 – 1/4	30 × 36 – 1/4
Screen size openings selected, inches	1/2	1/2
Number of hammers per rotor revolution	42	42
Weight per hammer, pounds	1.52	1.52
Feed size, inches	Not specified	1 – 1/2
Intermediate product size, inches	Not specified	0.9
Final product size, inches	Not specified	1/2
Size of hammers, inches	7 × 2 × 3/8	7 × 2 × 3/8
Diameter of rotor discs	12 in.	12 in.
Swing of extended rotor hammers, inches	22	22
Fan provided	No	No
Feed opening, width × height, inches	30 × 11	30 × 11
Bottom screen openings, inches	Not specified	1/2
Number of crushing passes for product to pass through screen openings	Not specified	2

an exhaust fan that extracts the final product by creating a flow of entrainment air in an upward direction through the mill enclosure.

A momentum balance, wherein the change in hammer velocity on impact multiplied by the mass flow rate of the hammers, is used to determine the force necessary to fracture the feed to the final product size desired. Thus,

$$((N)_h ((\text{RPM})/60))(W)_h((V)_{hi} - (V)_{hf}))/ (g) = (F)_p \quad (27.7)$$

$$(V)_{hi} = (\pi)(D_h)(\text{RPM})/(60) \quad (27.8)$$

$$(F)_p = (S)_c(L)_{p\text{-avg.}}(N)_{p\text{-avg.}} \quad (27.9)$$

$$(N)_p = (t)_p(W)_p/(w)_p(3600) \quad (27.10)$$

$$(w)_p = (L_p)^3/(1728)(\text{Sp.vol.}) \quad (27.11)$$

Regarding Equation (27.7), the hammer motor drive is to be such as to maintain a reasonably constant initial hammer velocity at a level which ensures proper feed size reduction, since it has been determined from Equation (27.7), that the initial velocity of the hammers decreases considerably after impacting the feed particles. Proper motor selection will, however, quickly return hammer velocity to its initial value.

Drive motor horsepower is determinable from Equation (27.12) and rated HP, so calculated, is in reasonably good agreement with the specified HP given in Table 27.2.

$$(\text{HP}) = (S)_c(144)(N)_{p\text{-avg.}}((w)_p/(60))/(33,000)(\text{Eff.})(\text{Sp. vol.}) \quad (27.12)$$

where $(W)_h$ is the hammer mass flow, pounds/second; $(V)_{hi}$ the hammer initial velocity, feet/second; (D_h) the rotor diameter with hammers fully extended, feet; $(V)_{hf}$ the hammer final velocity, feet/second; (g) the 32.2 feet/(second)²; $(F)_p$ the average force on particles, pounds; $(w)_p$ the particle weight, pounds; $(t)_p$ the residence time at hammer face, based on free fall velocity of particles, seconds; $(W)_p$ the feed flow rate, pounds/hour; (HP) the horsepower required; $(S)_c$ the crush strength of particles, PSI; $(L)_p$ the width or length of cubical particle, inches; $(N)_p$ the number of particles, based on free fall velocity; (Eff.) the overall fractional efficiency of Mill; and (Sp. Vol.) the specific volume of feed, Cubic feet/pound.

To evaluate $(L)_{p-avg.}$ and $(N)_{p-avg.}$ in Equations (27.11), calculate $(N)_p$ and w_p using Equations (27.10) and (27.11), with initial and intermediate values of $(L)_p$. $(L)_{p-avg.}$ and $(N)_{p-avg.}$ are then considered equal to the arithmetic average of the latter variables at the initial and intermediate values of $(L)_p$.

27.3.4 Ball Pulverizer Performance

For illustrative purposes a B&W Ball Pulverizer, Model EL 76, as depicted generically in Figure 27.4, was selected for Stage 3 size reduction. Pertinent data for this pulverizer are as shown in Table 27.3.

Feed enters the top of the mill and onto and between the circular arrangement of balls. A ball size of 8 in. size was selected so that cubical feed particles, 0.5–1 in. in size, would not be pushed by, but rather would be over ridden by the balls. This was done by ensuring that the force pushing the particles forward was less than the frictional force between the feed particles and the ball race, that is, less than the downward force on the balls multiplied by the coefficient of sliding, or in this case, rolling friction.

An upward flow of preheated air dries the particles so as to facilitate their breakup and to remove those particles having the desired final product size from the pulverizer.

A total of 12 crushing passes were calculated as being necessary to reduce 0.5 in. cubical feed particles to a –200 mesh product, using the procedure described previously, in the case of the primary jaw crusher. This compares with a total of 24 crushing passes available on the basis of the specified rotational speed of the pulverizer, equal to 90 RPM, and a total of about 50, 0.5 in. feed particles at the base of each ball, occupying an area of 3.5 × 3.5 in. under each ball.

TABLE 27.3 B&W Ball Pulverizer Model EL 76

	Specified	Calculated
Horsepower	300	278
RPM	90	90
Diameter of ball race, inches	76	76
Diameter of balls	Not specified	8
Number of balls	24	24
Feed capacity, tons per hour	20	20
Number of crushing passes	24	12 for 200 mesh, 12 for –200 mesh
Initial particle size, inches	Not specified	0.50
Final particle size	Minus 200 mesh	0–200 mesh

Based on the latter calculations, we may calculate the required HP as being equal to the following:

$$\text{HP} = (F)_b(N)_b(C_{rf})(V)_b/(33,000)(\text{Eff.}) \quad (27.13)$$

$$(F)_b = ((0.785)(D_b)^2/(2))((S_c)/(2)) \quad (27.14)$$

$$(V)_b = (\text{Pi})(D_{br})(\text{RPM}) \quad (27.15)$$

where HP is the mill horsepower; $(F)_b$ the load on ball, pounds; (C_{rf}) the coefficient of rolling friction; $(N)_b$ the number of balls; $(V)_b$ the linear velocity of ball race, FPM; (S_c) the crushing strength, PSI; (D_{br}) the diameter of ball race, feet; (RPM) the ball race rotational speed, revolutions per minute; (C_{rf}) the coefficient of rolling friction; and (Eff) the overall pulverizer fractional mechanical efficiency.

The HP so calculated was almost equal to the specified HP and consistent with a coefficient of rolling friction equal to 0.003, a value typical for that of ball bearings.

The calculation of the total load on the balls was based on the assumption that the maximum compressive stress on the balls, based on their spherical shape, could be approximated by the average of the compressive stress immediately below the ball and 0 stress at the ball diameter. Similarly, the contact area of the ball with the feed particles would be 0 immediately below the ball and equal to the maximum cross-sectional area of the ball at the ball diameter.

It has been demonstrated that specifications normally provided by size reduction equipment manufacturers, perhaps at the time a prepurchase quotation is provided, can be used to predict performance of the equipment, should the need arise. For the purchaser to perform the calculations needed to do this, using the calculations provided herein, the basic data required, namely, the crushing strength, tensile strength, bulk density, and true density of the feed material, are needed and are obtainable from an appropriate laboratory.

28.1 INTRODUCTION

Environmentally conscious manufacturing (ECM) has made significant gains on account of advances in energy efficiency. Energy efficiency relates to reducing wasted energy, hence reducing energy consumption. Utilization of fossil fuels adversely affects the greenhouse gases released into the atmosphere and results in undesirable quantities of emissions. Increasing energy efficiency will reduce the unwanted environmental effects produced by manufacturing industry.

28.1.1 Energy Usage in Manufacturing Industry

U.S. manufacturing plants, mines, farms, and constructions firms currently consume about 25 quads (quadrillion British thermal units, or Btu) of energy each year, which is about 33% of the nation's total consumption of energy (Gopalakrishnan et al., 2005b). A few of the cost-effective methods for improving energy efficiency are general housekeeping and maintenance programs, energy management and accounting programs, improved methods, and procedures for existing production methods and product changes. There are several technologies associated with heat recovery, high efficiency motors, variable speed drives, and cogeneration that have applications in many industries. Potential areas can be identified for energy conservation measures, namely lighting, boilers, motors and pumps, destratification of air, insulation of steam lines and process equipment, air and steam leaks, and compressors.

An important factor for industrial energy utilization and efficiency is the corporation's internal culture and external relationships. Capital investment in modern equipment usually enhances energy efficiency even when efficiency is not the primary purpose of the investment. An operations manager's key priorities are retaining efficiency of the production line. In this context, reducing energy costs tend to be a low priority.

28.1.2 Benchmarking Industrial Energy Consumption

The energy costs at a facility can be controlled by effective energy analysis, diagnostics, and management. Energy management is an important aspect for various manufacturing and service operations across U.S. industries to reduce operating costs (Gopalakrishnan et al., 2005a). The management in manufacturing companies is often interested in focusing on efficiency targets and comparing their performance with respect to established industrial practices. In this process, *benchmarking* is often used to identify performance levels with respect to the competition or the industry on an average. In terms of energy consumption in a manufacturing facility, benchmarking can be used effectively to judge whether there is an opportunity to implement significant energy efficiency measures. As an example, the energy use for a particular mill can be compared with that for similar mills or with that for a model mill representing the current best practice (Francis et al., 2004).

28.1.3 Potential for Industrial Energy Conservation

A significant potential indeed exists for energy reduction in the manufacturing community. Energy efficiency and subsequent reduction can be achieved by focusing on the manufacturing processes, utilities that support these processes, and total productive maintenance

procedures. Achieving energy efficiency depends on the technical aspects of operations, as well as the necessity for a cultural change in the viewpoint of management, in day-to-day operations (Sundarajan, 1999).

Industry's options for reducing energy costs were summarized in a study (National Association of Manufacturers, 2005). This study primarily identified energy efficiency measures that yield energy and environmental benefits for large volume, commodity and process industries. Prioritization of these opportunities based on various criteria incorporated in the study suggested 5.2 quadrillion Btu—21% of primary energy consumed by the manufacturing sector. These savings equate to almost \$19 billion for manufacturers, based on 2004 energy prices and consumption volumes (National Association of Manufacturers, 2005).

28.1.4 Initiatives of the U.S. Department of Energy for Energy Efficiency

The major initiatives taken by the U.S. DOE toward industrial energy efficiency include the establishment of industrial assessment centers, BestPractices, plant-wide energy assessments, industrial systems initiatives, and Industries of Future (IOF) program. In order to help industries identify and then capture EEM (energy efficiency measures) and EEO (energy efficiency opportunities) as of 2006, the USDOE EERE/ITP has supported the establishment of 26 industrial assessment centers (IAC) throughout the country. The IAC are located in universities and avail themselves of engineering students under the guidance and supervision of professors to conduct facility resource assessments. The assessments then help industries identify measures they can take to harness EEM and EEO. The IAC have been funded by the U.S. Department of Energy (USDOE), Office of EERE, Industrial Technologies Program (ITP) since 1976.

The focus of the IAC has been toward reducing industrial energy consumption, mainly for small and medium-sized facilities. The no-cost industrial assessments performed by the IAC are available to manufacturing facilities in the SIC 20–39, provided that they have no in-house professional staff to perform the assessment, have gross annual sales below \$100 million, have less than 500 employees at the plant site, have annual utility bills more than \$100,000 and less than \$2.5 million, and be located within 150 miles of the IAC. The energy assessment process includes the analysis of the utility costs and on-site data gathering using effective instrumentation. The discussion with the plant personnel adds to the practicality of the recommendations and the use of the proper support data. One additional benefit from the program is that the data generated by the assessments provides a unique opportunity to quantify the state of energy, waste and productivity management in small and medium-sized manufacturing facilities and the potential of the assessment process to improve efficiency. Since 1981, the data have been compiled from the assessment performed under this program (Department of Energy, 2005a).

Another initiative started by U.S. DOE is BestPractices, a program area within the ITP that supports ITP's mission to improve the energy intensity of the U.S. industrial sector through a coordinated program of research and development, validation, and dissemination of energy-efficient technologies and practices. BestPractices develops, implements, and disseminates best practices in energy management. The manufacturers' participation in BestPractices program can earn the organization technical, financial, and engineering personnel support for achieving energy efficiency. The BestPractices program has provided invaluable software for industrial use known as decision tools for industry.

These decision tools include tools such as process heating assessment tool (PHAST), steam system assessment tool (SSAT), steam system scoping tool (SSST), AirMaster+, MotorMaster+, PEP, and 3Eplus.

Plant-wide energy assessments help large-sized industries to save energy. Plants are selected on a competitive basis and agree to share costs of energy assessment spaced throughout a year. A maximum award of \$100,000 can be granted to a plant in this type of assessment, and equivalent or greater cost is shared by the selected company (Department of Energy, 2006a). Since this assessment is spaced throughout a year, it is a comprehensive energy consumption study and leads to significant EEM.

Industrial energy systems account for 80% of energy consumed by industry. Industrial energy systems are an initiative by which research and development efforts are focused on improvements in basic systems such as steam, process heating, compressed air, motors, pumps, fans, and combustion. This area provides potential of 10–20% reduction in energy usage, which converts approximately 1.6–3.2 quads (Department of Energy, 2005b).

The U.S. DOE has developed the Industries of Future (IOF) program to develop energy conservation opportunities in energy-intensive industries such as aluminum, steel, chemicals, metals casting, glass, mining, forest products, and petroleum and refining. Each project under this category meets rigorous criteria of industry participation, cost sharing, and relevance to industry-defined priorities. To date, the savings from this initiative have totaled to 1.6 quadrillion Btu, or \$6.5 billion (Department of Energy, 2006b).

28.1.5 Economics of Energy Efficiency and Importance to Company's Bottom-Line

Most manufacturing facilities seek a 2-year payback on investment in terms of any projects. It is important that the projects that promote energy efficiency be practical and that they afford economic desirability in terms of implementation by the manufacturing facilities. U.S. manufacturing must extract the highest percentage of productive energy from each Btu of energy produced, especially since it has a high per capita consumption of energy in the industrial sector. This is necessary for competing in the global marketplace. A significant portion of the operating costs of any manufacturing or service industry is in the form of energy costs. Hence, energy conservation and management is an important activity within any manufacturing or service organization, as it can reduce operating costs. The ability of a company to compete for business in an international scale is very important, especially in today's global business environment. Energy management is an important function within any manufacturing or service organization as it pertains to operating costs. Any reduction in operating costs is bound to increase the competitive edge of the industry.

28.1.6 Environmental Benefits of Energy Efficiency

Burning fossil fuels generate CO₂, NO_x, SO_x, and other gases that create an environmental problem. For each kWh of electricity that is reduced, the CO₂ emissions are reduced by as much as 2.19 lb. Similarly, for every MCF (1000 cubic feet) of natural gas that is not burned, the CO₂ emissions are reduced by approximately 113 lb. This indicates that significant emissions reductions are possible due to energy efficiency measures implemented in manufacturing facilities.

28.2 LITERATURE REVIEW

Since the mid-1990s, manufacturing plants in the United States have been undergoing a major shift with measures to reduce energy consumption. The U.S. Department of Energy's Office of energy efficiency and renewable energy (EERE) has encouraged the efforts through its various programs.

A key feature of any energy conservation program is the energy assessment (U.S. Department of Energy, 1978). Management commitment is the most important thing in an overall sense (Capehart et al., 1997). The methodology for conducting an energy assessment that attempts to obtain a comprehensive view of the energy utilization in all forms is important (Warfel, 1993). It addresses the issue that many of the energy assessments conducted by companies have the potential to overlook substantial energy conservation opportunities. It describes how plant performance is estimated based on limited data. According to the *Energy Auditor's Handbook* (Thumann, 1979), the energy audit is a brief, on-site survey and analysis of a plant and its energy usage patterns, identification of opportunities to save energy through the implementation of operational and maintenance changes, and an assessment of its need for implementation of energy conservation measures. Energy auditing is the first phase in improving the energy efficiency of a facility (Hoshide, 1995). Preparation of the energy management report, implementing, and monitoring are the other three phases. The implementation of energy-efficient technologies among manufacturing firms can lead to short-term as well as long-term benefits (Brown et al., 1994). There is also an environmental benefit from projects, the reduction of fossil fuel consumption. For example, the Pacific-Northwest region pursues energy conservation as a source of energy (Spanner et al., 1993). When energy problems caused by the rapid increase in demand in the face of dwindling fuel supply first became apparent, the immediate response was to seek new supplies and alternative fuels (Mate, 2002).

A rational approach to targeting energy costs and outlining the key strategies in energy assessment has been specifically determined for iron foundries (Meffert, 1999). Large metal-casting foundries are excellent targets for energy saving opportunities and should be targeted for continuous technological improvements. The nature of energy conservation opportunities that exist in glass manufacturing facilities are varied (Gopalakrishnan et al., 2001a). The energy management program pursued by a specialty chemical manufacturer has shown significant benefits (Fendt, 2001). The strategy used in a chemical plant to reduce energy consumption is unique in terms of process and utility parameters (Weber, 2001). Effective instrumentation is needed to facilitate a chiller plant energy efficiency monitoring as a prerequisite to any efficiency improvement initiatives for centrally air-conditioned buildings (Yik and Burnett, 1995).

As mentioned earlier, the U.S. DOE Industries of the Future (IOF) program includes industries such as agriculture, aluminum, chemical, forest products, glass, metal casting, petroleum refining, and steel, and these industries consume around 33% of all energy used in the United States¹ (OIT Clearinghouse, 2001). These industries have developed strategies to forecast growth and have identified the tools that are needed to increase their competitiveness. The plant-wide assessment at a paper mill identified five opportunities resulting in overall savings of over \$1.5 million (Augusta Newsprint: Paper Mill Pursues Five Projects Following Plant-Wide Energy Efficiency Assessment 2003).

¹Energy Information Administration. United States Background. Available at <http://www.eia.doe.gov/emeu/cabs/usa.html>.

Assessments at the world's leading aluminum manufacturing plant identified \$60 million in annual savings opportunities companywide.² Energy-saving opportunities included improved heat recovery, better furnace operations, and development of process-energy use targets.

Since DOE began the plant-wide energy assessments program, several plants have submitted successful proposals (Department of Energy, 2006a). The total energy savings that have been realized through this program has been significant and has saved millions of dollars (Department of Energy, 2006a). Only when the energy problems faced in the plant are reviewed in a total perspective do the solutions and the various conservation opportunities become visible. This is called the *systems engineering approach*. In a systems approach, the systems are evaluated macroscopically first and then micro studies are initiated only within the framework of the macro study to ensure the effectiveness of the assessment.

The effectiveness with which energy resources are converted into work is often termed as *energy efficiency* (National Association of Manufacturers, 2005). One example of a metric used often in evaluating heat-producing systems is thermal efficiency. Factors that have an effect on thermal efficiency include completeness of combustion, heat balance, and operating system characteristics (Role of Energy Efficiency: Understand the Value of Energy System Efficiency, 2004). The manufacturing facilities have varied overall energy efficiency that depends on operating system characteristics, production aspects, and technological considerations. Efficiency can be influenced by the design aspects of the manufacturing equipment, as well as by the extent of use. In the manufacturing sector, these energy losses amount to several quadrillion Btus (quadrillion British Thermal Units, or quads) and billions of dollars in lost revenues every year (Department of Energy, Industrial Technologies Program, 2004).

28.3 DATA ANALYSIS OF ENERGY EFFICIENCY MEASURES

This section describes the energy cost components for the energy bills and the analysis of the IAC database. Every manufacturing facility needs to understand how it is being billed for electricity and natural gas. Many facilities do not understand their rate structure, especially when it comes to charges for electrical billing demand. In terms of natural gas, many facilities may be placed in a position to pay high rates based on the type of contract they negotiate.

The Industrial Assessment Center database is extensive and contains elaborate information on all energy assessments conducted by the various IAC since 1981. The analysis of the database can reveal interesting energy profile and savings potential for various types of manufacturing facilities. The database is also a treasure house of knowledge in terms of energy conservation opportunities and the economic impact potential of these opportunities in terms of industrial implementation.

28.3.1 Utility Bill Analysis

The utility bill for a facility may have different components based on the need of the processes. Typically, the facilities have electricity and natural gas as major energy

² Alcoa teams with DOE to reduce energy consumption. Available at <http://www1.eere.energy.gov/industry/bestpractices/pdfs/36152.pdf>.

sources, and some of them may have other utilities such as oil, coal, wood, and water. Since electricity and natural gas are common components in most utilities, this section will be focused on discussion of these utilities. In general, all the facilities will have a contract with the utility company that will dictate the price per unit of electricity and natural gas. Many a time, the facility may have two or more rate schedules to choose from. Based on the data collected from different facilities, analysts may be able to study monthly or yearly usage pattern to find significant savings in terms of utility charges. In some cases, the facility may have done the analysis and chosen the best possible rate but over time, because of change in the usage pattern, the current rate schedule may not be optimal. In other cases, the utility company may decide the rate based on the maximum need of the facility without considering the usage pattern, which may result in more utility cost to the facility. The following section will discuss some key components in electricity and natural gas energy bills.

28.3.1.1 Components in Electricity Energy Bills The required energy cost mainly has three components (Will, 1993): (1) fixed costs (consumer/customer charges, administrative costs), \$/month; (2) electricity costs—that is, the real cost of electricity that is consumed by the process (variable costs); and (3) demand costs—that is, the cost of maintaining a level of energy to run the operation (investment costs), \$/kW. Fixed costs (consumer/customer charges, administrative costs) have no direct relation to the amount of energy used during the billing period. They cover the expenses in readings, accounting, and billing by the power supplier company, which is fixed in any billing period. In general, this cost component is insignificant in comparison with the energy and demand charges. The major components in the electricity bills are electricity (or usage) and demand cost.

28.3.1.2 Energy Charges Energy charge is based on the direct consumption of the electricity in terms of kilowatt-hours (kWh) during the electricity consumption period. The kilowatt-hours value is multiplied by the energy charges per unit (\$/kWh) for the total bill in the billing cycle. These charges may vary based on the service provider, voltage, and energy consumption during each billing cycle (Industrial Rates, Utilities in Greater Cleveland, 2005; West Penn Power Company, 2005; Monongahela Power Company, 2005a, 2005b; Allegheny Power, 2005). A summary of different rate structures may be given as a flat rate for each kilowatt-hour consumed by the facility, a variable rate based on the time of day during which the electricity is consumed, a variable rate based on the time of the year during which the electricity is consumed, a flat or variable rate with low power factor penalty, or a flat or variable rate based on the total amount of power (kVA or kW) consumed.

28.3.1.3 Demand Charges This charge is to compensate the utility company for the capital investment required to serve peak loads, even if that peak load is used only for partial operating period. The demand is measured in kilowatts (kW) or kilovoltamperes (kVA). These units are related to the energy (kWh) consumed in a given time interval of the billing period. The demand periods vary with the type of energy demand. The high fluctuating demand has a short-demand period, which can be as short as 5 min, but is generally 15, 30, or 60 min long (Monongahela Power Company, 2005a, 2005c; Buffington and Wolf, 2005). The utility companies use the period with the highest average demand for determining the demand charges in any billing cycle.

It should be noted that not all the utility companies charge their customers based on energy and demand. Also, there is no specific ratio or number of utility companies that

TABLE 28.1 Example Demand for a 15-Min Interval

Demand (kW)	Time Units for This Demand
10	2
12	4
2	7
10	2
Total	15

charge based on energy only and do not include demand in their bills. The calculation of the demand can be explained with a simple example. Assume that the demand pattern for any particular process is as given in Table 28.1. The average demand charged to the facility for this 15-min interval can be calculated as follows:

$$\text{Demand charged (kW)} = ((10 \times 2) + (12 \times 4) + (2 \times 7) + (10 \times 2)) / 15 \\ = \text{kW}$$

Similarly, the demand will be calculated for each of the 15-min intervals. Finally, the facility will be charged for the maximum of all these calculated values for each 15-min interval during the billing period. It may be noted that in some cases, the demand rate is also a variable charge based either on the time of the day or time of year (Industrial Rates, Utilities in Greater Cleveland, 2005; West Penn Power Company, 2005; Monongahela Power Company, 2005a, 2005b; Allegheny Power, 2005). Finally, the energy charge may be based on the demand (kW or kVA).

28.3.1.4 Rate Schedules We can compute an energy bill for a sample facility. The energy rate structure for the facility is as follows:

Minimum monthly charges	\$2.75/kVA of demand
<i>Energy charges</i>	
	\$0.10599 for first 30 kWh per kVA of demand
	Next 170 kWh per kVA of demand:
	\$0.06965/kWh for first 2,000 kWh
	\$0.05883/kWh for next 8,000 kWh
	\$0.04867/kWh for next 90,000 kWh
	\$0.04175/kWh for all over 100,000 kWh
	For kWh in excess of 200 times kVA:
	\$0.03341/kWh for first 200,000 kWh
	\$0.02855/kWh for all remaining kWh
Average fuel cost adjustment (FCA)	\$0.01902/kWh
Average tax on kWh	8.27% of the kWh cost

Note: The average FCA and tax rates may be calculated from the energy bills or can be obtained directly from the utility company.

28.3.1.5 Example of the Electricity Cost Calculation As an example, for one of the billed months, the readings are assumed to be

$$\text{Total energy} = 201,800 \text{ kWh} \\ \text{kVA recorded} = 416 \text{ kVA}$$

Therefore, the cost of electricity can be calculated as follows:

$$\begin{aligned}
 &\text{Minimum monthly charges} = \$2.75/\text{kVA} \times 416 \text{ kVA} = \$ \\
 &\text{Energy charges} \\
 &\quad \$0.10599 \text{ for first 30 kWh per kVA of} = \$1,322.76 \\
 &\quad \text{demand} = \$0.10599/\text{kWh} \times 30 \text{ kWh/kVA} \times 416 \text{ kVA} \\
 &\text{Next 170 kWh per kVA of demand (or 170 kWh/kVA} \times 416 \text{ kVA} = 70,720 \text{ kWh}) \\
 &\quad \text{First 2,000 kWh: } \$0.06965/\text{kWh} \times 2000 \text{ kWh} = \$139.30 \\
 &\quad (\text{Note: remaining kWh in this bracket is} \\
 &\quad \quad 70,720 - 2,000 = 68,720 \text{ kWh}) \\
 &\quad \text{Next 8,000 kWh: } \$0.05883/\text{kWh} \times 8,000 \text{ kWh} = \$470.64 \\
 &\quad (\text{Note: remaining kWh in this bracket is} \\
 &\quad \quad 68,720 - 8,000 = 60,720 \text{ kWh}) \\
 &\quad \text{Next 90,000 kWh: } \$0.04867/\text{kWh} \times 60,720 \text{ kWh} = \$2,955.24 \\
 &\quad (\text{Note that only 60,720 kWh was available in this bracket}) \\
 &\quad (\text{Note: remaining kWh in this bracket is } 60,720 - 60,720 = 0 \text{ kWh}) \\
 &\text{All over 100,000 kWh: } \$0.04175/\text{kWh} \times 0 \text{ kWh} = \$0.00 \\
 &\quad \text{For kWh in excess of 200 times kVA (201,800 kWh} - \\
 &\quad \quad (200 \text{ kWh/kVA} \times 416 \text{ kVA}) = 118,600 \text{ kWh}) \\
 &\quad (\text{Note that only 118,600 kWh is available in this bracket}): \\
 &\quad \text{First 200,000 kWh} = \$0.03341/\text{kWh} \times 118,600 \text{ kWh} = \$3,962.43 \\
 &\quad (\text{Note: remaining kWh in this bracket is } 118,600 - 118,600 = 0 \text{ kWh}) \\
 &\quad \text{All remaining kWh} = \$0.02855/\text{kWh} \times 0 \text{ kWh} = \$0.00 \\
 &\text{Sub-total cost} = \$1,322.76 + \$139.30 + \$470.64 \\
 &\quad + \$2,955.24 + \$0 + \$3,962.43 + \$0 \\
 &\quad = \$8,850.37 \\
 &\text{Average fuel cost adjustment (FCA)} = \$0.01902/\text{kWh} \times 201,800 \text{ kWh} = \$3,838.24 \\
 &\text{Average tax on kWh} = 8.27\% \text{ of } \$8,850.36 = \$731.92
 \end{aligned}$$

Therefore, the total cost (TC) for the month is calculated as

$$\begin{aligned}
 \text{TC} &= \text{Subtotal cost} + \text{FCA} + \text{Tax} \\
 &= \$8,850.37 + \$3,838.24 + \$731.91 \\
 &= \$13,420.53
 \end{aligned}$$

It may be noted that the FCA rate may change from month to month. The same calculation method will be used to calculate the cost savings from any recommendation. The energy savings will be calculated in terms of kWh and kVA (derived from the kW savings as ratio of kW to the average power factor of 0.9788).

28.3.1.6 Example of Energy Cost Savings Calculation The energy cost savings calculations are based on the average monthly value of energy and demand usage. As an example, for one of the manufacturing facilities, based on the energy bills for 12 months in 2005, the average energy used was 222,533 kWh and the average demand usage was 475 kVA. Based on the values in the bills, the average FCA rate is assumed as \$0.01902/kWh and the average tax will be taken as 8.27%. As discussed earlier, the total average cost of the electricity per month is calculated as \$14,869.65. To calculate the savings from any recommendation, the savings in the energy and demand usage will be calculated in terms of kWh/year and kW-month/year. As an example, if the proposed savings are

10,000 kWh/year and 50 kW-month/year (or a reduction of 4.26 kW in the peak demand in each month), the new average usage can be calculated as follows:

$$\begin{aligned}
 \text{Proposed average kWh} &= (\text{Current average} - \text{proposed savings})/\text{month} \\
 &= (222,533 \text{ kWh}) - [10,000 \text{ kWh/year}/12 \text{ months/year}] \\
 &= (222,533 - 833.33) \text{ kWh/month} \\
 &= 221,699.7 \text{ kWh/month} \\
 \text{Proposed average kVA} &= (\text{Current average} - \text{proposed savings})/\text{month} \\
 &= (475 \text{ kVA}) - [50 \text{ kW/year}/(12 \text{ months/year} \times \text{PF})] \\
 &= (475 - 4.26) \text{ kVA/month} \\
 &= 470.74 \text{ kVA/month}
 \end{aligned}$$

(Note: PF is the average power factor is used to convert the kW to kVA.)

Based on the proposed average kWh and kVA and the method of energy cost calculation discussed in cost calculation section, the new cost of electricity is calculated as \$14,801.66. Therefore, the savings can be calculated as

$$\begin{aligned}
 \text{Savings} &= (\text{current cost} - \text{proposed cost}) \times 12 \text{ months/year} \\
 &= (14,869.65 - 14,801.66) \times 12 \\
 &= \$816/\text{year}
 \end{aligned}$$

28.3.1.7 Components in Natural Gas Bills The utility bills for the natural gas are rather simple as compared to the electrical energy bills. In general, the units for the measurement of natural gas consumption are based on volume or energy. Some common units in these categories are

Volume

Cf: Cubic foot $\cong 1030$ Btu

Ccf: 100 cubic feet

Mcf: 100 cubic feet

Tcf: Trillion cubic feet $\cong 1$ quad.

Energy

DTH: One deca-therm = 10 TH $\cong 1$ MMBtu

TH: One therm $\cong 100,000$ Btu

MMBtu: 1 million Btu

MBtu: 1000 Btu.

The total cost of the natural gas for a billing period may have one or more components and depends on the supplier and amount of natural gas usage in the facility. Some common billing terms used in the natural gas bills are

- *Gas Usage Rate*: usage rate determined by the utilities (\$/unit of gas),
- *Standby Charges*: charges to maintain a constant supply of gas to the facility (\$),
- *Customer Charge*: covers the cost of billing, meter reading, and equipment (\$),

Account number	Previous balance	Payment received	Current billing	Total due	Tariff MCF	Trans- port MCF	Total MCF
	2,005.83	2,005.83	1,835.00	1,835.00	4.00	0.00	4.00
Account no.:			Invoice detail			Billing month: APR 05	
Contract	Description			Basis		Dollars	
	Commodity charge			4.00	MCF	31.31	
	Customer charge			1.00	MON	18.38	
	Delivery charge			4.00	MCF	12.86	
	Gas cost adjustment			4.00	MCF	5.58	
	Standby service			1.00	MON	1,661.82	
	Tax surcharge			1,729.95	DOL	1.21	
	Transition cost			4.00	MCF	0.00	
	Tax surcharge			4.00	MCF	0.03-	
	Pa sales tax—100% taxable			1,731.13	DOL	103.87	
	Total current bill			4.00	MCF	1,835.00	
Includes	0.00 of late fees in previous balance					0.00	
	Late payment charges					0.00	
	Total due					1,835.00	

FIGURE 28.1 Example of natural gas bill with high standby charges.

- *Purchase Gas Adjustment (PGA)*: to recover the cost (fuel cost) of purchasing natural gas (\$/unit of gas),
- *Transportation Charges*: to recover the cost of transportation of gas to the customer site (\$/unit of gas),
- *Taxes*: applicable taxes on the total bill for the facility (\$/unit of gas).

An example of a natural gas bill is given in Figure 28.1. It may be noted that the standby charges for this facility is much more than the usage cost of the gas. This facility was using the gas company as a standby to their gas wells, from which they were getting the natural gas for their process use. It is evident that the usage pattern of the utilities should be considered properly to minimize the unnecessary charges.

28.3.2 Analysis of IAC Database

The IAC perform industrial assessments for small and medium-sized manufacturing companies to identify opportunities to save energy, reduce waste, and increase overall plant productivity. The program maintains a database of all the recommendations from assessments performed by the IAC and currently has a listing of 12,987 assessments and 97,205 recommendations (IAC Database, 2006). This database is continuously updated after any of the centers upload the report from their assessment. The database has many features to find any recommendation that the user may be interested in. The assessments/recommendations can be filtered based on manufacturer codes (NAICS or SIC), IAC, year of energy assessment, annual sales of the facilities, number of employees, annual energy cost, and state of facilities.

28.3.2.1 Recommendations To facilitate the search for a particular recommendation, the database has assigned special codes, called as Assessment Recommendation Code

(ARC), for each of the recommendations. The ARC contains six numbers with a format as X.YYYY.Z. The first number is designated for the recommendation type, the next four numbers detail the actual recommendation within the main category, and the last number is the application of the recommendation (e.g., building, process, or other applications). All the recommendations are mainly categorized as energy management, waste minimization/pollution prevention, and direct productivity enhancements. Each of these categories has lists of subcategories based on the energy systems. The general categories of these recommendations are as follows.

28.3.2.2 Energy Management The recommendations related to energy management deal with combustion systems, thermal systems, electrical power, motor systems, industrial design, maintenance and equipment control, lighting, space conditioning, administrative and other costs, and alternative energy sources such as wind and solar energy.

28.3.2.3 Waste Minimization/Pollution Prevention This includes the recommendations related to reduction of waste and therefore pollution through operations, equipment, maintenance, raw materials use, water use, and disposal.

28.3.2.4 Direct Productivity Enhancements The example recommendations in this category are manufacturing enhancement, purchasing, resource optimization, reduction of downtime, management practice, and other administrative savings. The top five recommendations in the list are shown in Table 28.2.

28.3.2.5 Implementation The IAC program keeps a track of the recommendations implemented in the facilities, which are called 6–9 months after the assessment date. This information is reported to the IAC database and is accessible to the public. The program has an excellent implementation record of more than 50% implementation rate for its recommendations. Table 28.3 lists the top five recommendations that were implemented

TABLE 28.2 Top Five Recommendations

Recommendation	Number of Times Recommended
Utilize higher-efficiency, lower-wattage lamps, or ballasts	8189
Eliminate leaks in inert gas and compressed air lines	4828
Use most efficient type of electric motors	4372
Install compressor intakes in coolest locations	3860
Utilize energy-efficient belts and other improved mechanisms	3227

TABLE 28.3 Top Five Implemented Recommendations

Recommendation	Number of Times Implemented
Utilize higher-efficiency, lower-wattage lamps, or ballasts	4700
Eliminate leaks in inert gas and compressed air lines	4020
Use most efficient type of electric motors	2877
Install compressor intakes in coolest locations	1911
Utilize energy-efficient belts and other improved mechanisms	1815

the most by the manufacturing facilities. It may be noted that the same recommendations that were recommended the most have been implemented the most as well.

28.3.2.6 Energy Savings Based on the analysis of the database, the total amount of energy savings from all the recommendations in terms of electricity is over 2 billion kWh and natural gas is over 38 million MMBtu. It is worth mentioning that the database has the records for many other fuel sources such as #2 oil, coal, and wood, but have not been considered here because electricity and natural gas are main energy sources in most of the industries visited through the IAC program.

28.3.2.7 Cost Savings The IAC program has recommended savings over \$1.5 billion. The average savings per assessment is estimated as \$55,000. The database lists the energy savings for each recommendation in terms of the utilities (electricity, natural gas, oil, coal, water, etc.) related to the process. The total annual cost savings from recommendations related to electrical energy exceed \$120 million, and natural gas savings recommendations result in an annual savings of more than \$180 million. Top 10 recommendations and their cost savings are shown in Table 28.4.

28.3.2.8 Payback on Investment Based on the total cost savings and the implementation cost of the recommendations, the average payback on the implementation cost for all the recommendations is estimated as 4 months. It may be noted that some of the recommendations do not require any implementation cost and thus result in an immediate payback, whereas others may have some implementation cost in terms of capital or labor cost investment. For most of the recommendations, the average payback is within 2 years.

28.3.2.9 Reduction in Emissions The recommendations during the assessments not only save money for the facilities but result in reduction in emissions. Based on the analysis performed in the energy savings section, the reduction in CO₂ emissions through electricity and natural gas recommendations are estimated as approximately 9 billion pounds.

TABLE 28.4 Top 10 Cost Savings Recommendations

Recommendation	Total Savings (\$)
Add equipment/operators to reduce production bottleneck	88,846,940
Replace existing equipment with more suitable substitutes	44,651,442
Install automatic packing equipment	40,672,093
Use a fossil fuel engine to cogenerate electricity or motive power and utilize heat	37,876,660
Utilize higher-efficiency lamps and/or ballasts	35,925,118
Use waste heat to produce steam to drive a steam turbine generator	24,659,543
Eliminate leaks in inert gas and compressed air lines/valves	24,504,452
Replace electrically operated equipment with fossil fuel equipment	23,947,776
Change procedures/equipment/operating conditions	23,336,815
Repair and eliminate steam leaks	22,959,756

28.4 ENERGY EFFICIENCY MEASURES IN MAJOR ENERGY CONSUMING EQUIPMENT

This section discusses a sample of the important energy-saving opportunities for major energy-consuming equipment commonly used in facilities (e.g., boilers, furnaces, ovens, electric motors, lighting, chillers, cooling towers, heating ventilation and air-conditioning, air compressors, and combined heat and power systems). Description for assessing equipment, data collection requirements, related theory, necessary modifications in the equipment setup, implementation cost, and benefits of implementation are discussed further. U.S. DOE's BestPractices tools can be used to determine the energy savings in several areas of equipment usage.

28.4.1 Furnaces, Ovens, Boilers, and Steam Systems

Furnaces and ovens are equipment used to heat air, material, or other fluids. Common applications can be melting, annealing, preheating, heat treatment, and baking. Boilers produce hot water or steam under pressure in a closed vessel used in various processes.³ Furnaces/ovens/boilers burn different types of fuel to generate heat, which is then used for the desired purpose. Following are some of the energy-saving opportunities that can be realized for furnaces/ovens/boilers.

28.4.1.1 Insulate the Bare Surfaces of Ovens, Furnaces, Boilers, and Steam Pipes The bare surfaces of crucible furnaces, reverberatory furnaces, electric ovens, pit ovens, and boiler and steam pipes, if not insulated, will radiate significant energy due to lack of insulation. These surfaces can be insulated, thereby reducing the heat losses. Energy savings is a function of the difference in heat loss from the bare and insulated surface, area of the surface that needs insulation, annual operating hours of the equipment, and the efficiency of the heat supply. The DOE BestPractices tool 3E Plus can be used effectively for this energy efficiency measure (BestPractices Software Tools, 2006).

28.4.1.2 Preheat Natural Gas Oven/Furnace/Boiler Combustion Air Using Hot Flue Gas Significant amount of waste heat is available in the oven/furnace/boiler stack. This heat can be recovered by preheating the combustion air. A heat exchanger along with the necessary ductwork can be installed to preheat the intake air of the natural gas oven/furnace/boiler. The combustion air can be preheated and directed into the natural gas-fired oven/furnace/boiler air intake port using galvanized steel insulated ductwork. Warmer combustion air leads to increase in combustion efficiency. An increase in efficiency of approximately 1% is possible for every 40°F increase in combustion air temperature (Dyer and Dyer, 1981). The existing combustion efficiency of the oven/furnace/boiler can be determined by using a stack gas analyzer. The energy savings to be realized by directing preheated air to the oven/furnace/boiler air intake is a function of the rating of the oven/furnace/boiler, the annual operating hours, and the existing and proposed combustion efficiencies of the oven/furnace/boiler (Industrial Assessment Center Reports, 1992–2006). The USDOE's BestPractices software tool PHAST can be used to determine the improvement in efficiency by preheating the combustion air (BestPractices Software Tools, 2006).

³ Wikipedia. The free encyclopedia. Available at <http://en.wikipedia.org/wiki/Motors>.

28.4.1.3 Recover Waste Heat from Gas Ovens/Furnaces/Boilers Air-to-air type heat exchangers can be used to capture heat from the exhaust gases from the gas oven/furnace/boiler to heat the plant area during winter. By recovering the waste heat from the oven/furnace/boiler stack, the plant space heating system will be used for less time. The recovered heat would be used to heat the plant area during the heating season. The outlet temperature for the hot side of the gas oven/furnace/boiler can be determined using a stack gas analyzer or an infrared temperature gun in case the stack is not insulated. Outside fresh air or plant air can be used on the cold side of the heat exchanger. The potential annual space heating energy savings is a function of the exhaust gases' mass flow rate from the stack, specific heat of exhaust gases, temperature of exhaust gases from stack before heat exchanger, minimum practical exhaust temperature after heat exchanger (Dyer and Dyer, 1981), operating hours during the heating season, and efficiency of the heating system (Industrial Assessment Center Reports, 1992–2006).

28.4.1.4 Adjust Air-Fuel Ratio on the Natural Gas Oven/Furnace/Boiler Adjust the combustion system air-fuel ratio for the oven/furnace/boiler to reduce the amount of excess air passing through the oven/furnace/boiler and to improve the combustion efficiency of the oven/furnace/boiler. Based on the field combustion test conducted on the oven/furnace/boiler, it can be determined whether they need air-fuel ratio adjustment. Combustion test on the oven/furnace/boiler can be done using a stack gas analyzer. The optimum amount of O₂ in the flue gas of a natural gas-fired oven/furnace/boiler is 2.2%, corresponding to 10% excess air. In practice, a reduction in excess O₂ to about 3.5% (about 18% excess air) can be achieved. This estimate is based on discussions with several local oven/furnace/boiler adjustment contractors, who have indicated that a reduction in excess O₂ to less than about 3% is difficult for most oven/furnace/boiler. The corresponding CO₂ value for an O₂ value of 3.5% should be about 9.8%, as seen in Table 28.5, assuming no change in stack gas temperature before and after the adjustment. Combustion efficiency will increase due to the adjustments on the air-fuel ratio (Industrial Assessment Center Reports, 1992–2006).

The energy savings is a function of the rating of the oven/furnace/boiler, the annual operating hours of the oven/furnace/boiler, the firing factor of the oven/furnace/boiler, and the existing and proposed combustion efficiencies of the oven/furnace/boiler (Industrial Assessment Center Reports, 1992–2006). The USDOE's BestPractices tool PHAST can be used to determine the improvement in efficiency by adjusting the air-fuel ratio (BestPractices Software Tools, 2006).

28.4.1.5 Inspect, Repair, and Maintain Steam Traps Steam traps are used to separate the steam from condensate, air, and other noncondensable gases (Industrial Assessment Center Reports, 1992–2006). Institute a permanent steam trap management program. The program should include inspecting the steam traps, cleaning the traps, replacing the trap

TABLE 28.5 Optimal Percentages of O₂, CO₂, and Excess Air in the Exhaust Gases

Fuel	O ₂ (%)	CO ₂ (%)	Excess Air (%)
Natural gas	2.2	10.5	10
Liquid petroleum fuel	4.0	12.5	20
Coal	4.5	14.5	25
Wood	5.0	15.5	30

disc or lever if not working properly, and replacing the trap itself if it is defective. This program could be implemented by the plant maintenance staff. Steam traps are the key to an efficient steam system. The objectives of the steam traps are to remove condensate, air, and other noncondensable gases, and prevent steam loss. Efficient operation of any steam system requires well-designed trapping, which is periodically inspected and properly maintained. It is only in this way that condensate and air will be removed automatically as fast as they accumulate without wasting steam (Energy Conservation Program Guide for Industry and Commerce, 1974). The traps can be tested using an ultrasonic testing device. Common outcomes of steam trap testing are continuous blowing, partial or complete blockage, or the trap functions properly. Energy savings is thus a function of the total steam loss from steam traps, heat content of saturated steam, specific heat of water at constant pressure, feed water temperature, boiler overall efficiency, and annual operating hours for which the steam source operates (Industrial Assessment Center Reports, 1992–2006). The USDOE's BestPractices tool SSAT can be used to determine the losses through steam traps (BestPractices Software Tools, 2006). The inputs to the tool are mainly the steam pressure, total number of steam traps in use, number of steam trap failures, boiler fuel source, and the number of steam trap failures after repairs. Based on these inputs to the tool, savings in fuel and makeup water cost can be determined.

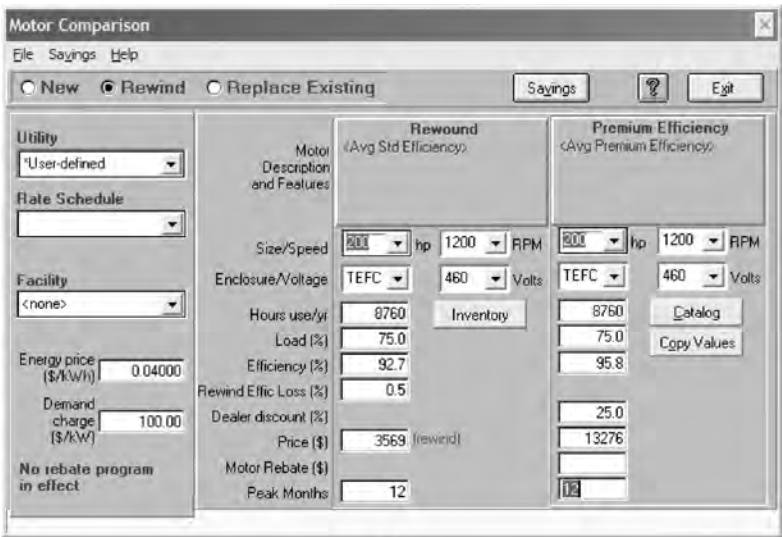

28.4.1.6 Other Steam-Related Energy-Efficiency Measures The other steam-related energy-efficiency measures can be listed as follows: (1) install reverse osmosis unit to reduce boiler blow-down rate; (2) inspect and repair steam leaks; (3) implement a condensate recovery system; (4) install waste heat boiler to produce steam; (5) install deaerator unit to reduce steam system corrosion; and (6) install turbulators on fire tube boilers (BestPractices Software Tools, 2006).

28.4.2 Motors

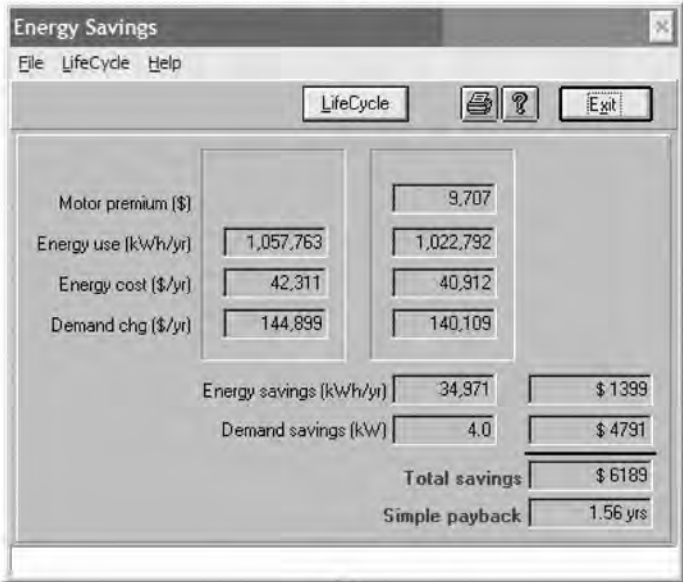

Electric motors are used to convert electrical energy into mechanical work (Industrial Assessment Center Reports, 1992–2006). There is a drop in motor efficiency with its use. The following energy-saving opportunities discuss ways to reduce transmission losses and improve motor efficiency.

28.4.2.1 Implement a Motor Management System Implement a motor management system (MMS) such as MotorMasterTM to help document motor inventory and to identify/analyze motor-driven systems for various energy conservation opportunities. Implementing the motor management system requires the facility to first obtain MotorMasterTM software, which can be downloaded at no charge from the U.S. Department of Energy (USDOE's) web site (BestPractices Software Tools, 2006).

After obtaining the software, the user can develop an inventory of motors organized by facility, department, and process. Information such as nameplate data, load profile, field measurements, and energy cost can be stored for each motor so that motor performance can be tracked. A motor management system is designed to assist the facility to reduce energy costs through maximizing production efficiency, minimizing energy consumption, correcting for power factor, understanding utility billing statements, and establishing a preventative and predictive maintenance program. MotorMasterTM software (Figure 28.2) is capable of analyzing the energy and cost impacts of various hypothetical situations that occur either before and/or after a motor failure. These situations include downsizing to a

(a)

(b)

FIGURE 28.2 U.S. DOE’s BestPractices Tool MotorMaster™ for determining energy savings through use of energy-efficient motor.

smaller motor, rewinding a failed motor, replacing a failed motor with same size motor, and replacing a failed motor with a larger spare motor.

28.4.2.2 Other Motor-Related Energy-Efficiency Measures The other important energy-efficiency measures as related to motors are: (1) perform vibration analysis on equipment; (2) replace drive belts on motors with energy-efficient cog belts; (3) maintain properly sized motor system; and (4) install variable-speed drive on the motors.

28.4.3 Lighting

Lighting systems use considerable amount of electrical energy to produce desired illumination levels.³ Lighting technology has made significant developments with time and provides state of the art energy solutions (Industrial Assessment Center Reports, 1992–2006).

28.4.3.1 Replace the 400 W Metal Halide Lamps with 360 W Metal Halide Lamps The lighting energy usage can be reduced by replacing the 400 W metal halide lamps with 360 W metal halide lamps. Because of more efficient 360 W bulbs, the illumination level practically remains the same with the reduction in power used. This is an option for reducing the amount of energy used for lighting. The replacement does not require the change of the fixture and the ballast. The lamps can be retrofitted with 360 W metal halide lamp, as the existing 400 W lamps burn out with time. Energy savings is a function of the difference in power used by the 400 W and 360 W lamps, the ballast factor of the lamp, the annual operating hours of the lamps, and number of similar lamps to be replaced in the facility (Industrial Assessment Center Reports, 1992–2006).

28.4.3.2 Replace the Existing T12 Lighting Fixtures with Magnetic Ballasts by T8/T5 Lighting Fixtures with Electronic Ballasts and Reflectors Install T8/T5 lighting fixtures using electronic ballasts with reflectors in place of the T12 fixtures containing magnetic ballasts. This will reduce the lighting energy usage while maintaining the same lighting levels at the work surface. Lighting technology has evolved rapidly in recent years. In commercial buildings, significant reductions in energy use can be achieved by installing energy-efficient bulbs, fixtures, and controls. Retrofits to install new technologies such as electronic ballasts and specular reflectors are often cost-effective, providing a reasonable payback. T8/T5 bulbs provide almost the same light levels as T12 bulbs with the reduction in power consumption. Electronic ballasts consume less (approximately 5–10%) power as compared to the regular magnetic ballasts (Industrial Assessment Center Reports, 1992–2006). Hence, the energy savings is a function of the number of bulbs per fixture, the number of florescent fixtures in the facility, existing and proposed wattage of each fixture, the ballast factor, and the annual operating hours (Industrial Assessment Center Reports, 1992–2006).

28.4.3.3 Install Occupancy Sensors in Designated Areas Occupancy sensors can be installed in some areas to reduce the electrical usage for lighting during unoccupied periods. If certain areas in the facility with less utility are heavily lit, then by wiring occupancy sensors into these areas, the lighting usage could be reduced during the unoccupied periods. Energy savings will result from reduced electrical usage for lighting. Some lights can be left on in the room for emergency purposes. Energy savings is a function of the total power consumption by the lights and the annual hours for which the lights can be controlled (Industrial Assessment Center Reports, 1992–2006).

28.4.4 Chillers

Chillers are used to produce chilled water for plant and process cooling. Mechanical chillers and absorption chillers are the two commonly used types.³ Mechanical chillers use electric motors to drive the refrigerant compressors, whereas heat source is used in absorption chillers.

Increasing the chiller set point temperature would save electrical energy. Generally, the efficiency of chillers increases as the chilled water temperature increases. This is because in order to obtain lower-temperature chilled water, the refrigerant must be compressed at a higher rate, which in turn increases the compressor power requirements and decreases the efficiency of the chiller. There is approximately 1% increase in efficiency for each degree Fahrenheit increase in the chilled water set point temperature (Modern Industrial Assessments, 2004). Before implementing this recommendation, it is advised to first check any effect of changing the set point temperature on the process. Thus, the energy savings can be realized by increasing the chiller set point temperature and is the function of the chiller capacity, increase in chiller efficiency due to increased set point temperature, chiller coefficient of performance, annual operating hours for the chiller, and operating load on the chiller (Industrial Assessment Center Reports, 1992–2006). The USDOE's BestPractices software tool CWSAT can be used to determine the energy savings from this recommendation (BestPractices Software Tools, 2006).

28.4.5 Heating, Ventilation, and Air-Conditioning Equipment

Heating, ventilation, and air-conditioning (HVAC) units are used to condition air (i.e., control temperature, humidity, and air flow as per the space requirements). Heating is provided to heat the air in the heating season, whereas air-conditioning is used to cool the air in the cooling season. Ventilation involves air makeup units to maintain positive air pressure in the plant.

Older air-conditioning units used for cooling were not made with installed economizers. Space cooling energy usage can be reduced by adding an economizer. Economizers are essentially a duct and damper system that allows fresh outside air to be used directly for space cooling whenever outdoor air has a lower total heat content, *enthalpy*, than return air. Using cool outside air whenever possible, the energy usage by the mechanical cooling units can be reduced significantly. To determine possible energy savings, the enthalpy of outside air should be known. The enthalpy is a function of the dry bulb temperature and the humidity. The higher the dry bulb temperatures and humidity levels, the larger the enthalpy value is. Using the ASHRAE Handbook of fundamentals, enthalpy values can be determined directly from wet bulb temperatures. Using TMY data and a bin analysis, 5°F wet bulb temperatures can be determined with their associated monthly hours. The enthalpy can also be determined directly from a psychometric chart. In order to use this, the user needs the dry bulb temperature and the humidity or both the wet bulb temperature and the dry bulb temperature. Energy savings is a function of the total Btu \times h per lbm of air for a month during the cooling period, total cubic feet per minute of the cooling capacity, density of air, coefficient of performance of the air-conditioning unit, and the annual usage of the unit (Industrial Assessment Center Reports, 1992–2006).

28.4.6 Air Compressors

Air compressors are electric motor driven systems used to increase the air pressure by reducing its volume. Compressed air finds wide range of application in industries.

28.4.6.1 Use Outside Air for Air Compressor Intake Duct outside air to the air compressor intake. This can be done by connecting one end of the pipe to the compressor intake. The other end is routed through the wall to the outside. The existing intake

temperature at the compressor intake can be measured using an infrared temperature gun. On average, the outside air is cooler and therefore denser than the indoor air. The compressor's work for the usual operating conditions in manufacturing plants is proportional to the absolute temperature of the intake air. Being denser, cooler air has higher mass and thus compresses more mass of air in one compression cycle (BestPractices 2006). Therefore, by utilizing the outside air as supply to the air compressor intake, it can be compressed easily with reduced energy requirement. Energy savings is a function of the compressor motor capacity (horse power rating); fractional reduction in the compressor's work is due to lowering the compressor's intake air temperature; the horsepower reduction factor, based on operating pressure and power consumption at maximum pressure; operating load on the compressor; annual operating hours; and efficiency of the compressor motor (Industrial Assessment Center Reports, 1992–2006).

28.4.6.2 Repair Compressed Air Leaks Repair compressed air leaks on a regular basis. Air leaks in the facility can be detected using an ultrasonic leak detector. The leak detector detects noises caused by air leak that are not audible to human ears in a noisy production setup. Output from the detector can be read from a visual analog (or digital) display or can be heard using earphones. Air is compressed from atmospheric pressure to the compressor discharge pressure at the expenditure of compressor work. Considerable volume of high-pressure air is lost through air leaks. At discharge pressure conditions, power is lost due to loss of compressed air volume through air leaks. Repairing air leaks result in reduced compressed air wastage and thus reduced artificial demand on the compressor. Air leaks are typically present near pipe joints, fittings, valves, and regulators. Energy savings is a function of the power loss due to leak, which is a function of the volumetric flow rate of free air exiting the leak and annual hours during which the leak occurs (Industrial Assessment Center Reports, 1992–2006). The USDOE's BestPractices tool AIR-Master+ can be used to determine the amount of energy lost through air leaks (BestPractices Software Tools, 2006).

28.4.7 Combined Heat and Power (CHP)

Combined heat and power systems generate heat and electricity as against traditional power plants only producing electricity. A CHP system typically involves a compressor, combustion chamber, gas turbine, and mechanical equipment or a generator coupled to the turbine shaft. The exhaust gases leave the turbine at an elevated temperature. Considerable heat is lost from the turbine exhaust. This heat energy is recovered and serves as a heat source for process heating, space heating, and boiler feedwater heating (Oland, 2004).

A back pressure turbine can be installed at the boiler house to use the potential pressure difference between the turbine's inlet and exit steam as a prime mover or power source to any equipment using electricity. The high pressure steam produced by the boiler is often throttled at reducing stations to a lower pressure before it is used in the production process. There exists heat energy potential in this steam, which can be used by replacing the reducing station with a back pressure turbine. Therefore, the back pressure turbine will use the energy between the high-pressure steam at boiler operating conditions and the low-pressure steam being supplied to the plant. The back pressure turbine can, therefore, serve as a prime mover to any rotating equipment such as an electric motor. Also, a generator can be coupled to the turbine shaft to generate electricity, which can serve as a source of power for any equipment (electric motors) using electricity. The energy savings

is a function of the mass flow rate of the steam, difference in enthalpies of the high pressure and low pressure steam, overall efficiency of the back pressure turbine, and the efficiency of the mechanical coupling between the back pressure turbine and the rotating equipment (Industrial Assessment Center Reports, 1992–2006).

28.5 CASE STUDIES OF DEVELOPMENT OF ENERGY-EFFICIENCY MEASURES

Various types of industries have implemented energy-efficiency measures to improve efficiency of their existing operations. This is especially true for manufacturing industries that have high energy intensity in their operations. These include manufacturing plants in glass manufacturing, plastics manufacturing, primary metals manufacturing, and chemical manufacturing industries. Some of the case studies that reveal typical energy-saving opportunities that existed in this industry segment and savings realized as a result of a particular measure are discussed here.

28.5.1 Glass Manufacturing

The manufacturing activities carried out in the glass-manufacturing facilities range from glass decorating using purchased glass to manufacturing glass from basic raw materials using the hand-blown or machine-based processes. Four factors that characterize the manufacturing facilities are energy consumption, the plant size, the number of employees, and the annual sales (Gopalakrishnan et al., 2001b). The industrial assessments conducted at the glass-manufacturing facilities revealed a variety of Energy Conservation Opportunities (ECOs). The manufacturing variety for glass was as follows: hand-blown glass, machine-made glass, pressed glass, flat glass, glass bending, cut glass, glass fabric production, window manufacturing, decorative glass manufacture, hermetic seal production, and marbles. Significant relationship exists between the annual energy usage and the plant size (Gopalakrishnan et al., 2001b). A list of ECOs was recommended for each plant assessed. The energy conserved was reported for each ECO. The ECOs were selected for each plant based on the percentage of energy savings they contributed with respect to the total energy savings recommended for that plant. In general, for each plant, ECOs that had energy savings of 20% or higher with respect to total recommended energy savings were selected for this list, as they were considered to be the most significant. The ECOs found in the glass-manufacturing facilities were adjusting air to fuel ratios, preheating combustion intake air, heat recovery and distribution, insulating hot surfaces, replacing motors with energy efficiency motors, modifying chiller operation, modifying heat output in process, improving compressor operation, and reducing infiltration and space-heating loads. A total of 280,000 MMBtu of energy savings were recommended at the 32 glass-manufacturing facilities as a result of these energy-efficiency measures.

28.5.2 Plastics Manufacturing

Energy assessment at a leading plastics manufacturer done by Industrial Assessment Center at West Virginia University has helped the company save nearly \$100,000 per year in energy costs. The company is one of the largest plastic-packaging specialists in Europe and is expanding into the U.S. market. The plant manufactures injection-molded, rigid

containers with open tops. The facility measures 187,000 square feet in size and operates continuously, 7 days per week. Energy costs before the implementation of energy-efficiency measures at the plant totaled approximately \$760,000 per year, most of which was for electricity and the remainder for natural gas. Of the total 12 opportunities found feasible after study by assessment team, 6 were implemented at the manufacturing plant within first year. The implemented energy efficiency measures are briefly listed here. It was found that some bare surfaces of molding machines were radiating significant energy due to lack of insulation. However, by insulating these surfaces, the machines' heaters will operate less frequently, which will reduce energy consumption. USDOE-developed MotorMaster+ software was suggested to be used for motor management system. This software helped the company in evaluating economic decisions about buying new premium efficiency motors and rewinding or replacing a motor. Compressed air is used significantly in the plant. To help the company improve compressed air system energy efficiency, the assessment team suggested that the company reduce the compressor pressure to a safe minimum required by the system, repair compressed air leaks, and install engineered nozzles to reduce air consumption. As a result of the energy efficiency study and recommendations made by assessment team, the company is able to save 2.3 million kWh or 7950 MMBtu annually. This translates into significant amount of energy costs savings of nearly \$100,000 (Department of Energy, 2005c).

28.5.3 Metals Manufacturing

An energy-efficiency study carried out at a leading steel manufacturer in West Virginia has helped the company survive the market slowdown. The company recycles scrap steel from adjacent areas to produce steel sections, channels, and structural beams that are used in fabrication of frames, grousers, and welded frames for heavy equipments. The plant is approximately 40 acres in size and has been in operation since 1906. The plant operates approximately 8,160 h annually. The energy consumption of the plant before energy assessment was 1,216,753 MMBtu/year, or \$10,029,682/year. The assessment team found the following feasible energy-efficiency measures at the time of assessment: "ladling preheat energy reduction, hand-held cutting flame torches energy reduction, reduce infiltration in doors on furnace openings, preheat combustion air in ceramic recuperator, motor management, downsize motors, variable speed drives in several applications, cogged belt drives, improve power factor, insulate the furnaces and tundish dryer, synthetic lubricants, repair air leaks, outside air, lighting efficiency." The assessment recommendations made by assessment team helped the company save an estimated 139,843 MMBtu/year. The total energy cost savings were approximately \$1,034,547/year (Gopalakrishnan and Plummer, 2003).

28.5.4 Chemicals Manufacturing

One of the leading chemical manufacturers in the world undertook a plant-wide energy assessment with West Virginia University. The objectives were to identify energy-saving projects in the company's utilities area, including boilers and associated steam systems, compressor systems, and electrical motor-driven pump systems. The project evaluation process was unique in that the company has obtained very favorable rates for electricity. Even so, the company found strong economic justification for several projects that would reduce either electricity consumption or fossil fuel consumption. The plant produces more than 1.2 billion pounds of chemical products each year. These materials are used in cars,

appliances, furniture, home construction, steel manufacturing, food preparation, and many consumer products. The group operates around 350 companies worldwide and employs 117,000 workers. The energy-efficiency measures that were determined were replacing burner, condensate return, using VSDs on pumps, optimizing compressed air system, insulating steam system components, repairing steam leaks, adjusting the fuel/air ratio in one of the boilers, and repairing compressed gas leaks (air, NG, and nitrogen). The total cost savings were identified as 1,427,800 with an estimated implementation cost of \$937,200, which results in a simple payback of less than 8 months (Department of Energy, 2003).

28.6 CONCLUSION

Industrial energy efficiency is necessary for several reasons. The energy efficiency will reduce operating costs and hence lead to manufacturing industry becoming globally competitive and contribute to increased profitability and growth in terms of jobs and market share. Energy efficiency will make the nation more secure and economically strong as it reduces the consumption of fossil fuels, hence playing a role in controlling the cost of energy to have a positive impact on every facet of the society. Energy efficiency will also enable the protection of the environment in terms of reduction in emissions. Pure and simply put, energy conservation makes sense.

Manufacturing facilities have the goal of putting the product “out the door” on a daily basis to survive and be profitable and they often do not have enough time and resources to ascertain whether they are using the least amount of energy possible per unit of product manufactured. The programs of the U.S. DOE’s EERE and Industrial Technologies Program have gone a long way in helping industry and hence the nation to become energy efficient through a myriad of programs. Energy costs may or may not be a significant part of the product costs, hence not appearing in the top list of priorities of many companies. Rising fuel costs have changed some of that attitude. Aiding industry to save energy is a smart option that cannot simply be viewed as corporate welfare because the benefits are significant to the nation as a whole.

ACKNOWLEDGMENTS

The authors wish to thank the U.S. DOE’s Office of EERE and ITP program for supporting the Industrial Assessment Center (IAC) at West Virginia University since 1992. The development of this chapter by the director and the students of the IAC is a direct result of their experience gained at the IAC. We also thank the West Virginia Development Office’s Office of Energy Efficiency for providing support to conduct energy assessments within the state of West Virginia for manufacturing facilities that do not qualify for an IAC assessment.

29.1 OVERVIEW

In the pursuit of *sustainable production and consumption*—as the true value of natural resources and nonrenewable energy sources are being globally perceived—wastes can no longer be viewed as substances that are spendable. Research shows that wastes traditionally discharged into natural bodies as unwanted substances still possess some economical value. What is useless in one context can be useful in other. Importantly, pollution problems can be significantly reduced if wastes can be reused and recycled instead of being discharged to natural bodies. There is a radical shift in the perception of opportunities with industrial waste, and the current tone is to *conserve and cultivate* rather than *deploy and deplete*.

In many countries, the manufacturing industry is one of the largest polluting sectors, and every year enormous effort and financial resources are spent worldwide to deal with industrial waste. Therefore, from an industry perspective, a global change in the environmental perception has a profound significance. Industrial processes, management, goals, and ethics

are under pressure from a rising environmental awareness. There is an ever-increasing demand to externalize the environmental cost of industrial activities. Gradually, a stage is set to internalize the environmental cost, not by marginalizing environmental concerns but, contrarily, by increased environmental stewardship of products and processes.

In response, the global industry is embracing proactive methods that principally focus on energy conservation and waste minimization by the application of cleaner production techniques. These techniques are progressively conceived to meet the goals of environmental and economical sustainability of industries in a more dependable way. Use of traditional *end-of-pipe* treatment of waste alone is progressively becoming inadequate to satisfy the tightening requisites of modern environmental legislations. Industrial processes are also impacted by progressive phasing out or banning of several chemicals that have been regularly used in industries. These include ozone-depleting substances (ODS) and persistent organic pollutants (POPs), for example. Several national governments have pledged in various global multilateral environmental agreements to gradually eliminate such substances.

Open or global market regimes are bringing additional complications on top of environmental needs by putting up a stiff pricing competition. Over and above, the questions of sustainability are becoming more pressing as several global institutional buyers are including environmental criteria (such as ISO 14000 certification or others) in the procurement specification. This is driving industries to reevaluate their activities and associated costs, which also include waste treatment cost that covers roughly 15–30% of the total operational cost. The most assertive way is to reduce energy consumption and waste generation in the first place, which improves the overall process efficiency. Several case studies proved that such proactive approaches reduce the overall production cost and environmental liabilities. Moreover, being *greener* is also helping companies to market their products with institutional buyers and attract wider public attention.

With increasing popularity and attention to proactive methods, structured methodologies are being developed to systematically explore, analyze, and implement energy conservation and waste minimization or cleaner production programs in industries. In many industries, such techniques are now being used as one of the management tools to monitor and control process efficiency and environmental liabilities.

Traditionally, environmental impacts from industry are mainly assessed based on the type, characteristic, and volume of waste that it generates. However, recent analyses show that higher use of energy create significant environmental impacts when environmental issues related to energy production are taken into account (typical example is GHG emission). Therefore, energy use and waste generation in industries have been recognized as interlinked systems in the way that the more energy is used, the more pollution is produced, and the more waste generated, the more energy is required. As such, this chapter will refer to both waste and energy, beginning with waste minimization.

29.2 WASTE-MINIMIZATION PROGRAMS

All manufacturing processes will require raw materials and energy to produce a product (or an intermediary) and will generate waste in some form. Each manufacturing plant is unique in the type, characteristics, and quantity of waste generation. In other words, the manufacture of specific products creates particular waste quantity and quality. Thus, it is difficult to make generalizations regarding waste.

Since manufacturing is one of the largest single polluting sectors, several driving factors are compelling the manufacturing industries to change their outlook about waste management. Six major factors are described:

1. *Changing Perception of Industrial Pollution*: There has been a tremendous rise in awareness about industrial pollution in general public and institutions. This has forced governments to take steps to control pollution from industries.
2. *Changing Legislations*: Environmental laws and regulations for industries are tougher, and implementation is more rigorous. As a result, waste treatment technologies now require a stringent level of efficiency to meet the discharge standards.
3. *Changing Waste Treatment and Discharge Costs*: As a result of tightening legislation and discharge standards, waste treatment cost is continuously increasing.
4. *Changing Availability and Cost of Raw Material and Energy*: Greater demand of raw material and energy has tightened supply, causing their price to rise. This will definitely affect the cost of the finished products.
5. *Changing Traditional Markets and Trade Barriers*: The concept of protected markets is giving way to more competitive global markets. This is forcing industry to increase efficiency and reduce raw material and energy consumption. Buyers in many developed countries are progressively incorporating environmental specification (ISO 14000 certification, eco-labeling, green productivity) in their procurement processes to screen companies.
6. *Changing International Commitments*: More and more national and local governments and institutions are committing to international bilateral and multilateral agreements (such as UN-mediated multilateral environmental agreements) to curb pollution by reducing and eliminating known harmful substances such as ozone-depleting substances and persistent organic pollutants. Many of these substances are heavily used in manufacturing. This pressures industries to change their manufacturing processes and design new products.

As a result of these driving factors, many industries are taking new perspectives and strategies in handling their waste management issues, and are trying to resolve them in a more sustainable way. The current trend of waste management is to balance proactive methods with traditional reactive methods. The concept of *reactive method* is about treating the waste once it is generated, also called *end-of-pipe treatment*, while the *proactive method* includes energy and waste minimization, waste recycling and reuse, and cleaner production that reduces end-of-pipe waste. In brief, the main advantages of energy conservation and waste minimization are as follows:

- Raw material consumption can be reduced, which in turn reduces the product cost.
- Energy consumption can be reduced, thereby reducing specific energy required for the product.
- Process efficiency can be improved, increasing product yield and quality.
- Waste generation can be reduced, thereby reducing waste treatment and disposal cost.
- Waste materials can be segregated, leading to containment of hazardous and toxic waste, which in turn can improve workers' health and safety.

- By-products can be recovered from waste. In addition to recycle and reuse of waste, waste heat recovery and waste exchange (with other industries) can generate additional income.
- Increased environmental stewardship can lead to higher attention from institutional buyers and marketing of products.
- Investor confidence can be increased.

There are also some known barriers to implementing waste minimization:

- Some waste minimization or cleaner production techniques may involve significant capital investment.
- There may be obvious risk involved in implementing new systems.
- There is a lack of proper manpower and expertise in appropriate technology.
- There is a lack of information and awareness, especially among small and medium scale industries.
- Often there is a hesitation to change traditional ways of doing things.

The response of an industry will largely depend on several factors:

- nature of the industrial process,
- size and structure of the firm,
- technology and information available to the company,
- economics of prevention,
- attitude of the government to control industrial pollution through legislations, incentives, and penalties.

29.3 WASTE-MINIMIZATION CYCLE

Typically, a development cycle of industrial waste minimization programs comprises six phases: inception, audit, analysis, design and development, implementation, and evaluation, as illustrated in Figure 29.1. The overall goal of waste reduction and cleaner production program is to critically investigate, evaluate, design, and implement such environmentally benign processes and process improvements that would minimize consumption of resources, and energy and reduce waste generation in order to reduce adverse environmental impacts and effect in overall economic benefits.

These six phases can be discussed in more detail

1. *Inception Phase:* This phase comprises setting up the goals, commitments, methodologies, task force, time frame, and budget for the project. Such goals should be quantifiable, measurable, achievable, and usable to measure the success or failure of any waste minimization or cleaner production program in real terms. Senior management plays a key role in setting up the project framework, resources, and the project team.
2. *Audit Phase:* In the audit phase, the relevant factory processes include management processes and waste treatment processes. These processes are thoroughly

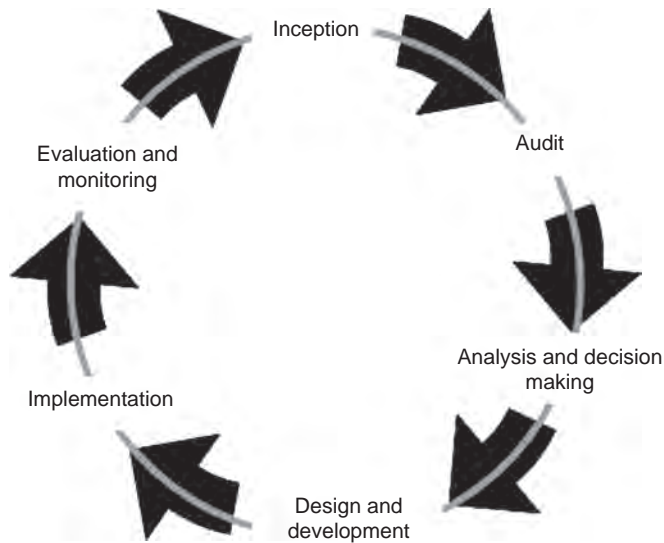

FIGURE 29.1 Typical waste minimization and cleaner production cycle.

investigated to obtain a complete balance sheet of the raw material and energy input and output, including waste. Over and above collecting and compiling all facts and figures, the audit exercise should recommend energy and waste minimization options to attain the desired goals of the program that could be carried to the detail analysis phase. If possible, preliminary technical and economical analysis may also be carried out to prioritize the options.

3. *Analysis Phase:* The analysis phase starts with detailed analysis of the findings and recommendation from the audit phase to explore the various opportunities and risks associated with the various options. It also explores further possibilities. This phase ends with making decisions on which options to be pursued and which to be dropped.
4. *Design and Development Phase:* The design and development phase starts with setting up the framework of design, development, and implementation of selected options. This would require planning of all actions. It is a good idea to implement different waste minimization and cleaner production improvements in stages to reduce impacts from introducing new process and process modifications. At this stage, process changes and new processes are designed and procured, and all preparatory works for implementation are undertaken.
5. *Implementation Phase:* In the implementation phase, processes and process modifications are installed and integrated to the existing system, commissioned, and put into operation. All operators and workers are trained for the changes in the process and new processes.
6. *Evaluation Phase:* This phase continues after the changes or new systems are fully integrated into the normal production processes. In this phase, the actual results from the process modifications are monitored, evaluated, and compared to that originally conceived. The cost of such monitoring is normally included in routine quality assurance/quality control activities.

This chapter deals with the audit phase. It discusses different aspects of waste and energy audit systems. The scope of such discussions has been limited to waste and energy audits within a typical manufacturing industry. For the purpose of this chapter, industry would be treated in general, with specific examples from different manufacturing sectors. The methodologies described here would generally apply to most manufacturing sectors. Some modification to the described methodologies would be necessary, depending on specific activities undertaken in the industry. Such modifications are left for the industry professionals to work out according to the requirements.

29.4 WASTE AUDITING

Once a waste-minimization program is set to be undertaken, the physical work starts with a series of detailed surveys of ongoing activities inside the industry, starting from raw material entering the premises to finished products and by-products (including wastes). These audits can be termed as *waste audits* or *waste-minimization audits*. The principal intent of such audits is to critically assess various inputs, processes and outputs to find methods and practices for minimizing waste and reduce the resource consumption in a more sustainable environmentally benign way. Traditionally, industrial waste audits do not include examination of the design of the product itself but investigate all activities of the production processes and opportunities of waste recycling/reuse, including waste treatment systems. Other terminologies may be used such as pollution prevention audit, eco audit, or green audit that essentially focus on some of the common objectives of preventive approaches.

The phases of a typical waste audit process are illustrated in Figure 29.2. Note that an energy audit process can also be divided into similar phases. The rest of the chapter discusses each of these steps in detail with illustrations, examples, and workouts.

29.4.1 Phase I: Preparatory Work for a Waste Audit

Preparatory work for a waste audit consists of three main steps:

1. getting the management and staff involved in the program,
2. forming an audit team and appointing a team leader,
3. planning the audit exercise.

Once a waste minimization program is begun, its time to provide the program with personnel, technical, and financial resources. The first step is to involve stakeholders in the program to get management and staff involved directly or indirectly in the program. This should be mainly done by one of the core management groups who would ultimately be responsible for managing the overall pollution prevention program. Normally, the production management or the environmental management group has the responsibility to execute such programs. Although all stakeholders can be involved in this process, more emphasis should be given on internal stakeholders such as the management, supervisors, and workers in taking up the initiative.

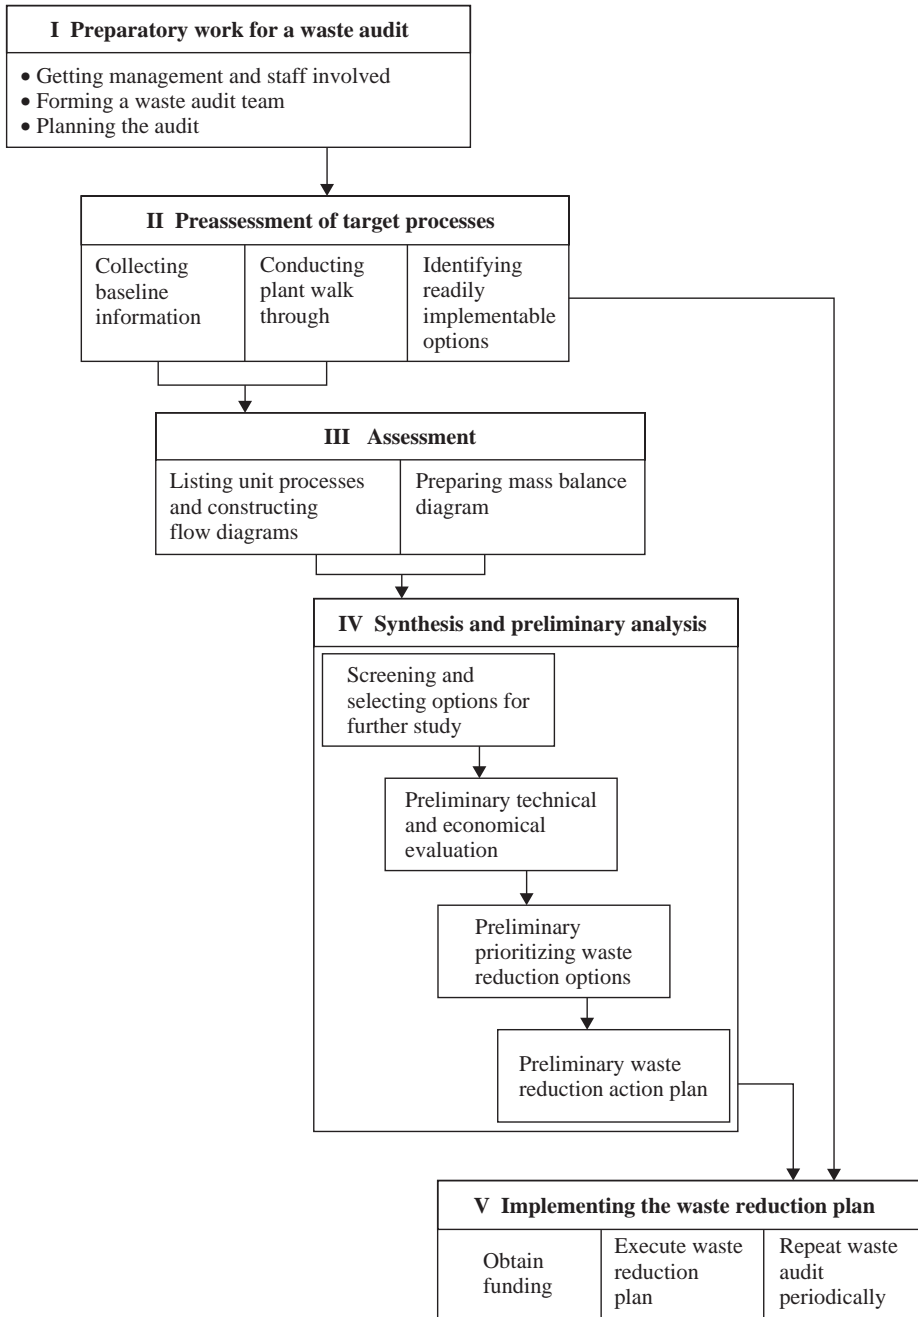

FIGURE 29.2 Steps of waste audit methodology.

29.4.1.1 *Getting Management and Staff Involved* Commitment from different management groups is a decisive factor in the success of a pollution prevention program. Management representatives from all relevant departments should be involved in the program. In a typical manufacturing industry, such departments may include the following:

- executive management (typically CEO or a deputy),
- product development and design (if present),
- production,
- procurement and inventory control,
- operation and maintenance,
- environmental,
- marketing,
- finance,
- quality control.

As the management staff would be supposedly aware of the environmental concerns and directly related to the welfare of the company, less effort would probably be required to motivate them for voluntary participation. However, it has to be confirmed that during the whole tenure of the program there is a high level of cooperation and support, even if such a program may cause short-term disruption to normal activities.

Involvement of the supervisors and workers is another key factor in the success of such programs. They have the hands-on involvement with each of the individual activities of the factory. In order to make the best use of their day-to-day experience with the machineries, processes, and a myriad of issues with the factory processes, audit exercise should be carried out with their full involvement and support. Typically, the barrier to such an involvement is fear on the part of certain supervisors and workers that a waste audit will expose inefficiencies that lead to job cuts. In order to overcome such a barrier, supervisors and workers should be assured of their job security, barring evidence of Fraud or sabotage.

The exercise can also be used as an opportunity to create more employee awareness about the environmental issues and energy and waste-minimization and cleaner-production program. Rewards in the form of bonuses, prizes, or acknowledgment would motivate employees to voluntarily participate in the program. There are several common ways of raising interest and motivation that could benefit the program (Box 29.1).

29.4.1.2 *Formation of an Audit Team* One of the key requirements of an audit exercise is to form a proper and balanced audit team that would be responsible for all subsequent audit works. The team is normally formed by the direction of the responsible management group, in discussion with senior management and all other management groups. If required, expert advice from external consultant may be sought at this stage.

Waste audit is an interdisciplinary activity. Therefore, the team should be formed with diversified expertise from representative groups or departments, which will have major contribution and interest in the program. Usually, an audit team is a subset of the project

BOX 29.1 COMMON WAYS TO RAISE INTEREST IN WASTE AND ENERGY MINIMIZATION PROGRAM

- Use posters or banners to inform the staff about the pollution scenario and the requirements, benefits, objectives, and goals of the upcoming waste minimization and cleaner production program.
- Publicize the upcoming audit exercise.
- Provide some prominent identification mark (such as badges) to the members of the audit team and also provide them some special privileges such as free access to any place or information during the audit program.
- Organize “Environment Week,” with programs such as speeches, videos, skits, or tree planting.
- Offer cash prizes/monetary incentives for the staff members who come up with innovative idea leading to cleaner production.
- Offer incentives for the machine operators/staff for quality production with minimum resources.
- Hold inter-departmental competition for waste minimization.
- Share the financial gains due to waste/energy minimization programs.

team but may include various other personnel whose contribution may be useful. For example, an audit team can be formed from these groups:

- environmental managers,
- plant managers,
- process or operation and maintenance engineers,
- occupational health and safety officers,
- supervisors and operators,
- laboratory technicians.

The team should appoint a team leader who will lead the audit team and coordinate the activities of all other team members. The plant manager or the environmental manager can be prospective candidates for team leader. It is recommended that a balanced audit team should be made up of three to six persons, including the team leader. This recommendation is based on typical industry structures but may be varied. In practice, the selection of the team leader and composition of the audit team will depend on the nature of the processes in the industry, scope of audit, and the scale of the industry.

Each of the audit team members should be aware of the goals and objectives of the overall energy and waste minimization program and should be able to contribute to it. The team leader should delegate duties to each of the members, depending on strength and capabilities, and should monitor them throughout auditing phase. Members of the audit team should be relieved from their routine activities during the audit exercise.

The requirement of external consultants or experts in the team would depend on the objectives of the program and complexity of the industrial processes. If the goals are to explore simple and readily applicable waste minimization or cleaner production

opportunities (e.g., reduction in general water and electricity consumption), plant engineers and supervisors may be sufficient for auditing purposes. However, if the requirement is complex, such as performance of cryogenic units or distillation columns, experts in these technologies may be required. In these cases, hiring an external consultant may be justified.

29.4.1.3 Planning the Audit Exercise Before the actual audit exercise is undertaken, a substantial amount of planning work is to be done in order to carry out the audit within time and budget and least interference to normal activities of the plant. Such planning works would mainly include the following:

- define the scope of the waste audit,
- develop an audit program,
- prepare specific workplan and checklists,
- develop uniform reporting procedures,
- inform all departments about upcoming audit programs.

However, depending on the specific need of the program, additional works may be added to the list.

Defining Scope of the Waste Audit Determining the scope of an audit is one of the fundamental steps before taking up the actual auditing process. Scope should be defined according to the goals and objectives of the waste minimization program. Goals should be quantitative, realistic, and achievable. Compliance with a set of legislative requisites within a fixed time period could be the prime goal in some instances. In other instances, there could be the need to reduce (by a certain percentage) the operation of waste treatment cost by reducing the quantity and strength of some priority pollutants (e.g., chromium, copper, or organic pollutants such as phenols, cyanides). In some other cases, the goal may be to reduce consumption of chemicals (by certain tonnes per unit product) by improving certain processes. Waste audits can also focus on specific objectives such as improving the general environmental management system in environmental management system audits, improving operational health and safety by reducing use of toxic chemicals in operational health and safety audits, or total environmental risk audits, and so forth. In every case, there should be some target sectors or processes, which have to be closely scrutinized. Identification of these target processes is crucial in defining the scope. The most common target processes of waste or energy audits are as follows:

- *Production Processes:* All unit production processes in the plant need to be audited to check for process inputs, outputs, operating conditions and controls, and process efficiency.
- *Inventory Processes:* Inventory processes such as storage and handling of chemicals, machine parts, and other accessories need to be evaluated to check loss of material while handling or storage, loss of chemicals that have expired, and so on.
- *Housekeeping Processes:* Housekeeping practices should be audited in order to check various losses during cleaning, arranging, and various types of maintenance practices. Better housekeeping practices can reduce leaks, spills, dragout, losses in rinsing, cleaning, and so on.

- *Waste Treatment Processes:* All waste treatment processes such as effluent treatment plants, gas treatment, and dust filters should be audited to determine treatment efficiency, operating conditions and controls, and so on.
- *Packaging Processes:* Packaging sometimes requires specialized systems that can generate wastes. Therefore, such processes must also be audited if waste generation or energy consumption is high in such processes.

Unless the scope of the waste audit is positioned to achieve the overall goals of the program, many efforts can go waste. Table 29.1 shows how some of the common objectives are related to the target processes. Defining anything more than what is required or less may result in a poor outcome. For example, if the objective of a waste-minimization project is to reduce water consumption in a factory, only those processes/activities (target processes) that are using significant amount of water need to be checked. In this case, it is not particularly useful to audit inventory processes or final packaging systems that consume no water or very little water. However, when the goals are to explore opportunities of electricity reduction, probably all activities need to be audited, as there are practically no areas in a factory where electricity is not consumed. But in the first instance, it may be better to audit those sections where large amounts of electricity are consumed. The scope can thus be much wider compared with water-reduction programs.

Defining a balanced scope is not generally a one-step procedure. Starting with preliminary scope, the audit team may modify the scope as the audit is undertaken and new information emerges, which may need extension of scope to certain target processes and elimination of certain other sectors that may not significantly contribute to the overall objective. The scope should also be subjected to debate by all team members of the program to arrive at a consensus.

Develop an Audit Program Similar to all other projects, an audit exercise should stick to a program and plan to avoid any overrun. The audit team should develop a series of programs for auditing each of the target processes and timeframe for each of the activities.

TABLE 29.1 Audit of Target Processes as per Objectives of Waste-minimization Program

Main Objective	Target Processes
Legislative compliance	Probably all processes, with more emphasis on production and waste treatment processes
Reduction of toxic and hazardous wastes	Production and inventory processes where hazardous and toxic chemicals are used. Special attention to be given on transport, handling, storage, and use of such chemicals, as well as treatment and disposal of the hazardous wastes
Operational health and safety Improvement	Special attention to production processes, especially with high temperature, high voltage applications, and so on. Attention to be given to handling, storage, and use of hazardous and toxic chemicals. Housekeeping processes need to be checked as well
Compliance audit	Mainly the effluent treatment units only, with emphasis to check if they are meeting the required discharge standards

Generally, for a complete waste and energy reduction audit, the following time frames can be used for manufacturing plants:

- small scale (less than 50 workers): 3–4 weeks,
- medium scale (50–100 workers): 4–6 weeks,
- large scale (more than 100 workers): 6–10 weeks.

This timeframe is generalized; several factors such as the number of steps in the production process, the degree of complexity, the level of automation, the quantity, and characteristics of different feedstock used should be considered for determining the timeframe. In the absence of any specific condition for the program, there are two ways of setting up an audit program:

1. follow the material flow path through the industry,
2. audit target processes according to the significance in terms of waste reduction.

Both systems have some merits. For example, following the material flow helps keep good track of several raw material as these are transformed into products and by-products, which gives a complete account of material inputs and outputs. While auditing according to priority of target processes, allow a thorough investigation of major target processes that can identify more waste-minimization opportunities. Development of program is a dynamic activity and can be modified as more and more audit exercises are undertaken and new clues evolve.

Audit timing and frequency are important factors in planning audit exercises. Timing and frequency can be fixed, depending on the following:

- type (continuous, batch, etc.) of the production process,
- number of parameters to be audited,
- scale of production,
- accuracy of audited information required.

Auditing can be scheduled during peak production hours or uniformly throughout a complete production cycle, depending on the nature of the production process. For example, in a typical batch production process (such as textile dyeing), quantity of wastewater discharged at the end of each cycle need to be audited, whereas in a continuous production process (such as pulp processing in a pulp and paper industry), discharge of wastewater may be monitored at 4-h intervals. Care should be taken not to disrupt the normal factory processes.

It is recommended that the major target processes are audited more than once, typically three times, to obtain good representative results and to ensure repeatability of the information, while less important sectors can be audited once. Quality and reliability of an audit exercise would very much depend on the frequency of audit on each process, as each time a process is studied, there is an increased chance of getting a new clue.

Prepare Specific Workplan and Checklists Each team member should prepare his or her own specific workplan and checklists, depending on the nature of the activities to be audited. Preparing workplan and checklists would enable auditors to focus on key activities to

be audited and collect all necessary information for those processes and activities. Some understanding of the processes would be required to prepare the workplan and checklists.

Develop Uniform Reporting Procedures The audit report is the final product from the audit phase. All subsequent activities would very much depend on the audit report, and its importance in the program is substantial. It is, therefore, recommended that the audit report should be well planned and easily comprehensible, and should contain all the information that may be required during the subsequent phases. The contents of the report should be determined based on the objectives of the program. A typical table of contents for a report is given in Box 29.2. Depending on the requirement, some of the sections can be excluded. However, important sections should be retained in a good audit report.

Inform All Departments about Upcoming Audit Programs Once the audit program is finalized, the audit team should notify all the respective departments about the upcoming audit. This would enable the departments to be prepared for the audit. The program should be advertised at suitable locations throughout the factory to remind the supervisors and workers about the audit schedule.

BOX 29.2 TABLE OF CONTENTS FOR A TYPICAL WASTE AUDIT REPORT

- title page,
- disclaimer, if any (disclaiming responsibility by the publisher for data or views expressed),
- table of contents,
- executive summary (summarizing the complete audit exercise in the industry),
- problem statement, objectives, and priorities,
- adopted approach and reasoning,
- process layout, description, and observations,
- sources and quantities of pollution load generated,
- existing treatment facilities and additional requirements,
- observations on proposed treatment systems,
- integrated pollution prevention strategy,
- generation of options, screening,
- option grouping and prioritization,
- identification of candidate systems,
- system evaluation criteria,
- calculations,
- method and results of system evaluation,
- recommendations,
- implementation strategy,
- suggestions to the management,
- summary and observations,
- appendices (tables, graphs, assumptions, and calculations).

29.4.2 Phase II: Preassessment of Target Processes

The purpose of the preassessment is to collect all information on the target processes that may be required in detailed analysis

- collect baseline information,
- conduct a plant walk-through,
- identify immediate implementable options.

29.4.2.1 Collection of Baseline Information Collection and compiling of information is one of the major tasks and purposes of waste auditing. While information on target processes would be of primary value, practical experience shows that various other information may be useful. As such, the scope of data collection can range over the entire cross-section of the factory:

- *Organizational Data:* Organizational chart, factory layout, and site plan are included. Also collect information about the surrounding area indicating topography, water bodies, hydrology, agricultural areas, and human settlements.
- *Material and Product Data:* Data include specifications of feedstock, process water, product and by-products with composition, instruction on usage and discharge, material safety data sheets, and usable and storage life. Information on quality assurance and quality control of feedstock, process water, products, and by-products must also be collected.
- *Raw Material and Logistic Consumption Data:* Feedstock, energy, and water consumption records are important. Possible source of records of feedstock consumption can be available from stores and accounts department. Water usage can be obtained from water meters or bills, and energy usage from energy bills.
- *Process Data:* Collect process flow diagrams, block diagrams, material balance diagrams, control and operational logic diagrams and instructions, manufacturer's data on each machine and process, and maintenance plans and records.
- *Environmental Data:* Collect data on air emission, solid waste generation and effluent from different machineries, including waste treatment systems, environmental directives, and licenses.
- *Management Data:* It is important to document the number of staff, their position and responsibilities, performance records, administrative instruction, occupational and safety procedures, quality assurance, and quality control procedures.
- *Financial Data:* Product, utility and raw material cost, cost of waste treatment, operating and maintenance cost are available as part of the company's financial statements.
- *Industry Data:* If possible, gather all of the data for industries of similar nature. Such information, though difficult to obtain, would however allow comparison with other plants that may help in defining realistic targets and goals.

All the audit members should be well familiar with the information that would allow them to objectively carry out the audit. To an experienced auditor, even scanning through such information can also give some clue about the opportunities, which areas need to be audited in detail, and room to improve the audit exercise. All information should be properly

preserved and sources of such information should be noted to check the reliability at a later date.

All information should be checked for underlying data quality in terms of correctness and repeatability. If possible, historical data should be gathered over a period of time (suggested 2–3 years' records) and the process of data collection should be continued during the entire audit phase on a monthly or quarterly basis. It is suggested that statistical analysis be performed on the collected data to ensure quality of data before these are used for analysis purpose.

29.4.2.2 Plant Walk-through Survey A thorough walk-through the plant is an essential part of the preassessment phase. It is recommended that all team members be involved in such audit exercise, which should generally be carried out over few days, with one or two sections covered in each day. Moreover, the audit team should be accompanied by the responsible section manager, engineer, or supervisor who is completely aware of each activity in the respective section. All types of management and technical information should be available during such surveys for the audit team to check. There are several benefits of such exercise:

- It is quite likely (especially in the case of large industries) that the members of the audit team may not be very familiar with the different activities carried out in each section other than their own. Therefore, this exercise would give them a chance to get conversant with many more activities and processes.
- It can reveal some obvious waste-minimization or cleaner-production options that may not need a detailed assessment to work out the recommendation. A common sense approach, or simple calculations with a lesser degree of accuracy or thumb rule estimates, may be sufficient for arriving at the conclusion. For instance, in situations where the steam pipes are not insulated or valves are leaking, there is no need to carry out a detailed assessment of energy or steam losses to arrive at the recommendation to insulate the steam pipes or repair the valves.
- By eliminating such obvious options, the auditors can narrow down the scope to those areas that require detailed assessment. This frees up some resources, and the auditors can then concentrate on more intriguing issues.
- With a balanced team of auditors, personnel from other sections or departments can more critically observe activities of another department. This can give rise to lateral thinking, and more avenues for improvement can be explored.

The best strategy for the walk-through is to follow the material flow path through the industry—from the storage of raw material, through various production processes, until it is converted to the final product and stored, in absence of any other plan. During the walk-through exercise, each member of the audit team should take detailed note of all the activities, facts, and figures; and any other information that may be useful at a later stage. It is suggested that even trivial observations are noted, as these can form some clue at a later stage. It is preferred that the auditors should prepare their own sketches, schematic arrangements, material flow diagram, block diagrams, and site plans during this walk-through exercise. Even if some process diagrams are already present, often minor changes are carried out in the plant during operations. Notes of such changes should be taken. At the end, team members should prepare their own report of the plant walk-through.

29.4.2.3 Identification of Readily Implementable Options After carrying out the plant walk-through and making detailed notes, the audit team must discuss the various observations made and should identify a number of simple and obvious measures to reduce waste generation. Such options should be simple, quickly implementable, and inexpensive. Significant waste reductions can often be achieved by such options, which are based on improved operation, better handling, and tightening up of housekeeping practices. For example, simple measures such as attending to leaking hoses or installing automatic level controllers may lead to significant water savings.

Segregation of waste is arguably one of the numerous measures that can effectively lead to waste reduction. It is the most central of such options, and is a universal issue that needs to be addressed. Segregation of waste can offer enhanced opportunities for recycling and reuse with resultant savings in raw material costs, at the same time reducing treatment costs. Concentrated simple wastes are more likely to be of value than dilute or complex wastes. The waste collection and storage facilities should be reviewed to determine if waste segregation is possible.

Such options are implemented as soon as possible without waiting for the final recommendations. Typically, implementation of such options should be completed within 2–3 weeks. If implemented, the performance and impacts of the changes should be closely monitored and included in the audit report. All the modifications made should be noted, and these will have to be considered in the later stage while developing the detailed process flow diagram.

It is expected that at the end of the preassessment phase, the audit team is

- organized and aware of detailed scope,
- aware of all target process layouts for further audit,
- aware of all unit operations in each of the target processes,
- aware of sources of waste and their causes.

At the end of the preassessment, the plant personnel should be well informed of audit purposes. Resources should be secured, and readily implemented waste-reduction measures should be identified and, if possible, implemented.

29.4.3 Phase III: Assessment

This phase can be broadly divided into two steps:

1. list the unit processes and constructing flow diagrams,
2. prepare a mass balance diagram.

29.4.3.1 Listing of Unit Operations and Constructing Process Flow Diagrams This step is essential for an audit program, as it gives a detailed insight into the production operations/process vis-à-vis sources of waste generation and hence enables identification of avenues for better operating practices and waste reduction.

To develop a good representative block process diagram, the audit team should undertake a detailed walk-through in the production units and utility areas, in order to gain understanding of all the processing operations and their interrelationships. The production or plant staff should be interviewed to know about the actual operating controls,

parameters, and issues. Only after conducting a detailed walk-through and interviews with the production staff, should the audit team compile the required baseline data.

By connecting the individual unit operations in the form of a block diagram and highlighting the flow of materials, a process flow diagram can then be prepared. All the information related for example to raw materials, products/by-products, energy, water inputs, waste discharged, material and energy flows, motion, and time should be compiled during this preassessment stage and should be presented on the block diagram.

The input and output information for each unit operation should be summarized in standard units by reference to the process flow diagram. Standardized color coding may be used to represent, say, raw material input by a black line, products by blue line, wastes by red lines, and recycled stream by green lines. Intermittent operations such as cleaning, makeup, or tank dumping may be distinguished by using broken lines to link the boxes. Similar notation may be used to distinguish batch and continuous discharges.

29.4.3.2 Material Balance: Process Inputs and Outputs In the material balance exercise, a detailed account of the process inputs and outputs is made to identify the problem areas and thus the need for improvement. Material balance is important for any waste-minimization project to identify and quantify previously unknown losses or emissions. Material balance is also useful for estimating the costs of additional installations and/or modifications.

By definition, the material balance includes materials entering and leaving a process. Inputs to a process or a unit operation may include raw materials, chemicals, water, air, and energy. Outputs include primary product, by-products, rejects, wastewater, gaseous wastes, liquid, and solid wastes that need to be stored sent off-site for disposal and reusable or recyclable wastes (Fig. 29.3). In its simplest form, a material balance is drawn up according to the mass conservation principle:

$$\text{Mass in} = \text{Mass out} + \text{Generation} - \text{Consumption} - \text{Accumulation}$$

If no chemical reactions occur and the process progresses in a steady state, the material balance gets simplified to

$$\begin{aligned}\text{Mass in} &= \text{Mass out} \\ \text{Water in} &= \text{Water out} + \text{losses (evaporation, spills, etc.)}\end{aligned}$$

Sources of Information for Material Balance There are many sources of information in establishing material balances for the various unit operations within the plant. Data may be obtained from sample analysis and measurements of raw input materials, raw material purchase records, material and emission inventories, equipment cleaning and validation procedures, batch composition records, product specifications, operating logs, standard operating procedures, and manuals.

Material balances are easier, more meaningful, and more accurate when they are done for individual production units, operations, or production processes. For this reason, it is important to define the material balance envelope or boundary limit accurately, in addition to the tie compound. Ideally, a more accurate balance should be established for the unit operation that is more critical from the waste-generation and reduction point of view, and a less accurate balance could be established for other processes.

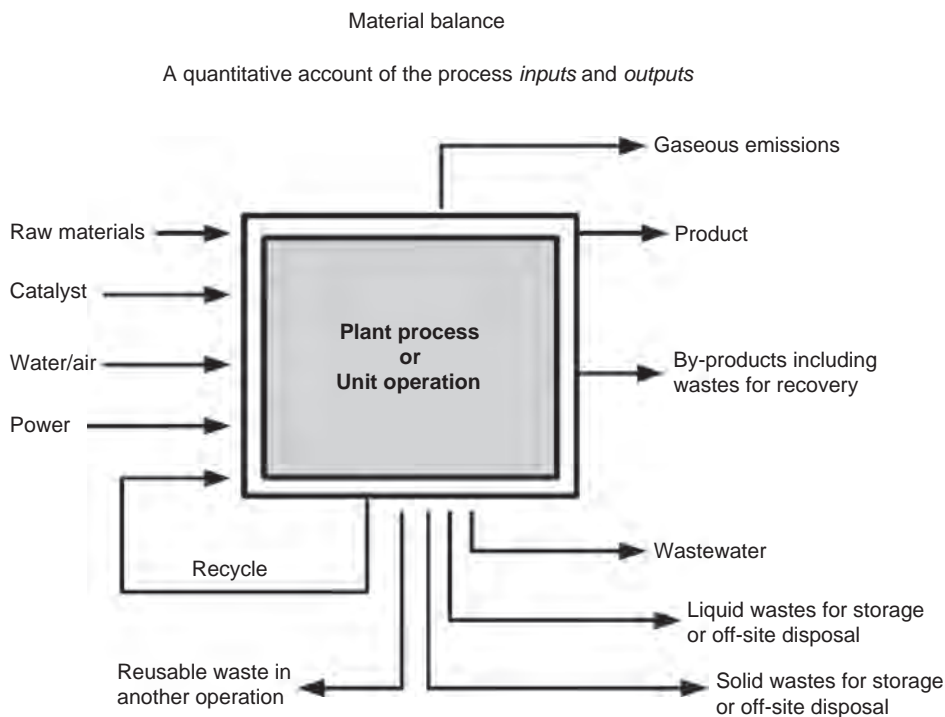

FIGURE 29.3 Schematic representation of a material balance sheet.

Although it is not possible to lay precise and complete guidelines for establishing the material balance, the following guidelines might be useful:

- In the case of an extensive and complex production system, it is better to first draw up the material balance for the whole system (or even the entire production facility as such), and then concentrate on individual operations.
- When splitting up or desegregating the total system, choose the most simple, individual subsystems that are critical from the waste reduction point of view.
- Choose the material balance envelope in such a way that the number of streams entering and leaving the process is the smallest possible.
- Always choose recycle streams within the envelope to start with.

For complex waste-minimization audit, it might be desirable first to make a preliminary or draft material balance and in the second step to evaluate and refine it. However, in case of simple audit for small plants, the steps can be merged into one.

Selection of Priority Unit Operation Although the material balance should be set up for all the unit operations, the unit operation most important from the point of view of waste generation must be identified and efforts are concentrated for that particular unit operation. This can be done by professional judgment and technical know-how of the audit team and specifically the production personnel.

Selection of Tie Compounds A tie compound is the parameter (or substance) for which the material balance is established around a unit operation or a process. It is important to select an appropriate tie compound. Criteria for selecting the tie compound could be

- expensive raw material/intermediate,
- material common in most processing stages,
- substance of hazardous nature,
- substance/compound easy to measure/estimate.

A simple example of a tie compound could be water to account for most wet operations. Establishing water balance for the processes using substantial amount of water can often provide useful clues for cleaner production. In practical situations, more specific tie compounds (e.g., nickel or zinc in electroplating shops or dyestuff in textile processing) would be ideal. Another good example could be that of chromium in leather tanning.

Chemical oxygen demand (COD) is another useful tie parameter that sharpens the material balance exercise, especially to link the production areas with the effluent treatment plant. The audit team can estimate the contribution of each process department in terms of total COD load in kilogram per day, knowing the volume of wastewater and the COD discharged by each department and cross checking it with the COD load observed at the treatment facilities.

One need not be very particular over the accuracy (of the order of 99%) of the material balance. In practice, such high accuracies are rarely achievable. Material balance within the tolerance range of 10% should generally be acceptable. However, if the tie compound for material balance is hazardous, a higher order of accuracy should be targeted.

Steps for Preparing a Material Balance There is a logical series of steps for preparing a constructive material balance:

1. *Determine Inputs:* The inputs to the process and to each unit operation need to be quantified. As a first step toward quantifying raw material usage, purchasing records should be examined; this readily gives an idea of the quantities involved. The raw materials purchases and storage and handling should be recorded in a table format in order to derive the net input to the process.

Water is frequently used in the production process, for cooling, gas scrubbing, washouts, rinsing, and steam cleaning. The water usage needs to be accurately quantified as an input. Also, some unit operations may receive recycled material from other unit operations. These also represent an input. Hence, water and recycled materials need special attention, and therefore steps 1A and 1B describe how to evaluate these two factors.

- 1A. *Record Water Usage:* The use of water, other than for a process reaction, should be covered in all cleaner production programs. The use of water for washing, rinsing, and cooling in process and in utility operations is often overlooked, although it represents an area where effective waste reduction can frequently be achieved simply and cheaply.

- 1B. *Measure Current Levels of Material Recycling:* Some materials may be transferred from one unit to another (e.g., reuse of the final rinse in a soft drink bottle washing plant as the initial rinse); either directly or after some modifications/treatment. If recycled materials are not properly documented,

double counting may occur in the material balance, particularly at the process or complete plant level; that is, a material will be quantified as an output from one process and as an input to another. Proper attention must be paid to this issue, and care must be taken to avoid any discrepancies.

2. *Quantifying Outputs:* To calculate the second half of the material balance, the outputs from unit operations and the process as a whole need to be quantified. Outputs include primary product, by-products, wastewater, gaseous wastes (emissions to atmosphere), and liquid and solid wastes that need to be stored and/or sent off-site for disposal and reusable or recyclable wastes. It is important to identify appropriate units of measurement.

If the product is sent off-site for sale, then the amount produced is likely to be documented in company records. However, if the product is an intermediate to be input to another process or unit operation, then the output may not be so easy to quantify. Production rates will have to be measured over a period of time. Similarly, the quantification of any by-products may require field measurement.

- 2A. *Account for Wastewater:* On many sites, significant quantities of both clean and contaminated water are discharged to sewers or to a watercourse. In many cases, this wastewater has environmental implications and incurs treatment costs. In addition, wastewater may wash out valuable unused raw materials from the process areas. Therefore, it is extremely important to know how much wastewater is going down the drain and what the wastewater contains. The wastewater flow, from each unit operation as well as from the entire process, must be quantified, sampled, and analyzed.

- 2B. *Measure Gaseous Emissions:* To arrive at an accurate material balance some quantification of gaseous emissions associated with the process is necessary. For example, a tea drier exhaust may carry fine particles of tea dust. Measurement in such cases calls for instruments such as thimble probe dry gas meter–vacuum pump assembly. In many instances, gaseous emissions carry some amount of hazardous materials also (such as VOCs). Expert assistance may be needed to determine the material/product loss through gaseous emissions.

3. *Prepare a Preliminary Material Balance:* A material balance is designed to provide better understanding of the inputs and outputs, especially waste, of a unit operation such that areas where information is inaccurate or lacking can be identified. The initial balance should be considered as a rough assessment that must be further refined and improved.

The units of measurement should be standardized (liter, ton or kilogram) on a per day, per year, or per batch basis. The measured values in standard units should be summarized by reference to the process flow diagram. It may be necessary to modify the process flow diagram following the in-depth study of the plant. It is highly desirable to carry out a water balance for all water inputs and outputs to and from unit operations, because water imbalances may indicate underlying problems such as leaks or spills. Similarly, a detailed material balance should be carried out for important tie compound, as agreed upon by the audit team during the planning phase.

4. *Evaluate and Refine Material Balance:* The individual and sum totals making up the material balance should be reviewed to determine information inaccuracies. Ideally, the input should equal the outputs, but in practice, this will rarely be the case. Some judgment will be required to determine what level of accuracy is acceptable. If there is a significant material imbalance, then further investigation is needed.

When constructing material balances, watch for factors that could overstate or understate waste streams. Sometimes, all or at least a few steps of material balance may need to be repeated a few times in order to refine the material balance. These may include quantification of a few input or output streams or even hunting for some material flows that might have been totally missed in the initial stage. Additional field sampling and analysis may also be required to be carried out in certain cases, and thus the data collected should again be organized and represented so as to establish an accurate material balance.

29.4.4 Phase IV: Synthesis and Preliminary Analysis

Phases I to II have covered planning and undertaking waste audit, resulting in the preparation of a material balance for each unit operation. Phase IV represents the interpretation of the material balance to identify process areas or components of concern. Figure 29.4 represents a material balance algorithm for the textile industry in establishing waste reduction options.

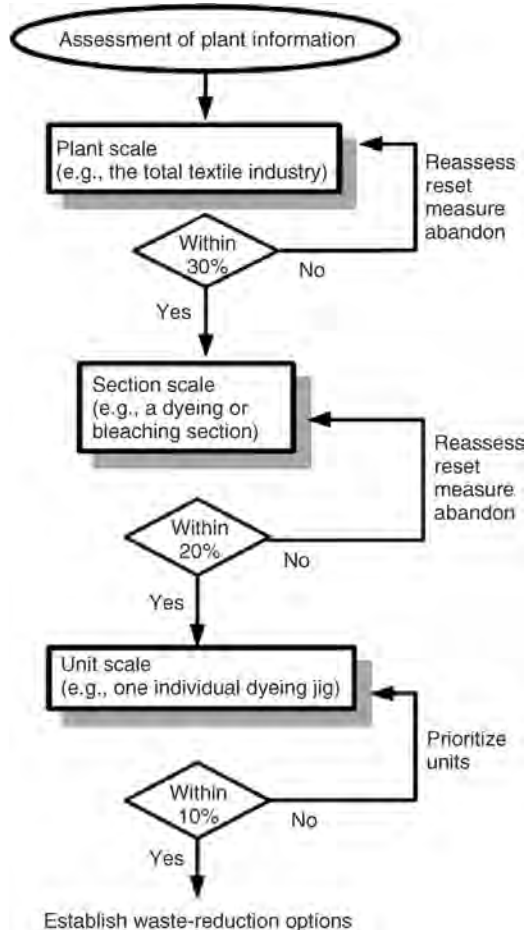

FIGURE 29.4 Material balance algorithm for textile industry.

To interpret a material balance, it is necessary to have an understanding of normal operating performance. Thus, a member of the audit team must have a good working knowledge of the process. To a trained eye, the material balance will indicate areas for concern and help to prioritize problem wastes. Using the material balance, major sources of waste may be identified, deviations from the norm in terms of waste production may be found, areas of unexplained losses may be determined, and operations that contribute to flows that exceed national or site discharge regulations may be pinpointed.

In this phase, several possible waste-reduction measures are identified that can be proceeded to the analysis phase. Different waste-minimization programs may require varying degrees of effort, time, and financial resources:

- obvious waste-reduction measures, including improvements in management techniques and housekeeping procedures that can be implemented cheaply and quickly,
- long-term measures involving process modifications or process substitutions to eliminate problem wastes.

29.4.4.1 Screening and Selecting Options for Further Study (Weighted Sum Method) For options that require numerical evaluation, the most commonly used tool is the *weighted sum method*. Screening and selection is recommended when a large number of options have to be considered. Only those options that have sufficient merits should be carried forward. The weighted sum method provides a means of quantifying the important criteria that affect waste management in a particular industry:

1. *Determine what criteria would be considered in evaluation of the options:* The higher degree of improvements achieve in the given criteria, the better is the result. For example, in a typical waste minimization program, such criteria can be
 - amount of reduction in waste quantity,
 - amount of reduction in raw material consumption,
 - amount of reduction in hazardous or toxic waste,
 - amount of improvement in health and safety condition,
 - ease of implementation,
 - cost of implementation,
 - amount of resource and time required.

These criteria should be determined in terms of meeting the overall waste-minimization objectives and goals. This should also take into consideration for various types of constraints that may be present. Judgment would be required to select the criteria.

2. *Once the Criteria Are Determined, Each Criterion Should Be Given A Weight:* The more important a criterion is, the higher its weight. Again, a fair amount of judgment is required to determine the weight for each criterion. Generally, a relative scale of 0–10 is used to allot weight. For example, if reduction in waste treatment and disposal costs is more important, while time of implementation is relatively less important, then the reduction in waste treatment costs is given a weight of 8, whereas the time of implementation is given a weight of 2 or 3.

3. *Each Option Is Then Rated for All the Criteria:* A scale of 0–10 could be used for rating. Marks are given according to the degree the criteria are satisfied (i.e., higher marks are given when the option fulfils or satisfies the criteria and low marks when the option does not suit the criteria).
4. *Each Rating (for the Option) Is Multiplied By the Corresponding Weight of the Criterion:* An option's overall rating is the sum of all the products of ratings times the weight of the criteria.

The options that carry higher marks would be carried for further analysis. Table 29.2 presents an option evaluation by weighted sum method.

29.4.4.2 Preliminary Technical and Economical Evaluation Once the options are screened and selected for further analysis, preliminary technical and economical evaluation may be required to set the priority of options and develop a preliminary action plan.

Technical Evaluation. The technical evaluation determines whether a proposed waste-minimization option will be technically feasible and achievable within the framework of existing constraints. A technical evaluation often begins with examining the impacts of the proposed option on production processes, production schedule, product quality, extra resource requirement, real estate requirement, operational feasibility, and safety. Several constraints such as disruption to normal production schedule, shutdowns, match of specifications (between the existing equipment and the new one), lack of technical knowledge, and trained manpower may be presented. Moreover, psychological resistance to changes may also be an issue. Therefore, it is recommended that all serious changes are first tested at a laboratory-scale and pilot scale. And, trial runs with the prototypes and test products are undertaken before the change is implemented and integrated to the actual production process. It is also suggested that engineers, supervisors, and operators are suitably trained for the change.

Waste-minimization options can also have some environmental impacts. During technical evaluation, the environmental effect of implementing the option needs to be checked. For example, if an option calls for recycling of rinse water, the effect of disposal of such water needs to be evaluated (as the concentration of solid in the recycled water would increase many times due to recycling), which may impact the receiving body.

Economic Evaluation. Economic feasibility is one of the most important criteria in determining the selection of an option. Unless forced by legislative requirement, there would be no cases where the economic merit of an option would be measured. Normally, each organization has its own economic criteria for selection of projects. However, three main criteria must be evaluated, irrespective of other criteria:

1. The capital, operation, and maintenance cost of the option.
2. The benefit that it would return over and above the existing system.
3. The resulting payback period.

The relationship among capital cost, payback period, and likely acceptance is given in Table 29.3. Payback period can be considered as *long* if it exceeds 2 years; *medium* if it is between 1 and 2 years; and *short* if less than 1 year for common waste minimization options.

TABLE 29.3 Relationship Between Capital Cost, Payback Period, and Likely Acceptance

Capital Cost	Payback Period	Likely Acceptance
High	Long	Low
High	Medium to short	Medium
Medium	Long	Medium
Medium	Medium	Medium
Medium	Short	Medium to high
Low	Long	Medium to high
Low	Medium	High
Low	Short	High

29.4.4.3 Preliminary Prioritizing Waste Reduction Options Once waste-minimization options are evaluated, they would need to be prioritized for further analysis, design, and implementation. A preliminary prioritization at the audit phase will expedite the process of analysis in the next phase. Prioritization can be done by weighted sum method, in absence of any special criteria (e.g., where some waste-minimization measures become mandatory due to legislative requirements, these can then be classed as high priority options, without further analysis). Some of the criteria that can be used to prioritize the options follow:

- technical ease in implementation,
- resource and time requirement,
- impacts on production schedule,
- short-term capital requirement,
- payback period.

29.4.4.4 Developing Preliminary Waste Reduction Action Plan Upon suggesting the priority, the audit report should also delineate a preliminary action plan for implementation. This can be represented as a regular bar chart or in any other form that is acceptable. In normal cases, the implementation sequence should follow the order of priority. It is suggested that implementation of waste minimization options is taken up in stages so that the cumulative impact on production processes, resources, and finance can be kept low. It is probably best to initially implement low-cost options with relatively simple technical requirements followed by progressive implementation of more complex changes that may require higher capital costs. It may also be a good idea to implement an option and test the success of it before the next one is undertaken to reduce the total risk involved in undertaking changes.

29.5 CONCLUSION

Waste auditing is as important as any other step in a waste-minimization or cleaner-production project. A proper waste audit should essentially provide a platform on which the rest of the project would be built. It should be a repository of all data and information that

would be required to carry out the rest of the phases. As information is the strength so is a successful waste audit.

The principal intent of a waste audit is to critically assess various inputs, processes, and outputs to find methods and practices for minimizing waste and reducing the resource consumption in a sustainable and environmentally benign way without compromising the commercial interest of the company. The waste audit phase would typically be a data collection and information synthesis phase that explores the current situation. Traditionally, an industrial waste audit also develops a list of waste minimization options and undertakes some preliminary technical and economic feasibility studies on the identified options to recommend about these options.

In general, the first step of a systematic waste audit is to prepare for the audit by forming a team, defining the scope, and programming the audit timings and budget. Scope should be defined in line with the overall objective of the waste-minimization program. The next step is to collect all baseline information, conduct plant walk-through surveys and identify readily implementable options. This would be followed by a detailed assessment of target sectors and unit processes and performing the mass balance analysis. At the end, the data should be analyzed to buildup an array of information and recommendation that would set the direction of the next phase. All data collected, information derived, and recommendation made should be presented in a form of a comprehensible and well-laid-out audit report.

It should be appreciated that a waste audit forms the vital activity of data collection and investigation of the current condition of the factory and its activities. Therefore, it is the very base of the next series of activities. The waste audit should be undertaken with utmost care and should be as thorough as possible. The more effort is spend at this phase, the better will be the chance of success of the project.

30.2 Summary

References

30.1 INTRODUCTION

Another challenging domain of measurement expertise for engineers is related to organizational performance measurement. An organizational performance measurement system attempts to provide a “dashboard” for the purposes of controlling and improving an organizational unit (referred to here as the “target system” or “target organizational system”), such as a work team, department, division, or the organization as a whole. The following chapter will discuss some key issues in the design, implementation, and use of organizational performance measurement systems. Before this discussion, we start with some basic definitions to lay a foundation for the rest of the chapter.

30.1.1 What is Organizational Performance Measurement?

Organizational performance measurement has been defined in various ways in the existing literature and is closely related to several similar terms—including “performance measures,” “performance management,” and “performance measurement system.” Although there is no one commonly accepted definition for any of these terms, we discuss here some of the alternate definitions proposed in the literature, as well as the definitions that will be used for the purposes of this chapter.

One recent source defined “performance measurement” in simple terms: “Performance measurement is the comparison of actual levels of performance to pre-established target levels of performance” (Slizyte and Bakanauskiene, 2007, p. 317). While perhaps incomplete in some sense, this definition highlights the key fact that the purpose of performance measurement is to be able to ascertain the extent to which the organization’s current performance meets organizational objectives related to maintaining or improving its processes, activities, functions, and/or outcomes. For the purposes of this chapter, *performance measurement (PM)* is defined as “the act of using a set of preidentified indicators to track the way the organization functions over time in one or more key areas related to strategic goals.” Thus, performance measurement is intricately linked to the organization’s strategic planning process, as will be discussed more in the following sections.

Meanwhile, an “organizational performance measure” can be defined as “a metric used to quantify the efficiency and effectiveness of business strategy. It conveys financial or nonfinancial information that influence decision-making and managerial action taking” (Chearskul, 2010, p. 16 adapted from Simons, 2000, and Neely et al., 1995). Other terms used for this concept include “performance metric” or “performance indicator.” In this chapter, *performance measure* is defined as “an individual indicator used to quantify some key aspect, either financial or nonfinancial, of one or more organizational functions related to strategic goals.”

Although sometimes used interchangeably with “performance measurement,” the term “performance management” has been used in the literature to denote the act of actually using the information provided by performance measurement activities for organizational decision-making regarding maintaining or improving performance. Specifically, Slizyte and Bakanauskiene (2007, p. 317) argue that performance management “uses performance measurement information to manage and improve performance and to demonstrate what has been accomplished.” In this chapter, *performance management* is similarly defined as “the process of using performance measurement information to maintain or improve organizational performance.”

Finally, the literature defines a “performance measurement system” as “the formal, information-based routines and procedures managers use to maintain or alter patterns in organizational activities. These systems focus on conveying financial and nonfinancial information that influence decision-making and managerial action taking. The recording, analyzing, and distributing of this information are embedded in the rhythm of the organization and are often based on predetermined practices and at preset times in the business cycle. These systems are designed specifically to be used by the managers (de Waal, 2002, p. 5). Thus, a “performance measurement system” includes the infrastructural elements used to support the performance management process, including methods used to gather and report performance information, although it is often taken to include the performance measures themselves. For the purposes of this chapter, a *performance measurement*

system (PM system) is defined as “the procedures and infrastructural elements—including personnel, computing resources, and equipment—used to gather and report performance measurement information for the purposes of supporting performance management, as well as the set of performance measures and goals.”

30.1.2 Why is Organizational Performance Measurement Important?

As previously mentioned, the goal of a PM system is to support the managerial control (decision-making) process within the target organizational system to maintain or improve performance. We can view PM as occurring within the iconic plan-do-study-act (PDSA) cycle of continuous improvement (Figure 30.1). Managers first use PM system information to evaluate the current situation and determine what course of action to take (*plan*). They must then oversee the implementation of this course of action, and it is also beneficial to track progress on implementation using the PM system and other tools (*act*). Following or potentially during action, managers will then use PM system outputs again to assess the extent to which the action appears to be effective; if the action is not as effective as planned, the organizational will seek to understand why (*study*), generating knowledge for further action. The action can then be adjusted, replaced, or discontinued as needed (*act*). This type of decision-making should be built into the rhythm of the organization through meetings held at regular intervals as part of the performance review process, which will be discussed in more detail later in this chapter.

The types of organizational functions supported through this cycle of decision-making using the PM system include

- strategic planning,
- problem identification,
- process improvement,
- forecasting,

FIGURE 30.1 PDSA cycle of continuous improvement.

- individual performance evaluation,
- organizational learning.

In particular, as indicated, effective use of a well-designed PM system can continuously improve overall organizational performance over time by increasing organizational learning in several different areas, including understanding of

- current performance versus goals;
- areas of competitive advantage;
- opportunities to improve performance;
- priority of performance objectives among various stakeholders;
- stakeholder beliefs about how performance is created (mental models of performance, which can be captured through the strategy mapping process);
- appropriate strategies for improving performance.

The types of performance improvements realized through this cycle of continuous improvement include significant improvements in

- *Overall financial performance* (Lingle and Schiemann, 1996; Scott and Tiessen, 1999; Hoque and James, 2000; Malina and Selto, 2001; Davis and Albright, 2004; Martinez and Kennerley, 2005; Crabtree and Debusk, 2008; Iselin et al., 2008; Gimbert et al., 2010);
- *Industry standing* (Lingle and Schiemann, 1996; Martinez and Kennerley, 2005);
- *Customer satisfaction* (Martinez and Kennerley, 2005);
- *Employee learning* (Martinez and Kennerley, 2005);
- *Employee accountability* (Martinez and Kennerley, 2005);
- *Organizational alignment* (Meekings, 2005);
- *Teamwork* (Martinez and Kennerley, 2005; Meekings, 2005).

Clearly, a well-functioning PM system can provide many benefits for an organization, including the ability to continuously improve itself to maintain or increase performance to survive in today's competitive industry. For this reason, many organizations have recently attempted to redesign their measurement systems to follow state-of-the-art guidelines on design, implementation, and use. Yet, as will be discussed in more detail later in this chapter, the majority of PM system change efforts fail (de Waal and Counet, 2009). Thus, careful upfront planning and a well-thought-out execution strategy are needed before an organization attempts any changes to its existing PM system. Yet, if the organization is willing to put in the work upfront, the benefits can far outweigh the costs.

30.1.3 What are the Key Components of a Performance Measurement System?

Because achieving PM system change is such an inherently difficult task in any case, it is helpful if the organization realizes that there are two key parts to any PM system. Although these parts must be addressed in an integrated fashion, they differ significantly in terms of content and types of organizational issues faced in attempting to change each of them.

First, a PM system contains a prespecified set of performance measures designed to be used to maintain or improve organizational performance. This set of measures must be carefully designed to give a holistic and actionable view of organizational performance. This includes selecting the measures themselves and also their portrayal mechanisms. Sufficient balance across key dimensions of organizational performance must be obtained, while also preserving a manageable set of measures and actionable portrayal design.

Second, in order to achieve its objectives, as previously discussed, a PM system must actually be used to manage organizational performance. Achieving effective PM system use implies the deployment or implementation of the system procedures and infrastructural elements, a commitment to continuously assess organizational performance, and the actual use of the system to make new decisions and follow-up on old ones, particularly through structured and regular performance review processes.

Thus, the discussion of PM systems can be separated into issues related to the *design* of the PM system and issues related to the *implementation and use* of the PM system. We now discuss each of the two components in turn.

30.1.4 How Should Organizations Design Performance Measurement Systems?

Although the focus on implementation and use of PM systems has been growing in recent years, the design of PM systems has still received the most attention to date in the PM community, including the research literature. A major emphasis of this work on PM system design has been on determining a balanced set of the measures organizations can use to measure performance. Until the latter part of the twentieth century, most organizations' PM systems focused on financial measures, such as return on investment (ROI), market growth, and share price, as well as financially based operational measures, for example, labor cost, scrap cost, productivity, and efficiency. While these measures may seem intuitive, as they are the "bottom-line" metrics most of interest to managers and shareholders, they pose several significant problems when the organization attempts to solely use them to maintain or improve organization performance. They only provide a partial view of organizational performance and are almost always lagging in time—that is, the performance level displayed at any point of time is often due to events which happened for weeks, months, or even years earlier. Thus, a focus on financial and operations metrics only often leads to inaccurate assumptions about an organization's competitive position and faulty decision-making due to lack of understanding of cause and effect relationships that link organizational performance with strategic thinking.

To illustrate this truth using a simple example, suppose a manufacturing department manager is given the objective of cutting costs within the department over the next 6 weeks. Due to the tight time frame and the fact that the options appear to be limited, the manager decides to eliminate 9 finished goods inspection operation in one of the manufacturing lines, despite a historical scrap rate of 2%. The initial impact of this decision is a reduction in operating expense and a reduction in scrap costs thus increasing departmental and organizational profit (total income – total expense)—and the department manager is applauded by the superiors. However, several weeks later, the organization begins to see a significant increase in the return of defective products, eroding the profits gained. Even worse, the organization's sales department begins to report that several long-term customers are failing to place new

orders. By the end of the year, the organization's profits have declined below baseline levels, the organization is dealing with a myriad of customer complaints about quality, and the manufacturing manager has been fired.

Although it may appear obvious in this simple example that the decision to cut the inspection operation without any other actions to improve quality is almost certainly a bad decision, this example illustrates the types of problems encountered when the organization focuses only on financial and operational metrics. In particular, the lack of other types of measures, in this case, related to quality or customer satisfaction, makes it difficult to detect poor decisions until they are ultimately felt—sometimes much later—in the financial measures themselves. Even when observed, it can be difficult to detect exactly what chain of events led to the degradation of the measures. Indeed, typical limitations of financial measures include (Neely, 1999)

- They encourage short-term thinking: that is, the tendency to delay capital investments and other decisions that will harm short-term returns, even if they improve the performance of the organization in the long run.
- They are historically focused: as mentioned, financial measures almost always focus on the past. Even as recently as 2007, Brown estimated that 75% of *all* measures used in organizations—including almost all financial measures and the majority of operational and employee metrics—were historically focused. A target is to have only one-third of measures focused on the past (Brown, 2007).
- They encourage suboptimization: financial measures may be more likely than other measure types to encourage performance at the organizational subunit level that decreases overall organizational unit effectiveness; for example, a manufacturing department may build more inventory than is required by the customer to maximize productivity and utilization measures, leading to increased inventory holding cost, increased defects or obsolescence, and possibly decreased selling prices.
- They typically are not linked to organizational strategy: at best, financial indicators serve as end-result metrics indicating when the organizational strategy has been achieved; they typically offer little insight into organizational progress toward achieving strategy and, even in the best case, are not linked to strategic performance dimensions beyond financial viability, for example, quality, flexibility, or responsiveness.
- They fail to provide information on customer needs (typically available through customer satisfaction or loyalty measures) or other key performance dimensions (such as quality): as a lagging indicator, the best financial measures can do is indicate that customers *are* buying from the organization; they do not indicate *why* they are buying or *how well* the organization is meeting customer needs.

Thus, there is clearly a need for a carefully designed set of performance measures that gives a holistic view of organizational performance, and allows the definition of causal relationships between measures to identify leading and lagging indicators of performance and other important relationships, for example, correlations between different lagging indicators which are driven by the same leading indicators. In addition, a structured approach to PM design B needed to ensure that the measurement system is aligned with the organization's strategic goals.

30.1.5 How Should Organizations Design More Effective Measurement Systems?

Perhaps, the most popular modern measurement framework is the balanced scorecard (BSC), introduced by Kaplan and Norton (1992). The BSC has been named one of the top 15 management tools of recent years (Andersen et al., 2001), and it is estimated that 70% of organizations worldwide have attempted to adopt the BSC (Rigby and Bilodeau, 2007). Specifically, the premise of the BSC is that, in order to fully understand its operations, an organization must design measures to balance performance in four key dimensions

- *Financial*: indicators of fiscal success to shareholders and other evaluators. Example metrics include traditional financial measures such as profitability, share price, and market growth.
- *Customer*: measures of the extent to which the organization meets the needs of the people who use its products or services. Example metrics include measures of customer perceptions (such as satisfaction) and behavior (such as loyalty or repeat visits).
- *Internal business process*: metrics capturing operating efficiency and effectiveness in creation of products or services. Example metrics include productivity, quality, and process lead time measures.
- *Learning and growth*: indicators demonstrating how the organization maintains its ability to innovate in a dynamic environment. Example metrics include measures related to employee satisfaction and learning, as well as measures related to process innovation (number of suggestions implemented) and product innovation (new product launch rate, number of patents granted).

Beyond merely measuring performance in the four key dimensions, however, the BSC approach specifies that organization must also seek to understand causal relationships across metrics both within and across the four key dimensions, which is the focus of the next section.

Meanwhile, Table 30.1 summarizes some other important PM frameworks (note, this list does not attempt to be exhaustive, but rather to highlight common themes and differences across existing frameworks). Despite the great variety in some individual elements, a set of common characteristics across existing PM frameworks can be identified. In general existing frameworks: (1) identify multiple key dimensions of business performance; (2) attempt to provide a balanced representation of performance across these dimensions; (3) attempt to provide a comprehensive representation of organizational performance across these dimensions; (4) attempt to enable discernment of the organization's overall performance through examination of the measures included; (5) allow integration of measures both vertically and horizontally across the organization; and (6) assume and allow testing of cause and effect relationships between measures (Kennerley and Neely, 2002).

It should be noted here, even if the organization does adopt a holistic measurement framework, there are a myriad of other problems that might be encountered with the PM system. Several of the most commonly documented problems with PM systems in organizations include

- There are too many measures: organizations may attempt to measure and control everything, leading to information overload and many trivial or nonactionable measures; and/or, organizations may simply neglect to delete measures as they add new

TABLE 30.1 Other PM Frameworks from the Existing Literature

Framework	Performance Dimensions
Tableau de Bord (Lebas, 1994)	Corporate/HQ Divisions Functions/Departments
Performance Measurement Matrix (Keegan et al, 1989)	External cost, for example, competitive cost position, R&D expenditures External noncost, for example, market share, customer loyalty (repeat customers), customer satisfaction (number of complaints) Internal cost—for example, design, material or manufacturing cost Internal noncost, for example, cycle time, service level, new product introductions
Sink and Tuttle Framework (Sink and Tuttle, 1989)	Effectiveness—output produced (“doing the right things”), for example, motors shipped, tons produced, rooms rented Efficiency—input resources consumed (“doing things right”), for example, labor hours, material Productivity—ratio of output/input, for example, tons produced/labor hour Quality—extent to which materials, work in process, finished goods and service support end customer expectations regarding goods and services; measured at several points in supply chain—from suppliers of raw materials to end customer satisfaction Quality of work life—response of employees to working conditions, for example, absenteeism or employee satisfaction Innovation—organizational ability to adapt to the changing environment, for example, number of improvements implemented, number of patents awarded Profitability/Budgetability—ratio of income to expenses; measured through standard financial measures
Five Critical Success Factors (CSF) (Beischel and Smith, 1991)	Quality Customer service Resource management Cost Flexibility
Performance Measures for Time-Based Companies (Azzone et al., 1991)	Cost Quality Innovation Time
Performance Pyramid (Lynch and Cross, 1991)	Overall corporate vision (corporation) Market (business units) Financial (business units) Customer satisfaction (business operating system) Flexibility (business operating system) Productivity (business operating system) Quality (department and work centers) Delivery (department and work centers) Cycle time (department and work centers) Waste (department and work centers)

TABLE 30.1 *(Continued)*

Framework	Performance Dimensions
Results and Determinants (Fitzgerald et al., 1991)	Competitiveness (result) Financial performance (result) Quality (determinant) Flexibility (determinant) Resource utilization (determinant) Innovation (determinant)*
Advanced Manufacturing Business Implementation Tool for Europe (AMBITE) (Bradley 1996)	Time Cost Quality Flexibility Environment At least one strategic performance indicator should be identified from each performance dimensions for each of five key “macro business processes”: customer order fulfillment, vendor supply, design co-ordination, coengineering, and manufacturing
Integrated Performance Measurement System Reference Model (Bititci et al., 1998)	System 1—core production system System 2—manages core production system System 3—monitors and sets goals for system 1 and system 2 System 4—monitors external environment and sets goals for improvement System 5—highest level of organization, which sets corporate vision and strategic direction
Performance Prism (Neely et al., 2002)	Stakeholder satisfaction—what stakeholders demand (need and want) from the organization Stakeholder contribution—what the organization demands (needs and wants) from the stakeholders Capabilities—the resources required to satisfy stakeholder and the organization’s needs and wants Strategies—the policies required to satisfy stakeholder and the organization’s needs and wants Processes—the procedures required to satisfy stakeholder and the organization’s needs and wants
Dynamic Multidimensional Performance (DMP) (Maltz et al., 2003)	Financial performance—traditional financial measures Market/customer—measures focused on understanding customer needs Process—metrics related to organizational efficiency and improvement People development—metrics related to employee skills and commitment Future—metrics related to strategic alliances and partnerships, and the development of new product and service offerings
Integral Framework for Performance Measurement (IFPM) (Rouse and Putterill, 2003)	Long-term dimensions: Stakeholder expectations—long-term desires of stakeholders Contributions—resources provided by stakeholders Benefits—long-term value provided to stakeholders Vision/goals of the organization—adopted to meet stakeholder expectations Mid-term dimensions:

(continued)

TABLE 30.1 (Continued)

Framework	Performance Dimensions
European Foundation for Quality Management (EFQM) Excellence Model (EFQM, 2011)	Organizational culture/structure—driven by stakeholder expectations
	Resource capacity—of organization, based on the contributions of stakeholders
	Strategic outcomes—outcomes of mid-term activities, goal is to drive long-term benefits
	Objectives—strategic objectives of organization in pursuit of its vision and goals
	Near-term dimensions:
	Evaluation—process of tracking organizational progress toward meeting stakeholder expectations
	Resource utilization—near-term utilizations of available resources
	Outcomes—impact of near-term activities toward achieving desired near-term strategic outcomes and long-term benefits
	Plans—near-term operating plans of organization
	Short-term dimensions:
	Measurement—short-term control processes of the organization
	Inputs—resources used in production activities in short-term
	Activities—processes used to produce short-term outputs
	Outputs—products or services produced in short-term, to ultimately drive desired benefits
	Performance norms—short-term strategies driven by near-term plans
	Customer results, for example, customer satisfaction measures
	People results, for example, employee satisfaction measures
	Society results, for example, ethics and environmental responsibility
	Key results—the most important financial and nonfinancial indicators of the organization, potentially including results from the other three categories
	Leadership (enabler)
Malcom Baldrige National Quality Award (MBNQA) Results Category Dimensions (NIST, 2011)	People (enabler)
	Policy and strategies (enabler)
	Partnerships and resources (enabler)
	Processes (enabler)
	Product and process outcomes, for example, supplier and partner results, operational and process performance
	Customer-focused outcomes, for example, customer satisfaction and customer loyalty
	Workforce-focused outcomes, for example, employee well-being and satisfaction, safety, work system effectiveness
	Leadership and governance outcomes, for example, measures of ethics and stakeholder trust in organization, energy consumption
	Financial and market outcomes, for example, standard financial measures

ones (Neely, 1999); either or both of these forces can ultimately lead to dozens, hundreds, or even thousands of measures supposedly in use.

- Measures are not reliable and/or valid: many metrics suffer from reliability and/or validity problems. This is especially true for subjective measures, for example, customer satisfaction, employee satisfaction, when designed by people who do not possess expertise in the design of psychological measurements using survey questionnaires (psychometrics).
- The system lacks effective visual and portrayal tools: portrayal tools should promote statistical thinking about trends over time, and other fact-based decision-making; where possible, a standardized format should also be used across metrics (De Waal, 2002).
- The measurement system is not fully deployed throughout the organization: for instance, Brown (2007) reported that the majority of balanced scorecards exist only at senior management levels.
- Targets are set arbitrarily: that is, targets are determined based on “gut feel,” management desire or institution only without any systematic comparison to competitors, industry averages or benchmarks (Brown, 2007).
- Performance measurement software is not exploited and some software is poorly designed (too complex, etc.) (Brown, 2007).
- Measures are tracked/reviewed too infrequently: for example, annual customer satisfaction survey—and data collection is too cost intensive (Brown, 2007).
- Measures drive the wrong behaviors: this includes any behavior not aligned with organizational goals and the actual intent of the PM system, such as the functional/departmental suboptimization previously discussed. However, the PM system can also encourage wrong behaviors at the top of organizations—for instance, executive bonuses are still tied to primarily to financial metrics (Brown, 2007).
- Measures not used to support decision-making: this may be linked to the previous problems, but also to the lack of understanding of causal linkages between measures. This also occurs when an organization focuses on measures that are not within its sphere of influence or control, or when metrics to do not vary sufficiently (i.e., the organization primarily collects data on “what it already knows” (Brown, 2000)). Conversely, however, organizations should not go too far in measuring only controllable factors—important external factors that influence performance should be included but should not comprise the majority of the scorecard (Brown, 2007).

Some of these problems—particularly measures that drive the wrong behaviors—can be at least partially alleviated through the identification of causal relationships between measures, as discussed in the next section. However, others require additional steps in the process of designing and implementing/using measures, as will be discussed later in this chapter.

30.1.6 How Should Organizations Identify Causal Relationships between Measures?

As previously indicated, all of the PM frameworks above assume, either explicitly or implicitly, that balancing PM across multiple dimensions is critical not only because

organizational success has different facets, but also because the dimensions are inter-related. Thus, one key to the creation of effective performance measurement systems is developing organizational processes that document and then empirically test causal relationships between metrics.

One tool that can be used to support such processes is a *strategy map*, which is a graphical depiction of the hypothesized interrelationships between the performance measures in the measurement framework adopted by the organization. A strategy map may also include: key performance areas; strategies adopted to improve performance in each dimension/key area; specific performance measures for each dimensions/key area; shorthand versions of action plans adopted to improve performance; and targets and timelines for metrics, improvement strategies, and action plans. Other common terms for a “strategy map” include “business model,” “causal model”, or “cause-and-effect map” (Chearskul, 2010).

A simplified strategy map adapted from Kaplan and Norton (1996) is presented as Figure 30.2. This represents only a subset of a map and does not contain all necessary elements. However, it demonstrates the basic construction of a strategy map and typical hypothesized relations between the BSC dimensions—that is, that learning and growth investments influence internal business process performance, which influences customer satisfaction, which in turn influences financial outcomes. Along with logical support, there is some empirical support for this hypothesized causal chain as well. One study conducted in Sears found that a 5% improvement in employee attitude was linked to a 1.3% increase in customer satisfaction, which was linked to a 0.5% increase in store revenue (Rucci et al., 1998).

Although the simplified map in Figure 30.2 includes only the relationships between performance dimensions and specific metrics, as mentioned, a mature strategy map would typically also include specific strategic initiatives related to the metrics (e.g., “develop a fan base of repeat customers”). The map could also include specific targets for the metrics (e.g., “increase customer loyalty by 10% over last year”) and potentially also for metrics

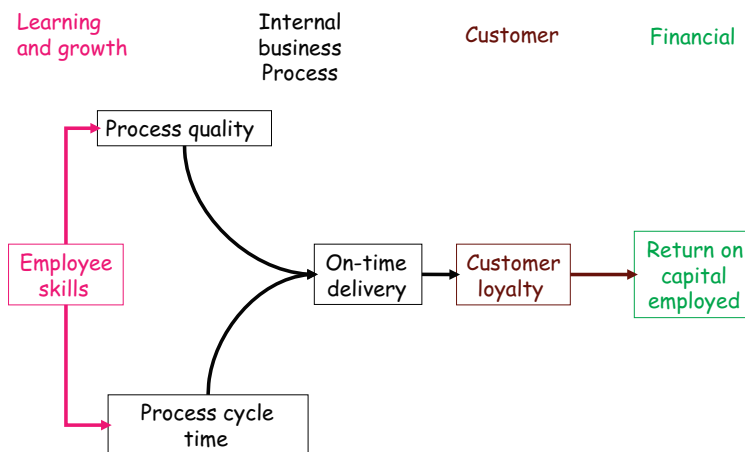

FIGURE 30.2 Simplified strategy map highlighting relationships between BSC dimensions. (Adapted from Kaplan and Norton, 1996, p. 66.)

related to strategic initiatives (e.g., “develop a fan base of at least 1000 repeat customers”), short-hand versions of action plans (e.g., “double the Facebook advertising budget and start a Facebook fan page”) and time frames (including potential time delays for seeing impacts) (e.g., 1 year).

Benchmarking, literature review, group brainstorming sessions, or historical data can be used to develop the initial strategy map for further testing. Once a strategy map has been defined, the organization must collect and analyze empirical data using its PM system to verify the extent to which the strategy map appears valid. Faulty assumptions regarding the linkages between performance dimensions can cause performance to stagnate or even worsen without the organization realizing the catalyst behind such effects. Although defining and testing a strategy map is clearly a challenging undertaking, studies have shown that this approach is necessary for achieving the most value out of the organization’s PM system (Ittner and Larcker, 2003; Chenhall, 2005). Several examples of approaches for exploring and testing causal relationships between performance measures can be seen in Santos et al. (2002) and Sousa et al. (2005).

30.1.7 What Process Should an Organization Use to Design its Performance Measurement System?

Just as many different frameworks have been proposed for defining a balanced set of measures, many different approaches to the actual PM system design process have also been identified. Some are detailed, while others are very broad. For instance, Bourne et al. (2000) identify two key parts to the PM system design process: (1) identifying the key objectives to be measured and (2) designing the measures themselves. One general process for designing PM system, the Measurement System Development Process (MSDP) (see Van Aken and Coleman, 2002), which is based on the more general TransMeth transformation methodology (Van Aken et al., 2003), is illustrated here

1. (in parallel with other tasks) create the infrastructure for the PM system design, implementation and use effort,
2. define the need for PM within the target organizational system,
3. define what the target organizational system does now and should do in the future,
4. define key performance areas in which the target organizational system must excel now and in the future,
5. define how the target organizational system will know if it is successful in its key performance areas,
6. implement the PM system,
7. utilize the PM system.

The first five steps will be discussed in this section, whereas the last two are discussed in the implementation/use section later in this chapter.

30.1.7.1 Create Infrastructure for the PM System Design, Implementation and Use Effort This step focuses on selecting the design team, communicating the results of other steps to various stakeholders within (and potentially external to) the organization,

acquiring needed resources, and providing necessary training. This is an ongoing process that occurs in parallel with the other steps.

The first thing for the organization to do will be to identify who will champion, lead and otherwise participate in the PM initiative.

The project champion, or sponsor, is usually a senior level manager within the target organization who provides guidance to the leader/project manager in terms of the vision for the project, internally links the project to the need for change within the organization, and helps the leader/project manager acquire any needed resources (personnel, budget, etc.). The champion also acts as a liaison between the leader/project manager and other members of the senior management team.

The leader or project manager is the person or persons who manage the actual PM system project, including negotiating for needed resources, scheduling activities, managing any relevant budget, managing the creation of deliverables, and reporting back to the project sponsor and other relevant stakeholders. To stimulate ownership and accountability, it is highly recommended that the same individual manages all the stages of the PM system project—from design to implementation and initial use of the PM system (“roll out”)—although this is not always possible. In addition, it is highly recommended that the leader should be internal to the organization, although in practice (particularly during the first stages of the PM initiative) it may be an external consultant working with internal liaisons, including the project champion.

In addition to the leader/project manager and the project champion/sponsor, it is essential to define a small team to assist the project manager throughout the various stages of the initiative. Members of this team can either be internal, external, or a mixture to the organization. In terms of rolling out the metric design process, one of the first decisions the organization will face is where in the organization to begin the rollout of the project management efforts. The literature suggests that PM system change can be successfully implemented using either a top-down rollout (central office first, deployed to work groups), bottom-up deployment (implemented first in one or more work groups or departments, then higher in the organization), or some combination thereof (e.g., implemented simultaneously in the central office and one or more workgroups) (Andersen and Faguerhaug, 2002; Letens et al., 2010). However, it does appear critical at this stage that the organization finds some way to control stakeholder involvement such that it is not soliciting active—or at least in depth—involvement from everyone in the organization. While open communication channels can be desirable for gathering input beyond the employees in the rollout group, attempting to involve too many stakeholders at once or to gather detailed input from everyone in the organization can lead to the failure of the initiative. Also, attempting a simultaneous rollout of the PM system to all areas of the organization appears to be destined for failure. It appears the organization should first select one or more smaller areas as test beds, implement, observe results, adjust and then continue to deploy the system across the organization. Thus, the most promising method appears to be to involve only a few key staff in the target areas, including key decision makers and a few other critical stakeholders, in the process of designing the metrics, while holding broader “all hands” meetings in the target area and other areas of the organization for information and buy-in purposes.

Once the leader, champion, and design team have been identified, a stakeholder analysis can be a useful tool to determine exactly how to communicate with the larger organization. The specific elements considered may differ based on the organization’s objectives, but the basic goals of a stakeholder analysis are to identify

- all relevant stakeholders (i.e., those who are at least affected by or interested in project outcomes);
- each stakeholder's influence on the project (e.g., has useful expertise, has decision authority);
- based on the two above relationships, how the project team should communicate with each stakeholder (from regular meetings to as needed); this analysis might also be used by the project sponsor or project manager at the beginning of the project to determine who should be targeted to participate in the project team.

Table 30.2 shows an example stakeholder analysis matrix for a hypothetical PM system project within a manufacturing department.

Needed resources initially include the PM system design/implementation team members, as well as any resources needed to support: team meetings, data collection, data analysis, actual metric/portrayal/system design, project planning, and communication to other stakeholders, among other processes. Later, necessary resources may include computing resources and personnel to support the implementation and ongoing use of the PM system.

Initial training will likely be focused on the design/implementation/use team and members of senior management. Both senior management and team members need to receive training in the basic concepts and benefits of PM systems. It will be useful for both team members and senior management to also receive additional training in group dynamics, the steps of the design/implementation/use process, and the PM systems of other companies. More detailed training can also be provided at any time during the process. As the PM system gets deployed to other organizational units, more training will be needed for the additional users of the PM system.

TABLE 30.2 Example Stakeholder Analysis for a Hypothetical PM System Project

Stakeholder	Relationship to Project						Communication/ Involvement Strategy						
	Is Affected by PM System	Can Influence PM System	Will Use PM System	Has Useful Expertise	Provides Resources	Has Decision Authority	Project Sponsor	Project Manager	Project Team member	Meet with Regularity	Invite to Team Meetings	Send Copy of Team Meeting Minutes	Speak with Informally as Needed
Department manager	X	X	X	X	X	X	X			X	X	X	X
Assistant department manager	X	X	X	X				X		X	X	X	X
Supervisors/other departmental senior staff	X	X	X	X					X	X	X	X	X
Lower level departmental personnel	X	X								X			X
Department customers	X												X
Organizational senior staff	X	X		X	X	X						X	X

30.1.7.2 Define the Need for PM in the Target Organizational System This step is focused on clarifying the objectives of the PM system, as well as who will play what role in developing, implementing and using the system. This includes

- linking the need for measurement with the general need for change in the organization;
- defining the overall purpose and impact of the PM system—that is, what questions are we trying to answer with the system and what is the expected impact of having these questions answered?
- defining the general types of information needed to answer these questions;
- identifying the users of the measurement system and other stakeholders, such as the sponsor, project manager, and design team;
- defining user expectations for the system design, for example, extent to which it is user-friendly, preferences about how information is portrayed, frequency needed to support decision-making, and how much time users expect to spend in reviewing information;
- identifying how the PM system development relates to any other ongoing improvement initiatives;
- communicating this information to relevant stakeholders.

The need for the PM system may often be identified initially by one or a few organizational personnel, who, if not members of the senior management team, may need to pass the idea up the chain of command until it gains traction.

30.1.7.3 Define What the Target Organizational System Does Now and Should Do in the Future Although the details of the various design methodologies differ, there is consistent agreement that the key objective of a PM system is to assist the target organizational system in achieving its strategic goals. In order to design a PM system that is aligned with the target system's strategic goals, this requires first identifying

- What the target system is: that is, the primary suppliers, inputs, processes, outputs, and customers of the system. This can be assessed using an input/output analysis, also called a supplier input process outcome customer (SIPOC) diagram, or similar tools. Other system models of organizations that can be instrumental in identifying organizational strengths and weaknesses include the Management Systems Model (MSM) (Kurstedt, 1985), the Malcolm Baldrige Criteria for Performance Excellence (NIST, 2011), or the European Foundation for Quality Management (EFQM) Excellence Model (EFQM, 2011).
- Why the target system exists and what value-added it provides to its customers: that is, what is the purpose of the organization, as captured in a unique mission statement. If a mission statement does not exist, the PM system development team will likely want to draft one at this time, with input from relevant stakeholders, especially the senior manager of the organizational system. However, care must be taken as creating a mission statement can easily become a controversial and lengthy task—particularly if many different organizational stakeholders are involved. Thus, some experts recommend involving only the senior manager of the organizational unit in writing

the mission statement (Brown, 2000), which can then be presented to other stakeholders for approval and fine-tuning.

- Where the organizational system wants to go in the next 3–10 years: this can be captured in narrative form through a vision statement. Here, a useful analysis tool is a strengths–weaknesses–opportunities–threats (SWOT) assessment. The SWOT attempts to identify the positive forces (internal strengths and external opportunities) and negative forces (internal weaknesses and external threats) affecting the organization. The identification of these forces can then be used as a key input to craft a vision of where the organization should go in the next 3–5 years. Other tools include environmental scanning, analysis of competitor mission and vision statements, market analysis (e.g., through Porter’s (1979) five forces model), and feedback from customers. It is recommended that members of the senior management team participate in creating ideas for the vision, but, as with the mission statement, a single individual, typically the senior manager, draft the actual vision statement and then present this draft to the rest of the management team for approval/refinement (Brown, 2000). Group creativity and brainstorming tools, such as analogies, tree diagrams, and pictorial representation of the future, can be used to help generate ideas for the vision statement. After identifying the narrative form of the core vision, the organization should then identify specific strategies to achieve the vision and qualitative or quantitative goals associated with these strategies. These in particular can be useful for identify key performance areas to be monitored, and appropriate targets for these metrics.

30.1.7.4 Define Key Performance Areas in Which the Target Organizational System Must Excel Based on the definition of the components of the target organizational system, its mission and its vision, the next step is for the organization to identify a “small number” of key performance areas (KPA) (typically three to seven), in which it must excel to achieve its mission and vision. A KPA describes a core dimension of performance that encompasses a number of potential measures, for example, customer satisfaction, and operational excellence. KPA form the core structure of organizational scorecards and strategy maps/business models. Similar terms include “critical success factor” (CSF) and “key results area” KRA. A good set of KPA will be succinct (“small number” of KPA), clearly aligned with the mission/vision, balanced, comprehensive, and unique to the target system. The set of KPA should also be reevaluated at regular intervals, typically every 3–5 years, for its continued applicability, and the KPA used should change as needed to align with changes in the mission, vision or external environment (e.g., regulatory requirements). While the organization may want to customize the number and names of dimensions to suit its unique environment, the performance measurement frameworks presented earlier—and particularly the BSC—are a starting point for identifying KPA. Identifying KPA should typically be a team process (Brown, 2000), which involves the project manager and design team members, with feedback from the sponsor and potentially other stakeholders.

30.1.7.5 Define How the Target Organizational System Will Know If It is Successful in Its Key Performance Areas Once the key performance areas have been defined, the organization should seek to identify a set of measures to evaluate each KPA. In particular, it is important to identify at least one outcome or end-result metric related to each KPA. An end-result metric is a lagging indicator of performance, measuring current—or, more

likely, recent past—success. An example of a lagging indicator may be purchases/customer. Although one is the minimum recommended number of end-result metrics, typically one to three is the desired range for each KPA. The organization should also seek to identify at least one driver metric related to each end-result metric. The driver metric is thus a leading indicator, which is believed to influence at least one end-result or lagging indicator. For instance, manufacturing batch size might be a driver metric for the end-result metric manufacturing lead-time. Again, the typical range would be one to three driver metrics per end result metric, although some driver metrics may be related to more than one end-result metric, and some end-result metrics may be drivers for others (e.g., customer satisfaction might drive purchases-per customer). In general, the PM literature seems to agree that 10–20 metrics in total appears to be an appropriate and manageable number for most organizational scorecards. However, an organization should not consider this a definite rule if more (or fewer) metrics appear appropriate for its specific case. As with the identification of KPA, identifying metrics should typically be a team process, involving the project manager and the design team. A good place to start is with an audit of existing metrics. However, the organization must be careful to avoid the temptation of “settling” for a subset of the existing metrics as its new PM system, merely because the existing metrics are already available. This is particularly true for organizations in the stage of refining their first (initial) PM system design efforts, where there is a tendency to identify too many measures. Thus, the existing number of metrics may be greater than the suggested 10–20, and the tendency is to merely cut down this set to an existing set of financial or operational control metrics without adding any new strategic improvement metrics. Organizations starting their efforts “from scratch” are likely to have few existing metrics beyond financial metrics and other required for regulatory purposes. For adding new metrics, the organization can review the metrics of competitor/comparison organizations or other benchmarks (e.g., quality award winners), review suggested sets of measures for different performance dimensions, or define entirely new measures unique to the organization. New measures for which data already exist (but simply have never been previously compiled into the metric as defined) are obviously the most tempting. However, the organization should not overlook more meaningful measures simply because the data are not available. Instead, the overall quality of each metric should be analyzed, for example, using the bullet point list below, to identify which among alternate metrics are most preferable for the system.

Finally, although not counted against the total number of metrics, it also may be useful for the organization to identify drill-down metrics for some or all end-result metrics, particularly those that are composite or index variables (Brown, 2007). For instance, an organization may have scrap rate as one of its end-result metrics within an *Internal Processes* KPA. To better understand changes in scrap rate, the organization may want to drill-down this metric into different categories of defects, to better understand the reasons for the change and specific areas (e.g., types of defects) to target for improvement. A drill-down metric therefore allows examination of the performance of different subcategories of the end-result variable and is different from a driver metric, which is a separate factor that causes changes in the end-result metric (and at least some of its subcategories). For example, employee skill level, machine maintenance audit score, and supplier quality could be driver metrics for defect rate. Meanwhile, subcategories of defect rate (drill-down metric) could include inadequate paint job, misaligned components, or failure to meet minimum functional performance standards during tests. An additional example of driver versus

end-result metrics can be found in the description of the organizational scorecard for the case study in Van Aken et al. (2003).

Similar to a lot of areas in PM system design, there are no hard and fast rules for metric design. However, from an examination of the literature, it appears that each metric should be

- *Clear*: each metric must be operationally defined (that is a formula must be developed that describes how the metric values are calculated) and the meaning of the metric should be readily understandable based on this operational definition (i.e., not obscure).
- *Aligned*: each metric must be aligned with the KPA and the vision and mission; further, the metric must be carefully selected such that it does not unintentionally drive the wrong behaviors; for example, use “first call problem resolution” instead of “talk time,” as a measure of operational excellence in a call center.
- *Reliable*: the method for collecting data and calculating the measure should be repeatable and precise, such that there is a minimum amount of measurement error in the metric. Note that measurement errors are particularly likely in the data collection stage (either the input data itself is faulty or the data collection process is unreliable), as calculations are often automated or semiautomated. However, errors can still occur at the calculation stage. Reliability is particularly a challenge for perceptual measures, such as customer or employee satisfaction.
- *Valid*: each metric must be recognized as a critical indicator of the KPA—one of the “vital few” versus the “trivial many.”
- *Variable*: measurement error aside, the underlying dimension being tracked must be likely to vary on a semiregular basis, and variation in this metric must have an impact on organizational performance. It is generally not worthwhile to track metrics that do not vary and, unless required for reporting purposes, it is hardly ever worthwhile to track a metric where variation does not noticeably impact organizational performance (either as its own performance dimension or through another metric).
- *User-focused*: metrics must be designed such that they are actionable (support decision-making) and, as much as possible, meet user preferences and expectations regarding portrayals, and so on.
- *Influenceable*: the majority of metrics must be within users’ sphere of influence or control, and it must be clear which individuals are responsible for which metrics (the limits of each users’ control should also be noted). Occasionally, it is permissible to include metrics that are not within users’ sphere of influence or control, if these are identified as key driver metrics or are needed for external reporting purposes. However, the fact that these metrics are not controllable for the organization must be noted in all communication, system documentation and metric portrayals. Individuals must never be held responsible for performance on metrics which have not been assigned to them or which are not within their sphere of influence or control, as this might lead to unacceptable or dysfunctional behavior, in particular when these performance metrics are linked to financial incentives or other rewards.
- *Cost-effective*: the cost of collecting data should not exceed the benefits of the metrics and, ideally, should be as low as possible to maintain the desired level of reliability.

Key performance area						
Key performance area						

As the metrics are developed, the required elements can be captured in a standard template, such as the metrics development matrix (MDSM) shown in Table 30.3—note that some elements here refer more to the implementation step than this design step.

Once the set of metrics has been designed, the organization should audit each metric using the criteria above (or similar criteria) to assess metric quality—and to improve the measurement system by refining, replacing, or removing individual metrics, if necessary.

The organization should then also audit the entire measurement system for balance across the different KPA to identify any potential gaps or KPA which are over-represented versus under-represented. Finally, the organization must observe the actual use of the metrics over time to assess the extent to which they are accurate, actionable, and drive the intended behaviors—as well as the extent to which the causal relationships hypothesized in the strategy map actually exist. The organization should also recognize that the set of KPA and measures which are most appropriate for its PM system will likely change over time, and must develop a system for regularly refreshing its PM system (Neely, 1999), as will be discussed in the next section.

30.1.8 How Should an Organization Implement and Use Its Performance Measurement System?

Despite significant potential benefits from successful implementation, the failure rate for PM system implementation is high—one study estimated that roughly 60% of PM system implementations fail, with exact rates depending on the context (de Waal and Counet, 2009). While deficiencies in the design steps, such as the selection of inappropriate KPA or measures, can certainly contribute to PM system failure, the literature suggests that the majority of failures are due to deficiencies in the implementation and use steps (Bourne et al., 2002; Braam and Nijssen, 2004; Franco-Santos and Bourne, 2005; Meekings, 2005; Meekings et al., 2009; Chearskul, 2010).

In addition to total failure of the system, if not carefully implemented, even a “successful” PM system can negatively impact the organization through the following effects, among others:

- system manipulation or “gaming,” for example, suboptimization (Propper and Wilson, 2003);
- information overload (Lipe and Salterio, 2000; Ittner, et al., 2003);
- high system cost (Halachmi, 2002; Ittner, et al., 2003; Marr et al., 2004; Tuomela, 2005);
- internal resistance to change (Tuomela, 2005; Martins and de Abreu, 2006).

As with PM design, there is no one accepted process for implementing a PM system, although various authors have proposed different approaches, with some common themes. The literature also typically separates “implementation” (the transition/adoption phase) from “use” (the perpetual, ongoing phase once initial adoption is achieved) in the discussion, as will be done here.

30.1.8.1 How Should an Organization Implement Its Performance Measurement System? As mentioned, the implementation step specifically refers to the transition phase where the organization is in the process of moving from current practice to the ongoing use of the new PM system. This includes three critical substeps

1. development of a change management plan;
2. development of a technology integration plan;
3. development of a plan for the regular performance review process (system use).

Developing the change management plan involves determining

- How and when to deploy (roll out) the actual changes associated with system implementation?
- What training is needed for people who use or support the system (e.g., through data collection or technical support)—and when and how this training will be provided?
- What other communication should be provided to stakeholders and how this communication will be delivered?

Deployment options will be influenced by previous decisions regarding the scope of the design/implementation efforts—that is, whether it is occurring simultaneously within many different areas of the organization or concentrated in a single area. In general, however, even if the design/implementation is occurring simultaneously in several different parts of the organization, it would be advisable to select one or two areas as pilot implementation areas, for the other areas of the organization to observe the results and the organization to fine tune the implementation process. The pilot area(s) should generally be those where the expected impact of the PM system is expected to be noticeable (to generate “short term wins” Kotter, 1996), and/or the area personnel are supportive of the PM system (or at minimum, open to change in general). If no area can be found that meets either criteria, the organization is likely not ready for implementation and the PM system design team, project manager and project sponsor should work on building support first. Similarly, it is also possible that the organization may want to deploy only part of its scorecard initially—in particular those measures that can be calculated with existing data. If possible, the organization should seek to have at least a few measures of this type on its scorecard initially—preferably balanced over the different KPA. They can always be refined or deleted with time.

Training should be provided to the individuals charged with collecting PM system data, analyzing PM system data, reporting PM system data in the performance review process, and supporting the PM system technology.

Training for individuals who collect PM system data should include training in

- the definition of the metrics within the PM system, their purpose, operational definitions, types of data required, sources of data collection, and potential errors in data sources;
- administration of any data collection tools, for example, customer satisfaction surveys, including possible errors in administration and frequency of administration;
- the recording/documentation of data, for example, in databases, spreadsheets, or directly into PM software;
- methods for retrieving PM system information;
- any other necessary aspects of interfacing with PM system software, if it exists.

Training for individuals who analyze PM system data should include the previous elements (except perhaps the details of the administration of data collection tools) plus training in any analysis tools or templates—whether built into PM system software or as stand-alone elements, for example, control charts, Pareto diagrams, regression, and simulation software.

Training for individuals who report PM system data for the performance review process should include training in

- the definition of the metrics within the PM system, their purpose, operational definitions, types of data required, sources of data collection and potential errors in data sources;
- an overview of data collection, recording, and analysis methods;
- methods for retrieving PM system information;
- preparation of reporting materials for performance review;
- any other necessary aspects of interfacing with PM system software, if it exists.

It is noted here that sometimes a single individual, often called the “metric owner,” may be charged with collecting, analyzing, and reporting PM system data for a given metric. (Note that an individual might be a metric owner for multiple metrics). However, the responsibilities might be separated into data collection/analysis versus reporting or data collection versus analysis/reporting, with the data collection-related responsibilities perhaps being conducted by a single individual within the target system (perhaps across all or at least multiple metrics) or an external department (e.g., information technology (IT) or accounting), and the reporting responsibilities being performed by a metric owner within the target system.

Finally, especially if a specialized PM software package is used, training may be needed for the individuals who manage the computers on which software used for the PM system is housed, to enable them to better manage the software and provide in house troubleshooting for other users.

Developing the technology integration plan includes determining what electronic data repository and electronic data-gathering mechanisms are required to support PM system implementation, and how these changes will interface with the organization’s existing IT system and other IT resources, including IT personnel and their capabilities (Leinonen, 2001; Franco-Santos and Bourne, 2005; Franco-Santos et al., 2007). This will likely require at least an informal audit of existing IT systems, with questions designed to gauge to what extent the current IT system and other IT resources are capable of the changes needed to support PM system implementation and what IT investments, if any, are needed to support PM system implementation. Key questions include

- What IT-related changes will be required to support PM system implementation?
- Is the current IT infrastructure capable of supporting these changes or will investment in additional IT resources be needed? (This includes personnel training as addressed above, as well as the potential hiring of additional personnel.) If so, what infrastructure resources are needed, and what is the associated cost and time frame for acquiring these resources?
- When exactly will the IT-related changes to support PM system implementation need to occur and at what cost?
- Are the above feasible given the needed implementation time frame? If not, what changes to the proposed PM system design/implementation plan will need to be made?

Finally, although the use of the PM system may to some extent evolve over time, to achieve the most benefit from its PM system and to decrease the likelihood of system failure, the organization should begin implementation with a plan for how the PM system will be used at regular, recurring intervals by a prespecified group of users to support business decisions. We refer to this as the performance review process. In general, in defining a structured review process, published guidelines suggest that it is important to determine appropriate answers to the following questions (Marr, 2006; Meekings, 1995, 2005; Neely et al., 2006; Meekings et al., 2009; Chearskul, 2010; Farris et al., 2011):

- At what organizational level(s) will each measure be reviewed and at what frequency? While a scorecard will be designed for a specific target system, different individuals within the target system may review the measures at different frequencies and some individuals may only review a subset of measures. Frequency depends on the needs of each organizational level and the role of the specific metric. However, typically it is recommended that the review occurs at least quarterly.
- Who will be the metric owner(s)? Will the metric owners collect the supporting data, or will the IT system or other individuals handle this step? What training is needed for metric owners?
- What methods will the owner(s) use to communicate performance results during performance review meetings and to other stakeholders? For example, some organizations have found it helpful to design standard graphical review templates that are used across all the different measures in the target systems scorecard (Farris et al., 2011).
- What statistical and other tools should be used to analyze current metric performance, and to what extent should analysis be done before versus during meetings? In general, a graphical representation of the metric trend over time and limits that denote the natural range of metric variation and the target for the metric are recommended for metric portrayal and analysis. Comparisons to competitors can also be added to this portrayal if it does not make the portrayal too busy, or as an additional chart.
- How should decisions be made regarding actions to improve organizational performance on metrics? What problem-solving tools or causal models, such as strategy maps, should support these decisions, who should be involved, and how should consensus be reached? It is also recommended that formal problem solving tools—for example, Pareto charts and correlation analysis—be used for drill-down analysis and other problem-solving efforts. Meanwhile, design of experiments and regression analysis can be used to verify hypothesized causal relationships. Structured group brainstorming tools, such as nominal group technique (NGT), can also be useful for the problem-solving process. Further, it is important that the organization emphasizes decision-making—a formal decision should be reached on each metric during each meeting—even if it is to do nothing at present and to continue to analyze/observe metric performance. Otherwise, it is easy for organizations to get caught up in the analysis and reporting cycle and to feel that they have achieved something through the identification of problem-solving efforts, without perhaps even realizing that they have failed to develop a clear plan for implementation (Farris et al., 2011).
- How should decisions and the effects of improvement actions be communicated to the rest of the organization? Documenting decisions and communicating them to the

rest of the organization is just as important as making them in the first place. Formal project manager tools can be used to document action plans and stakeholder responsibilities. A single individual from the performance review team, for example, a group secretary, might be charged with documenting group decisions and other highlights from the meeting, or metric owners might individually document the decisions and other findings related to their metrics, and these findings can then be combined and disseminated to the group as a whole in the full meeting minutes. Also, if the organization has developed a plan for communicating performance review information to individuals not involved in the meeting at regular intervals, for example, newsletters, visibility boards, regular updates to the PM software/organization's intranet, or briefing meetings, this will aid in communicating regular performance information to other stakeholders. As any of the stakeholders become involved in more specific initiatives to improve performance on a given metric or metrics, more detailed information (including any necessary training) should also be communicated to them under the leadership of the director of the initiative (who may or may not be the metric owner).

- How should the effect of improvement initiatives be tracked over time, and when should decisions be made to modify improvement initiatives? The organization should build the reporting on progress of improvement initiatives into their regular performance review process. However, it is likely that progress might need to be reviewed more frequently by the director of the initiative and his/her team, as well as possibly by the initiative sponsor. Although leeway is needed for individual manager judgment, the organization should also seek to identify what sort of warning limits may indicate when a modification is needed to the improvement initiatives. For example: How much time delay do we expect before we see performance improvements? What is the minimum acceptable performance improvement? Do we expect performance to get worse before it gets better? If so, how long will this worsened performance be tolerated and what is the maximum deviation allowed?

The organization should seek to develop, deploy, and continuously refine a comprehensive performance review plan addressing all the above elements as it implements its PM system. The initial performance review process may also need to be further refined in the use phase.

30.1.8.2 How Should an Organization Use Its Performance Measurement System?

Although it may be necessary to collect certain performance data purely for the purpose of reporting to external stakeholders, for example, for regulatory purposes or for the higher-level target system, for the most part, PM data that are not actively used at all to support organizational decision-making are ultimately worthless or, worse, detrimental to the organizational unit. As previously mentioned, this is a challenging prospect, with only the minority of PM system implementations achieving long-term success in ongoing use. In addition to the problems previously mentioned in the design and implementation sections, other challenges to achieving successful ongoing use include difficulty in effectively linking the PM system to: the strategic planning process, the organizational reward system, organizational learning mechanisms, and, in particular, broader organizational transformation efforts. However, if the organization is effective in achieving systematic, ongoing use of the PM system, the system can play an integrating role in overall organizational transformation (improvement) efforts. Specifically, effective PM system use can

increase employee learning and accountability, organizational alignment, and teamwork, which in turn leads to improved organizational performance.

In fact, one recent empirical study found support for this causal chain through certain PM use practices (Chearskul, 2010). Specifically, the study found that use of the PM system within organizations can be characterized as consisting of five distinct activities: monitoring, problem-finding, problem-solving, validating causal relationships, and validating improvement actions. The two most influential use variables both had positive impacts on performance: monitoring and problem-solving. Monitoring was found to directly impact nonfinancial performance, which in turn drives financial performance. Problem-solving was found to indirectly improve nonfinancial performance and financial performance by increasing organizational learning, specifically improving shared vision.

Meanwhile, the study also found that two variables (problem-finding and validating causal relationships) had smaller negative impacts on performance, while validating improvement actions had no impact on performance. Conversely to problem-solving, problem-finding was found to reduce shared vision within organizations, negatively impacting both nonfinancial and financial performance, although this effect was much smaller than the positive impact of problem-solving. Validating causal relationships had a smaller negative impact on financial performance by increasing team learning (another organizational learning variable), which, counter to the study hypothesis, was found to negatively impact financial performance. However, as the literature consistently supports the importance of validating causal relationships, it may be that there are delayed effects for this variable, which were not measured in the cross-sectional study. It also appears that the impact of team learning may be delayed or that too much emphasis on work team learning activities may reduce performance by taking too much time away from production activities.

The results from the above study, and others, suggest that organizations must carefully design and implement their PM systems to promote the right type of use activities, for example, monitoring and problem-solving, avoid focusing too much on potentially detrimental activities, for example, problem-finding, and carefully approach and study activities with effects which are not yet well understood, for example, validating causal relationships and validating improvement actions.

In order to increase the likelihood of success in long-term ongoing use, it is therefore clearly important that organizations follow the previous steps in achieving a sound design and initial implementation plan. However, the organization's efforts cannot stop there. Instead, the organization must seek to refresh and refine its PM system through regular assessment (either formal or informal) of PM system effectiveness (Bauer et al., 2004).

Although it contains elements that look beyond the actual performance measurement process, the improvement system assessment tool (ISAT) (Van Aken et al., 2005) is one tool developed to guide organizations through the process of auditing their PM systems to identify strengths and opportunities for improvement. Specifically, the ISAT uses scoring dimensions based on the MBNQA and EFQM evaluation approaches to determine the extent to which the organization demonstrates maturity in each of the three key aspects of its PM system: measurement system design (Table 30.4), measurement system development and implementation (Table 30.5), and results achieved through the PM system (Table 30.6). Measurement system design and measurement system deployment and implementation are scored using the four categories in Figure 30.3. Meanwhile, the results achieved are scored in terms of trends, goals, comparison, and causes (see Table 30.6). Each dimension is on an anchored scale of 0–100, using a format similar to the MBNQA template for scoring the results criteria.

TABLE 30.4 Assessment Template for the Measurement System Design Element within the ISAT

Scoring Dimension	Assessment Dimensions/Items	Examples of Supporting Tools
Approach	<i>Structured approach</i> for defining metrics <i>Cross-functional involvement</i> in defining metrics (e.g., leadership team, . . .) Use of group process <i>tools</i> to define metrics	Strategy mapping, BSC, Performance prism, and so on
Deployment	Metrics (scorecard design) <i>deployed</i> to lower levels if applicable Metrics clearly and consistently <i>communicated</i> Internal to the organization, promoting accessibility and real-time use External to the organization Metrics <i>cover</i> all critical Functions, processes, and work units in the organization	Visibility boards, email/intranet, newsletters, all-employee meetings, . . . Stakeholder meetings Audit of metrics deployment
Study	The scorecard has metrics that are <i>Focused</i> (the “vital few”) <i>Aligned</i> with Burning platform Vision and value-added Higher-level system Desired behaviors Reward system <i>Balanced</i> (across dimensions in multiple frameworks) . . . Proposed <i>relationships</i> across metrics have been defined. Metrics can be linked to employee work activities	Audit of metrics to vision, mission, KSFs Metrics Balance Check on System Components Metrics Balance Check on BSC/EFQM Metrics Audit Metrics Deployment Chart
Refinement	Metrics are refined based on <i>study</i> activities, if environment <i>changes</i> , and/or if they are no longer <i>needed</i>	Action reports and follow-up mechanisms

A case study of the use of the ISAT within the Belgian Railways demonstrated the usefulness of the framework in focusing organizational improvement efforts and providing a baseline for future assessments. Specifically, the assessment revealed the existing PM system was relatively strong in some, but not all, design elements, but weaker in implementation elements. In addition, the organization was noticeably stronger in approach than the other assessment scoring dimensions, particularly refine. Similarly, the

TABLE 30.6 Results Scoring Template for ISAT

Key Performance Area		Metric									
Rating Scale		Type of Metric: End-Result or Driver									
		0%		25%		50%		75%		100%	
Trends		No result, poor result or negative trend		Some improvement and early positive trend and/or fair performance		Positive trend and/or good performance		Sustained positive trend and/or excellent performance		Sustained excellent trend and/or sustained excellent performance	
What is our level of performance and trend?											
Goals		No result, poor result or negative trend		Some improvement and early positive trend and/or fair performance		Positive trend and/or good performance		Sustained positive trend and/or excellent performance		Sustained excellent trend and/or sustained excellent performance	
How are we performing against goals?											
Comparison		No comparison and/or unfavorable comparison		Somewhat favorable comparison, mostly internal sources		Somewhat to moderately favorable comparison with external sources		Favorable comparison, mostly external sources		Best in class and/or industry leader	
How are we performing against comparisons?											
Causes		No investigation of causes		Causes proposed and assumed		Causes monitored and some evidence for relationships		Causes monitored and strong evidence for relationships		Causes monitored and controlled	
How are we managing performance proactively?											
Overall Rating		No result, poor result or negative trend		Some improvement and early positive trend and/or fair performance		Positive trend and/or good performance		Sustained positive trend and/or excellent performance		Sustained excellent trend and/or sustained excellent performance	
Strengths		No result, poor result or negative trend		Some improvement and early positive trend and/or fair performance		Positive trend and/or good performance		Sustained positive trend and/or excellent performance		Sustained excellent trend and/or sustained excellent performance	
- T:		No result, poor result or negative trend		Some improvement and early positive trend and/or fair performance		Positive trend and/or good performance		Sustained positive trend and/or excellent performance		Sustained excellent trend and/or sustained excellent performance	
- G:		No result, poor result or negative trend		Some improvement and early positive trend and/or fair performance		Positive trend and/or good performance		Sustained positive trend and/or excellent performance		Sustained excellent trend and/or sustained excellent performance	
- C:		No result, poor result or negative trend		Some improvement and early positive trend and/or fair performance		Positive trend and/or good performance		Sustained positive trend and/or excellent performance		Sustained excellent trend and/or sustained excellent performance	
- C:		No result, poor result or negative trend		Some improvement and early positive trend and/or fair performance		Positive trend and/or good performance		Sustained positive trend and/or excellent performance		Sustained excellent trend and/or sustained excellent performance	
To be verified		No result, poor result or negative trend		Some improvement and early positive trend and/or fair performance		Positive trend and/or good performance		Sustained positive trend and/or excellent performance		Sustained excellent trend and/or sustained excellent performance

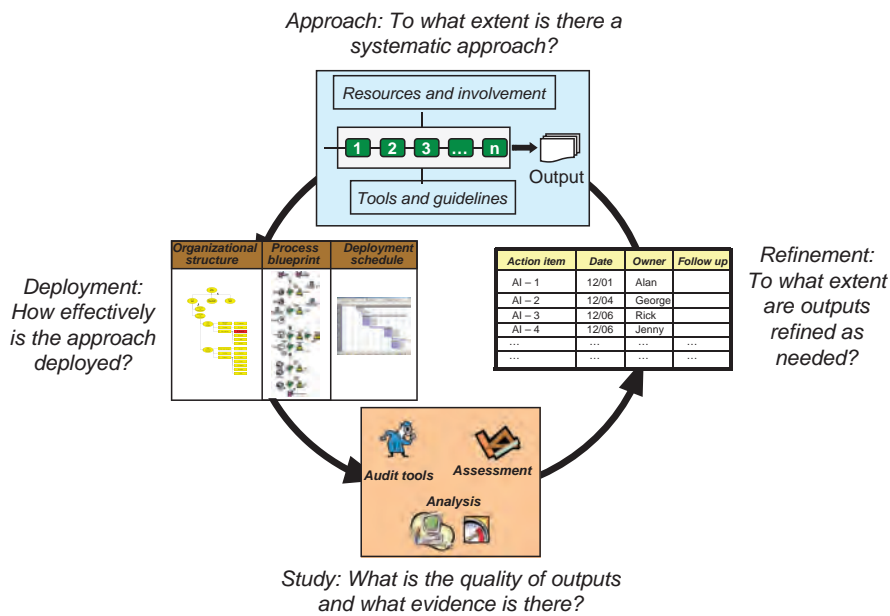

FIGURE 30.3 ADSR scoring dimensions used within the ISAT (Van Aken et al., 2005).

results assessment revealed the need to significantly improve performance on five of the six key measures assessed, and also to identify better benchmarks for comparisons and improve the monitoring of presumed driver.

30.2 SUMMARY

Developing an effective PM system is clearly a difficult prospect, with many different factors related to the design, implementation, and ongoing use of the system to which the organization must attend. The goals of this chapter were to provide an overview of the purpose and content of PM systems, as well as to provide high-level guidelines for their design, implementation, and use. The reader is encouraged to consult one of the full-length books on the subject—for example, Andersen and Faguerhaug (2002), Brown (2000), Brown (2007), de Waal (2002), and Neely et al. (2002)—for more detail and additional viewpoints on the design, implementation, and use processes.

31.1 VISCOSITY BACKGROUND

The most significant mechanical difference between materials classified as “fluids” and those classified as solids is in their reaction to shear stresses. (Recall that a shear stress is a distributed force, or force per unit area, whose direction of action is within the

FIGURE 31.1 Fluid (viscous) versus Solid (elastic) behavior. (a) *Fluid Behavior*: A thin layer of fluid held between two parallel plates, the top plate caused to move relative to the bottom plate by application of a shear stress, will continue to deform (experience shear strain) as long as the shear stress is applied. The *rate* of shear strain is related to the magnitude of the shear stress. When the shear stress is removed the fluid will remain in its deformed state. (b) *Solid (Elastic) Behavior*: A solid will deform (experience shear strain) through some fixed angle when a shear stress is applied. The *amount* of shear strain is related to the magnitude of the shear stress. When the shear stress is released the solid will return to its original form.

plane of application. If you slide your open hand over a desk top the friction between your hand and the desk will create a shear stress on your hand.) As illustrated in Figure 31.1, a solid (within its elastic limit) will deform through some limited angle while a shear stress is applied, and will then return to its original configuration when the stress is removed. A fluid on the other hand will deform continuously as long as a shear stress is applied, and will not return to its original shape when the stress is removed. For a fluid the *rate* of shear deformation is related to the magnitude of the shear stress applied, while for a solid the *amount* of shear deformation is related to the magnitude of the shear stress applied. This seemingly innocuous mechanical difference in reaction to shear stresses gives rise to the large difference in character between solids and fluids. In fact it gives rise to all of the behaviors that one thinks of as inherently "fluid": the ability to flow, the ability to fill volumes of arbitrary shape, the ability to spread out and "wet" certain surfaces, etc. It also gives rise to the complex nature of fluid mechanics because it allows for the very large material deformations that in turn give rise to phenomena like turbulence.

Viscosity (or more precisely the *shear viscosity*, defined below) is the material property that defines the quantitative relation between the applied shear stress and the shear deformation rate in a fluid. Qualitatively the viscosity indicates the "thickness" or resistance to flow of a fluid. Since viscosity is the property that controls and quantifies the shear stress/shear rate behavior that is definitional to fluids, it is in many regards the most important physical property of a fluid.

Unfortunately, as alluded to above, the term “viscosity” is actually used to denote several related, *but different*, physical properties. It is important to understand these distinctions in terms from the outset. First, the term “viscosity” is most commonly used in conjunction with effects arising from *shear* forces and *shear* deformations in fluids. When used in this context, the most common one, the property is more precisely called the “shear viscosity” or the “first coefficient of viscosity.” However, when used in this sense, it is almost always simply referred to as “viscosity.” This is contrasted with the “bulk viscosity,” associated with volume dilatation. Bulk viscosity is rarely an important parameter and hence is not as well known or understood as the more common shear viscosity. Bulk viscosity is discussed briefly in Section 31.1.3. Second, it should be noted that even the “shear viscosity” described above is often stated in two different forms, the *absolute* or *dynamic* viscosity, μ , and the *kinematic* viscosity or *momentum diffusivity*, ν , where $\nu = \mu/\rho$ and ρ is the fluid’s density. Although the *dynamic* and *kinematic* viscosities are clearly related properties, they are dimensionally dissimilar and it is critically important to always distinguish between them. More is said on the distinction between dynamic and kinematic viscosity in the following section on common viscosity units.

The remainder of this chapter begins by discussing the units in which viscosity is measured. Then the distinction between the larger field of rheology and its subfield viscometry is made in the context of differentiating between the so-called Newtonian and non-Newtonian fluids. After that the chapter provides a brief theoretical and mathematical overview of viscosity. Finally, the majority of the chapter provides detailed and practical information on methods for measuring viscosity.

31.2 COMMON UNITS OF VISCOSITY

There are several systems of units used with viscosity; many of them are archaic and/or closely tied to one specific viscosity measuring technique (e.g., the Saybolt cup and the “Saybolt Universal Second,” and the Krebs unit) or one particular industry (e.g., SAE oil grade and the automotive industry). It is impossible to capture all of these systems in one document, but an attempt is made below to define and relate the most common and standard units associated with viscosity measurement.

31.2.1 Absolute Viscosity, μ

In terms of the SI (Le Systeme Internationale d’Unites) system of fundamental units the derived units for absolute viscosity, μ , are $\text{kg}/\text{m} \times \text{s}$ which is equivalent to $\text{Pa} \cdot \text{s}$ (Pascal-seconds). This grouping of units has not received a name of its own. In the closely related cgs (centimeter, gram, and second) system of units, the derived unit of $\text{g}/\text{cm} \times \text{s}$ or $\text{dyne} \times \text{s}/\text{cm}^2$ is called a “Poise” (after Poiseuille). More commonly a centipoise, $\text{cP} = 1/100\text{th}$ of a Poise is used. In the FPS (foot, pound, and second) system of units, the units of absolute viscosity are $\text{lb}_F \cdot \text{s}/\text{in}^2$, which is called the Reyn (after Osborne Reynolds). Refer to Table 31.1 for a collection of units of absolute viscosity.

TABLE 31.1 Units for Absolute/Dynamic Viscosity, μ

Units System	Derived Viscosity Unit		Unit Name	Equivalence
SI	$\frac{\text{kg}}{\text{m} \times \text{s}}$ $\text{Pa} \times \text{s}$	or	none	$1 \text{ Pa} \cdot \text{s} = 10 \text{ Poise} = 1000 \text{ Centipoise}$
cgs	$\frac{\text{g}}{\text{cm} \times \text{s}}$ $\frac{\text{dyne} \times \text{s}}{\text{cm}^2}$	or	Poise	$100 \text{ Centipoise} = 1 \text{ Poise}$
English (FPS)	$\frac{\text{lb}_F \times \text{s}}{\text{in}^2}$		Reyn	$1 \text{ Reyn} = 68,948 \text{ Poise}$

31.2.2 Kinematic Viscosity, ν

Recall that the dynamic (kinematic) viscosity, ν , is defined as the absolute viscosity divided by the fluid density, ρ . In the SI system of fundamental units the units for kinematic viscosity are meter square per second, which is not a named grouping. It should be noted that the units of kinematic viscosity (m^2/s) are identical to the units of thermal diffusivity used in heat transfer, and mass (species) diffusivity used in diffusion. This leads to the kinematic viscosity being referred to as the coefficient of momentum diffusivity by analogy. In the cgs system the unit of kinematic viscosity is the centimeter square per second called the “Stokes” (after G.G. Stokes). More commonly the kinematic viscosity is given in centistokes (cSt) where $100 \text{ cSt} = 1 \text{ Stokes}$. In the FPS system kinematic viscosity would be foot square per second or inch square per second, neither of which is a named unit.

31.2.3 Nonstandard Units

Kinematic viscosity is also often given in “Saybolt Universal Seconds” or SUS (also sometimes SSU “Saybolt Seconds Universal” or SUV “Saybolt Universal Viscosity”), which is directly related to the Saybolt viscosity cup measuring system (see Section 31.2.2). Of course, the unit of “seconds” is not a dimensionally correct unit for the physical quantity of kinematic viscosity, so this system is problematic. The Saybolt measurement system is based on ASTM method D88 and measurements in SUS can be converted into more standard (dimensionally correct) viscosity units using procedures provided in ASTM 2161. There are countless other such “legacy” scales of viscosity associated with different industries, and unfortunately there is often no standard method for converting these legacy measures into dimensionally correct viscosity units. A number of online viscosity converters exist (see www.coleparmer.com, www.gardco.com, or www.cannon.com, for example) (Table 31.2).

31.2.4 Distinction Between Rheology and Viscometry

A simple linear relationship between shear stress and shear strain rate is observed in a wide variety of fluids (Figure 31.2a). The constant slope of the line labeled Newtonian is

FIGURE 31.2 Newtonian and non-Newtonian fluid behavior (a) shear stress vs. strain rate (b) shear stress vs. duration of applied strain rate.

the (shear) viscosity of the fluid. Fluids demonstrating such a relationship are known as *Newtonian fluids*. Many common fluids like air, gases in general, water, or simple oils demonstrate Newtonian behavior meaning constant viscosity with respect to strain rate over a very wide range (many orders of magnitude) of strain rates. The measurement of the shear viscosity of Newtonian fluids is referred to as *viscometry* and is the focus of this chapter.

Fluids with more complicated molecular structures (e.g., polymers) or fluids with other phases suspended in them (e.g., mixtures, slurries, and colloids) often demonstrate more complicated shear stress to strain rate behaviors (see Figure 31.2a). Fluids exhibiting such behaviors are broadly characterized as “non-Newtonian” fluids. Non-Newtonian fluids can be further classified according to how they react to changes in shear deformation rates, to the duration of application of the applied loading, and to whether or not they exhibit a threshold elastic (solid-like) shear resistance prior to deforming like a fluid.

Fluids that show increasing *apparent viscosity* (the *apparent viscosity* is the local slope of the stress versus strain rate curve, see Figure 31.2a) as the applied strain rate increases are called “shear thickening” or *dilatant* fluids. The classic example of a shear thickening fluid is a mixture of cornstarch in water. If one attempts to shear this fluid quickly (e.g., hit it with a hammer) the viscosity will rise to such a level that the fluid seems almost solid, the hammer blow will bounce off the surface. Yet at lower shear rates the mixture will act like a “normal” fluid (e.g., a hammer set on its surface would sink right into the fluid). Fluids which show the opposite behavior (decrease in apparent shear viscosity with increasing strain rate) are called “shear thinning” or *pseudo-plastic* fluids. A common example of a shear thinning fluid would be “no drip” paint, which behaves as a fairly thick (viscous) fluid while adhering to a paintbrush (a low shear rate circumstance), but which spreads easily (i.e., exhibits lower viscosity) when the paintbrush is dragged along a surface thereby increasing the shear strain rate applied to the fluid (Cengel and Cimbala, 2010).

Some fluids will “thin” (produce a lower shear stress resisting the motion) or some will “thicken” (produce a higher shear stress resisting the motion) as the *duration* for which a constant strain rate is applied increases, (see Figure 31.2b). Fluids exhibiting the former behavior are referred to as “thixotropic” the latter as “rheopectic.” Such fluids are also sometimes referred to as “time-thinning” or “time-thickening” fluids. Examples of thixotropic fluids include yogurt and some classes of paint. Rheopectic behavior is much rarer.

Examples include gypsum paste and printers ink. Newtonian fluids exhibit constant strain rate with regard to loading duration for a constant applied shear stress.

Newtonian fluids will exhibit constant strain rate to shear stress behavior down to very low (theoretically zero) applied shear stresses. However some fluids, called “Bingham plastic” fluids will initially show “solid-like” behavior until a threshold shear stress (called the “yield stress”) is applied; after which they will show “fluid-like” behavior (continuously deforming while the shear stress is applied) (see Figure 31.2a). A common example of this type of fluid is toothpaste, which will not flow at all until a threshold shear value is exceeded. Broadly this kind of behavior is described as viscoelasticity. Bingham plastic materials can show dilatant, Newtonian, or pseudo-plastic behavior after their yield point. It is also worth noting that these terms are often not consistently applied.

The study and measurement of these more complicated, non-Newtonian, shear stress/-shear strain rate behaviors is a subset of the larger science referred to as rheology and is largely beyond the scope of this chapter.

31.2.5 Mathematical Formalism

In this section we develop the mathematical formulations governing viscosity, and explain the roles and relations between “shear” viscosity and “bulk” viscosity. The discussion begins with the consideration of a very simple one-dimensional (1D) flow situation, and then introduces the more general 3D form of the equations.

Shear viscosity is defined mathematically by Newton’s Law of Viscosity. Newton’s law defines viscosity as the physical property that relates the shear stress produced as a reaction to an applied strain deformation rate. If one considers the simple flow shown in Figure 31.1a, a thin layer of fluid confined between two infinite parallel flat plates the upper moving within its own plane relative to the lower, the total *shear strain rate* on any layer in the fluid is given by $\partial u/\partial y$ which is the rate of change of x direction velocity in the perpendicular (y) direction. Newton’s law states that the shear stress experienced on the lower face of such a layer is given by:

$$\tau = -\mu \frac{du}{dy} \quad (31.1)$$

where μ is the (shear) viscosity of the fluid at the applied strain rate. If the shear viscosity is constant with regard to strain rate then the fluid is said to be “Newtonian.” If the fluid exhibits a more complex relationship between shear stress and strain rate the fluid is defined as “non-Newtonian.” Distinctions between Newtonian and non-Newtonian behavior is discussed in greater detail in Section 31.1.2.

The viscosity picture becomes more complicated if we allow for more complex (3D) motions of the fluid. Any motion that a “particle” of fluid can undertake can be constructed from a superposition of the following four simpler types of motion: pure translation (movement without rotation or deformation), pure rotation (rotation without movement or deformation), pure linear strain (deformation without motion that does not disturb angles within the fluid particle), and pure shear strain (deformation without motion which does change angles within the fluid particle). Figure 31.3 illustrates these types of motions in two dimensions. In a fully general flow any combination of these motions can occur in any or all of the three coordinate directions. In such cases independent shear deformations (Figure 31.3d) can occur on any or all of three orthogonal planes.

FIGURE 31.3 Types of fluid motion and deformation illustrated in 2-D.

The fluid can also undergo purely extensional deformations (i.e., elongations without shear, Figure 31.3c) in any or all of the three dimensions. These extensional deformations will in some circumstances also contribute to the stress response of the fluid, for example, if they combine in such a way that the volume of the fluid element changes then the “bulk viscosity” described below will also be important. Thus for general 3D deformations it is necessary to use tensors (a branch of mathematics that describes vectors pointing in several directions) to describe the full relation between the stress at a point in the fluid and the resulting strain.

The stress response of a Newtonian fluid element in response to a fully general deformation is given in White (2006) as

$$\tau_{ij} = -P\delta_{ij} + \mu \left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} \right) + \delta_{ij}\gamma(\nabla \cdot \vec{V}) \quad (31.2)$$

Here μ is the shear viscosity, γ is the “Bulk Viscosity” coefficient and δ_{ij} is the Kronecker delta function (i.e., $\delta = 1$ when $i = j$, and $\delta = 0$ when $i \neq j$), and i and j are indices used to refer to the three orthogonal planes. Those interested in the derivation of this relation are directed to White or any other graduate level fluids text.

One important point to note arising from Equation (2) is that the stress response to purely extensional strains is described by the bulk viscosity, γ , or through the closely related “second coefficient of viscosity” μ' (the bulk viscosity, γ is equal to the second coefficient of viscosity, μ' , plus $2/3 \mu$, see Owczarek (1964), for example, for a more thorough discussion). The topic of bulk viscosity is largely beyond the scope of this chapter, but these few comments are made to inform the reader of when it may be safely ignored, and when it may become important. First it is important to note that the bulk viscosity is not as well understood or characterized as the more common shear viscosity. Fortunately, for Newtonian fluids, the bulk viscosity coefficient occurs only in combination with the divergence of the velocity field ($\nabla \cdot \vec{V}$); and for incompressible fluids conservation of mass (i.e., continuity) requires that $\nabla \cdot \vec{V} = 0$. Hence the bulk viscosity will play no role in a truly incompressible fluid.

Of course no substance is truly 100% incompressible, so if one is concerned with acoustic issues (which are inherently a compressibility phenomenon) or flows at significant Mach number the bulk viscosity may play a role. One way to gain insight on when the bulk viscosity may play a significant role is to examine its role in viscous dissipation.

Ultimately the role of viscosity (shear or bulk) is to irreversibly convert the mechanical energy in a flow into thermal energy (heat). This effect is known as “viscous dissipation.” Hence the magnitude of the dissipation caused by the viscosity can give one indication of the qualitative importance of viscosity in the flow. The dissipation (Φ) caused by the bulk viscosity is given by Shaughnessy et al. (2005) as:

$$\Phi_{bulk} = \frac{\gamma}{\rho^3} \left(\frac{d\rho}{dt} \right)^2 \quad (31.3)$$

where γ is the “bulk viscosity” and ρ is the density. In order to be significant, either large changes in density are required, or the changes in density must occur over very short time scales. Thus, due to the relative magnitudes of the extensional strains typically involved, the dissipation due to bulk viscosity (and indeed the bulk viscosity itself) may safely be ignored for almost all practical applications except shock waves (which involve large changes in density) and attenuation of high frequency (small dt) sound or “ultrasound”. Henceforth in this chapter the term “viscosity” shall refer to “shear viscosity” only.

31.2.6 Relation of Viscosity to Molecular Theory

As discussed above, ultimately the role of viscosity is to dissipate the ordered kinetic energy associated with the macroscopic motions of a flow to disordered, randomly distributed, microscopic molecular energy (i.e., thermal energy). As such it becomes clear that the quantity that we refer to as viscosity is the macroscopic manifestation of molecular level effects; much in the same way that the macroscopic quantity of “pressure” represents the average net force per unit area caused by countless individual molecular collisions on a surface. That is to say that viscosity, like pressure, temperature, and density, is a “continuum property” of a substance. It makes no more sense to talk about the “viscosity” of a single molecule than it does to talk about the “density” of a single atom of a gas. The fact that the viscosity is an emergent property arising only for large collections of molecules places an important limitation on the concept of fluid viscosity, namely the continuum limit. Essentially the (continuum) concept of viscosity breaks down when applied on length scales that are comparable to the mean free path of the molecules in the fluid, or when applied on time scales that are comparable to the mean time period between molecular collisions in the fluid. For ordinary macroscopically sized flows at ordinary pressures the continuum limit is not a concern. However in applications such as nanotechnology (where the length scales of concern become very small) or rarefied gas dynamics (where the mean free path of molecules in very low density gases becomes very large) this limit should be kept in mind.

Examining how the macroscopically observed property of viscosity arises from molecular effects can provide insight and physical intuition about viscosity. If we examine how momentum is transported by the thermal (random) motions of molecules within a flow we can come to understand the molecular basis for viscosity.

First, let us consider the physics qualitatively. To do so consider again the simple 1D shear flow shown in Figure 31.1. Specifically consider the molecules near a plane parallel to the top plate and half way between the top plate and the bottom plate. All of these molecules will have velocities that are composed of their individual, random (thermal)

velocities (which average out to zero bulk velocity), plus a small extra velocity component which depends on the local value of the bulk velocity. Those molecules slightly above the plane will, on average, have slightly larger values of velocity in the x direction and therefore also have slightly higher values of x direction momentum. Similarly, on average, those below the plane will have slightly lower values of x velocity and momentum. All of the molecules (above and below the plane) will have random thermal velocities with components in all three directions. The y component of these random velocities will occasionally carry molecules across the plane in both directions. But because of the asymmetry in velocity above and below the plane (i.e., because of the gradient of velocity perpendicular to the plane) the net effect of these random cross plane exchanges will be to transport x momentum from above the plane to below the plane. That is, there will be a net flux of x momentum in the negative y direction.

In fact the quantity we call “viscosity” is precisely defined by this “diffusive” transport (i.e., transport caused by random molecular motions rather than bulk macroscopic fluid motions) of momentum in the direction opposite to a velocity gradient. A simple dimensional analysis will convince the reader that a stress, such as shear stress (measured in $\text{Pa} = \text{kg/m s}^2$), is dimensionally identical to a flux of momentum (transport of momentum per second per unit area $= \text{kg/m s}^2$). Thus, referring back to Equation (1), we can consider viscosity to be the fluid property that relates the diffusive momentum flux (τ) to the velocity gradient driving it.

31.2.7 Effect of Pressure and Temperature on Viscosity

31.2.7.1 Low Density Gases We can make this relationship more quantitative by examining the actual molecular interactions occurring in the fluid. The following development parallels that given by Bird et al. (1960), but similar developments can be found in any text covering the kinetic theory of gases. The simplest model of viscosity arises from a consideration of simple kinetic theory of a low density gas where we assume that the gas molecules are rigid spheres with diameter “ d ” that only interact through collisions (i.e., there are no forces causing “action at a distance” between molecules). Thus molecules will exchange momentum and come into equilibrium with their surroundings only through collisions. Kinetic theory for rigid sphere molecules also provides these other important results that will be used in this development:

- The average random (thermal) velocity of the molecules in the gas will be

$$\bar{V} = \sqrt{\frac{8kT}{\pi m}} \quad (31.4)$$

where k is Boltzman’s Constant, m is the mass of the individual molecules and T is the absolute temperature.

- The mean free path of a molecule between collisions, λ , will be

$$\lambda = \frac{1}{\sqrt{2}\pi d^2 n} \quad (31.5)$$

where n is the number density (number per unit volume) of the gas molecules.

- The average frequency of collision per unit area (from one side) on any plane in the flow

$$Z = \frac{1}{4} n \bar{V} \quad (31.6)$$

If one again considers the situation of a plane between the two plates in Figure 31.1 it can be shown that a molecule will travel an average vertical distance of $2/3 \lambda$ between collisions. The flux of x momentum transferred across the plane from below is then $Zm v_{x,y-2/3\lambda}$ where $v_{x,y-2/3\lambda}$ is the average excess (nonthermal) x velocity component at a y location “one collision distance” below the plane (i.e., at $y-2/3\lambda$). Similarly the flux of x momentum transferred across the plane from above is, $Zm v_{x,y+2/3\lambda}$. Thus the net x momentum flux is:

$$\tau = Zm v_{x,y-2/3\lambda} - Zm v_{x,y+2/3\lambda} \quad (31.7)$$

And, if the x velocity gradient in the vicinity of y is linear we can replace the v_x at locations above and below the plane with a first order Taylor series in terms of the gradient at the plane, yielding:

$$\tau = Zm \left\{ \left(v_{x,y} - \frac{2}{3} \lambda \frac{dv_x}{dy} \right) - \left(v_{x,y} + \frac{2}{3} \lambda \frac{dv_x}{dy} \right) \right\} \quad (31.8)$$

Simplifying and substituting in the definition of Z gives:

$$\tau = \frac{-1}{3} nm \bar{V} \lambda \frac{dv_x}{dy} \quad (31.9)$$

Comparing back to Equation (31.1) we can see that:

$$\mu = \frac{1}{3} nm \bar{V} \lambda \quad (31.10)$$

Further substitution for \bar{V} and λ yields:

$$\mu = \frac{2}{3} \frac{1}{\pi^{3/2}} \frac{\sqrt{mkT}}{d^2} \quad (31.11)$$

Thus if the molecules are considered as perfectly rigid spheres (the simplest model) then $\mu \sim \sqrt{T}$. Note also that the viscosity of such a gas is not expected to be a function of pressure based on this very simple molecular model. This is an important result which is largely borne out by experimental observations of real low-density gases; their dynamic viscosity is observed to depend only very weakly on pressure.

Of course molecules are not perfectly rigid spheres for that would imply no force whatsoever between molecules until they come into contact (when their center to center distance equals d) and then an infinite repulsion force. Clearly the idea of an infinite repulsion force is unphysical. In fact all molecules will show some “action at a distance” and, more importantly, act as if they have some “give” or flexibility when they “collide”

which will eliminate the unphysical infinite forces inherent in the simple rigid sphere model. Typically these interactions are modeled as an intermolecular “potential” function from which the magnitudes of attractive and/or repulsive forces as a function of center to center distance can be calculated; as can an “effective” molecular diameter. The exact nature of these intermolecular potential functions is complicated, and has received extensive study, but is largely beyond the scope of this chapter. The interested reader is directed to Kogan (1969) or Vicenti and Kruger (1965), for example. Here it is sufficient to make a few points. First, as more complex and precise relations for the potential theory are used, the predictions of macroscopic properties such as viscosity improve markedly. Second, the “action at a distance” effects associated with these potentials allow for pressure to have an effect on the viscosity of gases. But, as stated above, this is typically found to be a weak effect for common gases. And finally, the functional relation between the viscosity and the temperature in low-density gases depends critically on the details of this potential function.

The next simplest model of intermolecular relations (after the rigid sphere model) is one proposed by Maxwell. In such a model the potential function drops off as $1/s^4$ where s is the center to center distance between the molecules. With such a model it can be shown that the “effective molecular diameter” will vary as: $d^2 \sim 1/\sqrt{T}$ and so, referring back to Equation 11, $\mu \sim T$. That is, a gas composed of “Maxwellian” molecules will have a viscosity that will increase linearly with temperature, as opposed to with the square root of temperature predicted from the rigid sphere model.

31.2.8 Correlations of Viscosity with Temperature for Gases

In reality, gases typically exhibit behaviors between the two extremes discussed in the section above (rigid and “Maxwellian”) and so their viscosity’s dependence on temperature is commonly correlated with a power-type law, as given by White (2006):

$$\frac{\mu}{\mu_o} = \left(\frac{T}{T_o} \right)^n \quad (31.12)$$

Where the parameters n , T_o , and μ_o are specific to the particular gas. Values for “ n ” for most simple gas molecules fall between 0.5 and 1, as predicted by the above discussion. Some values for n , T_o , and μ_o can be found in White.

Another common correlation technique for gas viscosities is based on the work of Sutherland (1893) (as covered in Vicenti and Kruger, 1965). Here viscosity is correlated as

$$\frac{\mu}{\mu_o} = \left(\frac{T}{T_o} \right)^{\frac{3}{2}} \left(\frac{T_o + S}{T + S} \right) \quad (31.13)$$

where S is the so-called Sutherland Parameter and T_o , and μ_o are reference values. A completely equivalent form of this equation:

$$\mu = \left(\frac{C_1 T^{\frac{3}{2}}}{T + S} \right) \quad (31.14)$$

where

$$C_1 = \left(\frac{\mu_o}{T_o^{\frac{3}{2}}} \right) (T_o + S) \quad (31.15)$$

is often used as well. Poling et al. (2004) provided a detailed discussions of several much more detailed methods for estimating the variation of viscosity of both pure gases and mixtures of gases at various temperatures.

31.2.9 Correlations of Viscosity with Temperature for Liquids

In real (higher density, more complex molecular structure) gases and especially in liquids intermolecular forces (beyond the “collisional” forces discussed previously) play a critically important role. Molecules in such substances can exert significant force (and hence transfer significant momentum) “at a distance” without colliding. Since viscosity as a property arises from transfers of momentum, these “actions at a distance” must be accounted for in any physical model that hopes to adequately predict a material’s viscosity. The nature and magnitude of these non-collisional interactions are so complex and so large in liquids that currently no one general model exists that will adequately predict the viscosity of all liquids. Instead many specialized empirical and semi-empirical relations are available. Some general trends however are observed for liquids, the most important being that *the viscosity of liquids falls off strongly with increasing temperatures*. One type of curve fit that is recommended for liquid viscosity, recommended by White (2006) is

$$\ln \frac{\mu}{\mu_o} \cong a + b \left(\frac{T_o}{T} \right) + c \left(\frac{T_o}{T} \right)^2 \quad (31.16)$$

where a , b , and c are curve fit parameters and T_o and μ_o are reference values. Another, slightly simpler, empirical correlation often used is “Andrade’s equation” (Munson et al., 2009)

$$\mu = D e^{\frac{B}{T}} \quad (31.17)$$

which is often presented in the alternate form

$$\ln \mu = A + \frac{B}{T} \quad (31.18)$$

Viswanath et al. (2007) provide a lengthy discussion of such correlation methods and coefficients A and B for a wide variety of liquids.

31.2.10 Effect of Pressure on Viscosity

The effects of pressure on viscosity are not nearly as significant as the effects of temperature. In many practical circumstances it is entirely sufficient to simply neglect the effect

of pressure on viscosity. This has lead to pressure effects being much less studied, and to data on viscosity at different pressures being much more sparse.

For low density gases, the molecular dynamics models discussed above (refer to Equation 31.10) indicate that the absolute viscosity, μ , should not depend on pressure at all; due to the competing effects of increasing number density (n) and decreasing mean free path (λ) as pressure is increased. Of course the value of the kinematic viscosity, $\nu = \mu/\rho$, of gases will decrease with increasing pressure due to the increase in density, ρ , of the gas as the pressure increases. These predictions are largely borne out by experimental data for common low-density (ideal) gases. Poling et al. (2004) provide a detailed discussion of several methods for estimating the viscosities of both pure gases and mixtures of gases at higher pressures.

Viscosity data for liquids at high pressure is sparse when compared to the quantity of data available at or near atmospheric pressures. In general, as pressure increases, so does the viscosity of most liquids. Both Viswanath et al. (2007) and Poling et al. (2004) recommend a method for estimating the effect of pressure on liquid viscosity attributed to Lucas (1981):

$$\frac{\mu}{\mu_{SL}} = \frac{1 + D \left(\frac{\Delta P_r}{2.118} \right)^A}{1 + C \omega \Delta P_r} \quad (31.19)$$

where μ is the viscosity of the liquid at pressure P ; μ_{SL} is the viscosity of the liquid at vapor pressure P_{vp} ; P_{vp} is the the vapor pressure; $\Delta P_r = (P - P_{vp})/P_c$; $T_r = T/T_c$; P_c, T_c are the critical pressure and temperature; ω is the acentric factor

$$A = 0.9991 - \left[\frac{4.674 \cdot 10^{-4}}{1.0523 T_r^{-0.03877} - 1.0513} \right] \quad D = \left[\frac{0.3257}{(1.0039 - T_r^{2.573})^{0.2906}} \right] - 0.2086$$

$$C = -0.07921 + 2.1616 T_r - 13.4040 T_r^2 + 44.1706 T_r^3 - 84.8291 T_r^4 + 96.1209 T_r^5 - 59.8127 T_r^6 + 15.6719 T_r^7$$

In spite of the theory and correlation techniques described above, in many practical situations one must resort to simply measuring viscosity. The following section describes the different measurement techniques available.

31.3 MAJOR VISCOSITY MEASUREMENT METHODS

Viscometers are designed to make use of the theoretical relationship between shear stress and strain rate to measure viscosity. They do this using simple flows (1D, steady, fully developed) in which both the shear stress and strain rate can be measured. There are three primary types of viscometers: flow, drag, and resonant. The flow-type viscometers measure the rate of flow of the fluid in a tube or through an orifice. The shear stress can be calculated from theory (e.g., capillary tube viscometer) or estimated based on theory (e.g., orifice cup viscometers). Use of these types of viscometers yields values for kinematic viscosity. Design parameters for flow-type viscometers include minimizing entrance and exit effects, maintaining a constant pressure head (which drives the flow), minimizing surface tension effects and mitigating effects of temperature variation.

Drag-type viscometers measure either the force on an object as it moves at a specified rate in the fluid (rotational viscometers) or measure the time it takes for an object to move a specified distance through the fluid (falling object and bubble tube viscometers). Use of these types of viscometers yields values for absolute viscosity (except for the bubble tube which measures kinematic viscosity). Design parameters for drag-type viscometers include minimizing the effects of turbulence and flow separation through the specification of a flow condition (generally a low relevant Reynolds number), controlling for transients, minimizing surface tension effects and mitigating effects of temperature variation. The third type of viscometer is the resonant or vibrational viscometer which is most commonly used in in-line process applications. These are designed so that changes in the viscous damping bring about significant changes in the resonance behavior of the instrument. Use of these viscometers yields values for kinematic viscosity.

This section presents information on each of the three major viscometer types. It begins with the drag-type viscometers (falling object, bubble tube, and rotational) followed by the flow-type viscometers (capillary and orifice) and concludes with a discussion of vibrational viscometers. Each section includes information on the theory of operation, a description of the types of viscometers available, a list of available manufacturers, and the capabilities and advantages/limitations. This chapter focuses on the use of laboratory-type viscometers; however some information is included on the use of process viscometers. This list of viscometers is not intended to be exhaustive but includes many of those that are most readily available commercially. There are other specialized methods for measuring viscosity and the reader is referred to Viswanath et al. (2007) for more information.

31.3.1 Drag-Type Viscometers

31.3.1.1 Falling Object Viscometers

Theory of Operation Falling object viscometers determine viscosity (μ) by measuring the drag force acting on a falling object under specific flow conditions. Use of the falling object viscometer requires a separate measurement of density to calculate kinematic viscosity. Figure 31.4 illustrates the forces acting on a falling object. This case shows a spherical object (a ball), however there are a variety of falling objects that can be used such as needles, and cylinders. There are three forces acting on the object: F_B the buoyancy force and F_D the drag force act upwards while F_G the gravitation force (weight) acts down. The buoyancy force is calculated using Archimedes principle and is equal to the weight of the fluid displaced by the object:

$$F_B = \nabla_B^* \rho_f^* g \quad (31.20)$$

where ∇_B is the volume of the object, ρ_f is the density of the fluid, and g is the gravitational constant. The weight of the object is simply:

$$F_G = \nabla_B^* \rho_B^* g \quad (31.21)$$

where ρ_B is the density of the object. If the object is travelling at terminal speed, the acceleration will be zero and application of Newton's second law yields an equation relating the three forces:

FIGURE 31.4 Schematic showing the forces acting on a falling object.

$$F_D = F_G - F_B = V_B^*(\rho_B - \rho_f)^*g \quad (31.22)$$

The drag force is composed of a shearing force (due to the fluid) and a pressure force (due to flow separation). Falling object viscometers are generally designed to operate in the Stokes (creeping) flow regime which is characterized by a lack of flow separation and occurs for very low Reynolds numbers ($Re < 0.1$). In this case the drag force is due only to the shearing force. For example, if the object is a sphere then the Reynolds number is calculated as

$$Re = \frac{\rho_f VD}{\mu} \quad (31.23)$$

Where V is the terminal speed of the object, D is the diameter of the sphere, and μ is the viscosity. For the low Reynolds number situation, the drag force is related to Reynolds number by Stokes Law:

$$F_D = \frac{3\pi\mu VD}{Re} \quad (31.24)$$

Combination of these equations yields an equation for viscosity in terms of the speed, diameter, and density difference:

$$\mu = \frac{gD^2}{18V}(\rho_{obj} - \rho_{fluid}) \quad (31.25)$$

This theory applies to balls moving at low Reynolds number in an infinite media (see Brizard et al. 2005 for development of the theory accounting for more realistic conditions). In many commercial applications, the falling object is placed in a tube of specified diameter (see Figure 31.5). The object, typically a ball, will fall or slide down the tube and

FIGURE 31.5 Falling ball viscometers (a) Gilmont and (b) Hakke type (Courtesy of Brookfield Engineering Labs).

the user measures the time it takes for the ball to travel between two timing lines. The first timing line is placed sufficiently far from the top of the viscometer to allow the ball to reach terminal velocity. The manufacturer supplies a calibration equation of the sort:

$$\mu = K^* t^* (\rho_{\text{obj}} - \rho_{\text{fluid}}) \quad (31.26)$$

where K is a calibration constant and t is the measured time to fall the specified distance. To obtain the calibration constant the manufacturer measures the fall time of the ball in a series of liquids of known viscosity.

Types of Viscometers/Options Falling object viscometers use a variety of objects including spheres, needles, and cylinders. Falling object viscometers often come with a set of objects, each with different mass/density which allows one to measure viscosity over a range of values. The most readily available commercial falling object viscometers are the relatively inexpensive Gilmont-type falling ball viscometers and the more expensive, more accurate Haake-type falling ball viscometers as shown in Figure 31.5a and b. The Haake viscometers include a mounting mechanism and an outer chamber that can be used for temperature control of the sample during testing. Falling needle viscometers use thin needle like objects which are designed to minimize wall effects and are more stable as they fall (see Davis and Brenner, 2001). They can be used to measure viscosity of non-Newtonian fluids. Falling cylinder viscometers involve a more complex flow field subject to significant end effects; however, they are useful for measuring viscosity at high pressure (Cristescu et al., 2002). Table 31.3 provides further information about suppliers of falling object viscometers.

Summary Although falling object viscometers are relatively inexpensive, the use of one requires some skill and is labor intensive. The tubes must be carefully cleaned before use and when filling the tube with the fluid of interest, care needs to be taken to avoid air

TABLE 31.3 Sampling of Common Falling Ball Viscometer Types

bubbles. They cannot be used with opaque liquids. After setup, each individual measurement can take 1–2 min to complete. Gilmont-type viscometers must be mounted or held vertically and care needs to be taken when handling them to avoid heating up the fluid in the viscometer. Haake-type viscometers are pre-mounted at a specified angle and the falling ball tube is located inside an outer glass tube that can be easily connected to a circulating water bath for temperature control. They are not automated and require manual timing. However, it is relatively easy to compare the viscosity of different fluids by using multiple viscometers. The primary sources of error that arise in the use of a falling ball viscometer are related to temperature effects, handling and contamination.

31.3.2 Bubble (Tube) Viscometers

Theory of Operation Although most drag-type viscometers measure absolute viscosity and require a separate measurement of density to calculate kinematic viscosity, bubble viscometers measure kinematic viscosity (ν) by measuring the drag on a rising bubble of air which has low density compared to the fluid. The bubble tube consists of a glass tube (see Figure 31.6a) which is filled with the liquid of interest (leaving space for a bubble to

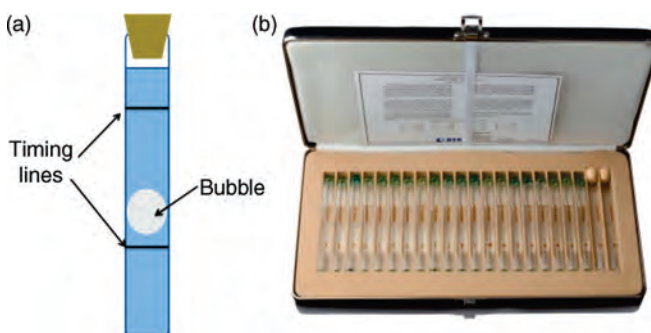

FIGURE 31.6 (a) Schematic of a bubble tube viscometer and (b) BYK-Gardner Bubble Viscometer Set (Courtesy of BYK Gardner USA).

form). The tube is marked with timing lines and the time for the bubble to rise is measured and compared to times for liquids with known viscosities.

The theory in this case is similar to that for a falling object, except that here one measures the time for the bubble to rise a specific distance (see Goldsmith et al., 1962, for more information on the theory). If we ignore the effect of bubble viscosity the same equation for viscosity applies:

$$\mu = \frac{gD^2}{18V}(\rho_{\text{obj}} - \rho_{\text{fluid}}) \quad (31.27)$$

However in the case of a rising gas bubble one can assume that the object (air) density is much less than that of the fluid and the calibration equation becomes:

$$\mu = \frac{gD^2}{18V}(\rho_{\text{fluid}}) \quad (31.28)$$

Or in terms of kinematic viscosity

$$\nu = \frac{\mu}{\rho_{\text{fluid}}} = \frac{gD^2}{18V} \quad (31.29)$$

In practical applications, bubble viscometers use carefully manufactured precision tubes which are calibrated using known viscosity standards. The kinematic viscosity is then calculated as:

$$\nu = k^* t \quad (31.30)$$

where k is the calibration constant for the tube and t is the time for the bubble to rise a specific distance. The faster the bubble travels, the lower the viscosity.

Types of Viscometers/Options Bubble tube viscometers are used to measure viscosity using either a direct measurement method or a comparison method. In the direct method, a single tube (like that shown in Figure 31.6a) is used to measure the bubble rise time and that time is converted to viscosity using information from the manufacturer. In the comparison method, the user selects reference tubes of known viscosity (see Figure 31.6b) and directly compares the bubble rise time in the fluid of interest to the rise time in the reference tubes. The fluid of interest is then assumed to have the same viscosity as that of the reference tube with the closest rise time. Table 31.4 includes a list of suppliers for bubble tube viscometers.

Summary Bubble tube viscometers are relatively inexpensive. Their use requires some skill and measuring viscosity is labor intensive. The tubes must be carefully cleaned before use. After setup, each individual measurement typically takes 1–2 min to complete.

TABLE 31.4 Sampling of Common Bubble Tube Viscometer Types

Type	Name	Manufacturer/Vendor	Range (St)	Price
Bubble viscometers	Gardner Standard Bubble Viscometers	Gardner/Gardco	0.5–5.5	\$\$
Bubble viscometers	Bubble Viscometer Kits	Cole Parmer	0.005–0.320	\$–\$\$

The viscometer needs to be held in a vertical position during measurement (some manufacturers supply a stand to hold and flip the tubes) and care must be taken not to heat the liquid in the tube when handling. They are not suitable for use with opaque liquids. They are not automated and require manual timing; however one can easily use multiple tubes to compare the viscosity of different fluids. The primary sources of error that arise in the use of a falling ball viscometer are related to temperature effects (it is not easy to supply external temperature control), handling, and contamination.

31.3.3 Rotational Viscometers

Theory of Operation Rotational viscometers determine viscosity by measuring the resistance on a shaft rotating in the liquid of interest. They are designed to make a direct measurement of the absolute viscosity μ . A schematic of a rotational viscometer is shown in Figures 31.7a and 31.8a. Figure 31.7b shows a commercially available Brookfield rotational viscometer. The viscometer includes a spindle (cylinder), attached to a rotating shaft. The spindle is placed in the liquid of interest and rotated at constant speed. The torque required to rotate the spindle is measured and then related to the fluid viscosity. Although their setup is somewhat more elaborate than that of the falling ball or capillary viscometers, they can be used to study the behavior of non-Newtonian fluids.

The theory of operation of a rotational viscometer is based on the Couette flow model for fully developed, steady, incompressible laminar flow between two surfaces, one of which is moving. If we model a viscometer as a rotating cylinder inside a stationary cylinder as shown in Figure 31.7a, the Couette flow solution for the wall shear τ , assuming the gap between the two cylinders is small and the velocity varies linearly, is given as

$$\tau = \mu \frac{du}{dy} = \mu \frac{\omega R_i}{R_o - R_i} \quad (31.27)$$

where ω is the rotational speed of the cylinder, R_i is the radius of the rotating cylinder, and R_o is the radius of the outer, stationary cylinder. The torque due to this wall shear is then equal to the shear force times the area over which the shear acts times the moment arm

FIGURE 31.7 (a) Schematic of a cylinder in cylinder rotational viscometer and (b) spindle-type viscometer (Courtesy of Brookfield Engineering Labs).

(in this case the inner radius):

$$T = \tau A R_i = \mu \frac{\omega R_i}{R_o - R_i} (2\pi R_i L) R_i \quad (31.28)$$

where T is the torque and A is the area of the rotating cylinder ($2\pi R_i L$). Under steady state conditions the torque due to the viscous forces equals that which is applied to keep the cylinder rotating. Therefore, the viscosity can be measured using the measured torque value and the geometry of the system:

$$\mu = T \frac{R_o - R_i}{(2\pi \omega R_i^3 L)} \quad (31.29)$$

In practice, rotational viscometers come with a variety of rotating spindles and calibration information that allows one to relate the torque measurement to viscosity. A typical calibration equation is in a form such as:

$$\mu = \frac{T}{c\omega} \quad (31.30)$$

where T is the measured torque at a given rotation rate, w and c is the calibration constant used to account for geometry and end effects. Some viscometers are equipped with a digital readout.

Types of Viscometers/Options There are three main types of rotational viscometers: Concentric cylinders, cone and plate, and parallel plate. The concentric cylinder theory is described above for a rotating inner cylinder which is more common. Systems are also designed to have a rotating outer cylinder to minimize the centrifugal forces which lead to the formation of Taylor vortices. A variation on the concentric cylinder-type viscometer uses a rotating spindle in an infinite medium.

Cone and Plate viscometers (see Figure 31.8b) are designed to provide a uniform shear rate across the rotating plate. They consist of a conical surface and a flat plate, separated by a small gap that is filled with the liquid of interest. One of the plates is rotated and the torque required to hold the other in place is measured. The theory of operation is similar to that described above for the concentric cylinder viscometer, although the geometry is different. The cone angle in Figure 31.8b is designed to provide the uniform shear rate.

FIGURE 31.8 Geometries typically used in rotational viscometer (a) cylindrical, (b) cone and plate, and (c) parallel plate.

Parallel plate viscometers provide a non-uniform shear rate. They consist of two parallel plates (see Figure 31.8c) separated by a gap filled with the liquid of interest. The shear rate acting on the fluid depends on the radial location. One plate typically rotates and the torque required to hold the other is measured. Again, the theory is similar to that described above; however in this case the shear rate varies with radial distance. Table 31.5 presents a listing of types and manufacturers of rotational viscometers.

Summary Rotational viscometers are more expensive than the other drag-type viscometers but they are somewhat easier to use. Measurements can be made rapidly. Rotational speed can be altered to vary shear rates and test non-Newtonian fluids. The spindles, cones and plates must be carefully cleaned before use so the testing of multiple fluids is more complex. The primary sources of error that arise in the use of a rotational viscometer are related to temperature effects, set up errors (the system must be level and care must be taken to avoid end effects and eccentricity) and calibration of the torque measurement system. Some rotational viscometers have built in temperature control. Process versions exist that can be used in-line (see Table 31.5).

31.3.4 Flow-Type Viscometers

31.3.4.1 Capillary Viscometers

Theory of Operation Capillary viscometers determine viscosity through measurement of the flow rate of the liquid traveling through a capillary tube. A capillary tube is one with a large length to diameter ratio (i.e., long and skinny). A schematic of a capillary tube

FIGURE 31.9 Capillary tube viscometer (Ostwald type).

viscometer is shown in Figure 31.9. Capillary viscometers are typically made of glass and consist of a bulb reservoir connected to the capillary tube. The theory of operation for a capillary tube viscometer is based on the Poiseuille model of laminar flow which describes flow through a round pipe. The volume flow rate, Q in a pipe can be derived from the Navier–Stokes equations for steady, laminar, and fully developed, incompressible flow as

$$Q = -\frac{\pi R^4}{8\mu} \frac{dP}{dy} \quad (31.31)$$

where R is the pipe radius, μ is the viscosity and dP/dy is the pressure gradient (i.e., the change in pressure over the length of the pipe) which is the driving head for the flow. In the case of a vertical tube with both ends open to the ambient, the pressure gradient is caused by the hydrostatic pressure gradient:

$$\frac{dP}{dy} = -\rho g \quad (31.32)$$

where ρ is the density and g is the gravitational constant. Combining equations and rearranging

$$\frac{\mu}{\rho} = \nu = \frac{\pi R^4 g}{8Q} \quad (31.33)$$

Which allows for calculation of the kinematic viscosity, ν , from the measured flow rate and the geometry of the capillary tube. In practical applications, capillary viscometers are carefully calibrated and the manufacturer supplies a calibration constant. The user is

instructed to measure the time for the fluid to travel a specified distance and then the kinematic viscosity is calculated as:

$$\nu = Kt \quad (31.34)$$

where K is the manufacturer supplied calibration constant and can be a function of temperature depending on the viscometer type.

Types of Viscometers/Options There are four primary types of capillary tube viscometers. They are the original Ostwald, the Modified Ostwald, the Suspended level (Ubbelohde) and the reverse flow capillary viscometers. Each is described below.

The Ostwald Viscometer is one of the simplest capillary tube viscometers. As shown in the schematic (Figure 31.9), the viscometer consists of a bulb connected to a long capillary tube. To use the viscometer one partially fills it and then draws the fluid to the upper mark above the right side bulb (typically using a syringe system). The fluid is released to flow through the capillary tube and the time for the upper bulb to empty (fluid level at upper marks to lower marks) is measured. Some of the problems associated with the use of the Ostwald viscometer include the need to keep the viscometer vertical, the requirement for a specific volume of fluid and the effect of temperature on the viscosity measurement.

A number of Modified Ostwald-type viscometers exist. These include the Cannon–Fenske routine viscometer, Pinkevitch viscometer, Zeitfuchs, (see Viswanath et al. 2007). Each is designed to address some of the sources of error found in the Ostwald type. For example, the Cannon–Fenske Routine viscometer is designed to minimize the effect of tilt angle by placing the upper and lower bulbs along the same vertical axis.

Suspended Level Viscometers are designed to address loading issues by using a constant pressure gradient (driving head) during measurement of viscosity. They do this by suspending the test liquid above the capillary tube and using a pressure equalization tube. They include the Ubbelohde and Cannon–Ubbelohde-type viscometers. To determine viscosity, the test liquid is loaded into the upper bulb and then released. The liquid flowing through the capillary is separated from the reservoir bulb at the bottom. The third tube which connects the bottom of the capillary tube to the ambient ensures that the only pressure difference between the top of the bulb and the bottom of the capillary is that due to the hydrostatic pressure that is, the weight of the liquid.

Reverse Flow Viscometers are used to measure the viscosity of opaque fluids (although they can also be used to measure that of transparent liquids). They measure the flow rate through a “dry” capillary tube so that the leading edge of the opaque fluid can be easily identified. Reverse Flow viscometers must be cleaned between each measurement.

There are a number of variations on the standard capillary tube viscometer, including small volume (micro or semi-micro) viscometers requiring 1 mL or less of fluid (useful in the measurement of the viscosity of blood and plasma), dilution viscometers with extra large reservoirs for dilution of the sample and vacuum viscometers for fluids with high viscosities such as asphalt. There also exist more rugged capillary tube viscometers that are used under continuous flow conditions in industrial applications, and disposable capillary models to avoid the labor (and error potential) associated with cleaning. Table 31.6 provides a sampling of the various capillary tube viscometers.

Summary Capillary tubes are used to measure viscosity for a wide range of fluids from oils to blood/plasma and even asphalt. They are relatively inexpensive (although generally

more costly than the falling ball and bubble tube viscometers). They require skill to use and can be labor intensive. Measurements take 1–5 min. Use requires manual timing and a method for filling the viscometer (a syringe system is typically used). The glass tubes are fragile. The tubes must be carefully cleaned before use but the viscosity of different fluids is easily measured using different tubes. The primary sources of error that arise in the use of a capillary viscometer are related to temperature effects, set-up errors (the tubes must be mounted vertically) and contamination. The tubes can be mounted in a temperature-controlled bath to minimize temperature effects and care must be taken not to affect the fluid temperature when handling. The calibration constant can be sensitive to temperature. Process versions exist that can be using in-line.

31.3.5 Orifice-Type (Cup) Viscometers

Theory of Operation Orifice-type viscometers measure kinematic viscosity by comparing the time it takes the fluid to pass through an orifice (the efflux time) to the time that it takes a fluid of known viscosity to pass through the same orifice. They generally consist of a fluid reservoir from which the fluid flows, an orifice and a capturing reservoir (see Figure 31.10). Although they were originally designed using the Poiseuille flow model, it was determined that entrance and exit effects in this type of device are significant. Therefore, cup methods only provide a relative measurement. Absolute values of viscosity cannot be measured using this type of viscometer.

In practice, a “cup” or reservoir is filled with a specified quantity of the fluid of interest and allowed to equilibrate thermally. Then a valve is opened at the bottom of the

FIGURE 31.10 (a) Schematic of cup viscometer and (b) image of a Ford cup viscometer (Courtesy of Paul N. Gardner Company, Inc.).

cup and the time for the cup to empty is measured. Viscosity is then calculated using an *empirical* equation:

$$\nu = k * t \quad (31.35)$$

where k is supplied by the manufacturer. These types of viscometers are commonly used to measure the viscosity of oils, varnishes, and paints. Specifications in certain industries or for certain industrial processes are often closely tied to one particular type of cup measurement, and thus it may be difficult to use or generalize viscosity information found with other viscosity measuring methods to these industrial applications.

Types of Viscometers/Options Cup viscometers are commonly used for in field measurements. There are a variety of cup types including the early models used in the petroleum industry such as the Saybolt, Redwood, and Engle Cups. The Ford, Zahn, and Shell viscosity cups (to name just a few) are more commonly used for measuring the viscosity of paints, varnishes, and lacquers. A sampling of cup viscometer types is listed in Table 31.7.

Summary Cup viscometers are relatively inexpensive but generally not very accurate. In fact cup “viscometers” do not produce true viscosity measurements, only relative ones. Their primary drawback is that information gained using them is not directly translatable or comparable to information obtained by other methods (although empirical relations making comparisons to other methods abound). In practice this leads to significant “legacy” effects, necessitating the continued use of the same exact cup method if comparisons to historical data are desired. Thus a particular type of cup’s use is typically closely

tied to a certain industry, industrial process, or product and the primary benefit of using such an “industry standard cup” is that their measurements can be directly compared to previous industrial knowledge or standards developed using the same method. Cup viscometers also require some skill to use (the cup requires steady holding during measurement) and can be labor intensive. Some models include a ring stand, others have handles, to hold the cup still and improve accuracy. Typical measurements are made in the field and each can take 1–2 min. The primary sources of error that arise in the use of a cup viscometer are related to temperature effects, setup errors, unsteadiness, and contamination. Most cups do not come with temperature control and this can affect the measurement although Saybolt-type cup viscometers do include temperature control. Cups must be properly cleaned because even slight clogging of the orifice can cause significant error.

31.3.6 Vibrational (Resonant) Viscometers

Theory of Operation Vibrational viscometers determine viscosity by forcing a resonator to vibrate in the fluid of interest and then measuring the damping that is associated with fluid viscosity. This dampening effect is measured by one of three methods: (a) through

TABLE 31.8 Sampling of Common Vibrational Viscometer Types

measurement of the power required to maintain a constant vibration (the higher the viscosity of the fluid, the higher the power need); (b) measurement of the signal decay time upon halting the vibration (higher viscosity fluids will have a shorter decay time); or (c) looking at the frequency of the resonator as a function of the phase angle between the excitation and response signals.

Types of Viscometers/Options Vibrational viscometers are commonly used in in-line process measurement applications, although lab versions exist. Table 31.8 presents information on a sampling of commercially available vibrational viscometers. The most common vibrational viscometers are configured as a tuning fork, an oscillating sphere, or a vibrating rod. Tuning fork vibrational viscometers have two sensor plates which are immersed in the liquid of interest. The plates (which have the same natural frequency) are made to vibrate at the same amplitude using an electromagnetic force. The viscosity of the liquid is determined by measuring the current required to maintain the constant amplitude motion. Figure 31.11 shows a schematic of one type of tuning fork viscometer.

The oscillating sphere viscometers use the dampening associated with the torsional motion of a sphere immersed in the fluid of interest to measure viscosity. Vibrating rod viscometers do the same with a rod shaped sensor. Tuning fork vibrational viscometers are capable of simultaneously measuring density and viscosity; however the oscillating spheres and rod types require separate measurement of density (see Retsina et al., 1987, for more details).

Summary Vibrational viscometers are more expensive than the other types of viscometers but they are much easier to use. Once they are installed inline they require minimal skill and measurements can be made quickly. Their fundamental lack of moving parts makes them more robust and resilient, and thus better suited for use in harsh environments. The primary sources of error that arise in the use of a vibrational viscometer are related to calibration and drift errors.

FIGURE 31.11 (a) Schematic of a vibrational viscometer and (b) Image of an SV-A Series Sine Wave Vibro Viscometer (Courtesy of A&D Weighing).

31.3.6.1 Viscosity Calibration Fluids Viscosity standards are standard fluids of known viscosity that are used to calibrate a viscometer. Most manufacturers recommend three or more fluids specified by NIST that can be used to calibrate a viscometer. Viscosity standard oils can be found through Sigma–Aldrich, Gardco, Cole–Parmer or other similar companies.

31.4 ASTM STANDARDS FOR MEASURING VISCOSITY

There are a variety of published standards available. In this section we focus on the standards put out by the American Society for Testing and Materials (ASTM). Many industries adhere to specific guidelines provided by these or similar standards.

The ASTM viscosity standards come in two types: (a) standards focused on methods (method standards) and (b) standards based on materials (material standards). A method standard describes a viscosity measurement method that can be applied in a variety of circumstances. An example of this would be the Standard Test Method for High-Shear Viscosity Using a Cone/Plate Viscometer, D-4287, which specifies a method for using a cone and plate viscometer and in particular applies this to paint. Because such standards specify the method, they can be applied beyond the particular material discussed in the standard. A material standard outlines multiple techniques that can be used to measure the viscosity of one specific material. For example, the Standard Test Methods for Viscosity of Adhesives, D1084, provides four different methods to test free-flowing adhesives with a viscosity range from 50 to 20 k cP. One limitation of the material standards is that they have a narrow focus.

Table 31.9 provides a starting point for finding both types of standards. In this table the different methods (viscometer type) are listed by column and the material types are listed by row. For example, if one wishes to use a cup-type viscometer to measure the viscosity of paints ASTM D1200-10, D4212-10 and D5125-10 apply. One can also utilize the ASTM website to search for standards. The bolded standards in Table 31.9 are the recommended starting standards as they are the most general and provide a good list of referenced documents.

31.5 QUESTIONS TO ASK WHEN SELECTING A VISCOSITY MEASUREMENT TECHNIQUE

This section is intended as a guide to the practicing engineer on how to choose the appropriate viscometer. It is structured as a series of nonhierarchical questions. Table 31.10 also provides a summary comparison of the different viscometer types.

1. *Do you need an online/process measurement, or an offline measurement?*

If you need to continuously monitor the viscosity of an industrial process stream online or *in situ* your choices of available technique will be limited, and the cost of your system will be higher. On the positive side, very little operator labor will be required once the system is installed and there will be no need to remove and handle samples from the process stream. Measurements can be taken at much shorter time intervals, and the viscosity will be known at exactly the conditions (temperature, pressure) associated with the process. The main viscometry techniques available for online measurement are resonant, capillary, and rotational. More information on the measurement range and suppliers of these viscometers can be found in Tables 31.5, 31.6 and 31.8.

2. *What is the viscosity range that you will be measuring?*

Matching the viscometer to the viscosity range to be measured is one of the most important tasks associated with selecting a viscometer. Since many techniques measure the time for a certain amount of fluid to flow (e.g., cup or capillary types), or for an object to fall through the fluid (e.g., falling ball or rising bubble types), if the fluid viscosity is higher than optimal for a given viscometer the measurements may take an exceedingly long time to conduct. On the other hand, if the viscosity is too low key assumptions related to the operation of the viscometer (e.g., the low Reynolds number assumption) may be violated and accuracy will be lost. Rotational-type viscometers simply will not give a reading, and may in fact be damaged, if the fluid being measured is too viscous for the instrument and settings selected. On the other hand if the viscosity is such that the reading is less than 10% of the instrument's full range (for a given setting) the uncertainty of the measurement will become unacceptably high. Thus good results necessitate careful matching of the viscosity range and the instrument. Operating ranges for many common types of viscometers are listed in Tables 31.3–31.8.

3. *What other characteristics of the fluid must be considered?*

Other physical properties of the fluid beyond viscosity are also important to consider. For example, certain techniques or instruments lend themselves to use with opaque fluids (e.g., the reverse flow viscometer) while others cannot be used because the technique depends on being able to see through the fluid (e.g., falling ball). Likewise, chemical compatibility of the fluid with the exposed viscometer surfaces is important to consider, as are any issues associated with safe handling of the fluid. Also various properties such as how difficult the fluid will be to clean off of the viscometer surfaces, and how likely the fluid is to solidify and clog are critical. Certain specialized fluids, like blood, have specific viscosity instruments designed specifically for use with them.

4. *Do you wish to measure kinematic or dynamic viscosity?*

Each type of viscometer fundamentally measures either the absolute viscosity of a fluid (μ) or the kinematic viscosity (ν). In order to convert between the two a separate

TABLE 31.10 Comparison of Viscometer Types

Type	Falling Object	Bubble Tube	Rotational	Capillary	Cup	Vibrational
Viscosity range	0.2–70 k cP	0.005–5.5 cSt	0.3–320 M cP	0.5–100 k cSt (general), 0.5–20 k cSt (small vol- ume) up to 5.8 MP (vacuum)	4–2600 cSt	4–2600 cSt
Labor/skill level	High	High	Med	High	Med	Low
Automated?	No	No	Yes	Some	No	Yes
In-line?	No	No	Some	Some	No	Yes
Expense	\$100–\$200 Gilmont \$1000 Haake	(\$50–100 each or \$400–1000 for a kit)	Expensive	\$200–\$300		Expensive

measurement of the fluid's density is required. Thus care must be exercised in selecting a viscometer if one wishes to avoid the need for this additional measurement.

5. *How much and what type of labor is required?*

The quantity of labor (time) and skill level required to make accurate viscosity measurements varies significantly among different viscometer types. Broadly speaking the lower cost viscosity measurement instruments (falling ball, rising bubble, and capillary tube) are more labor intensive to use and require significantly more skill (operator training) than the more expensive viscometer types (rotating disk, vibrating rod, etc.). The frequency of measurements required, as well as the labor associated with maintenance, calibration, and cleaning of the viscometer should be carefully considered in this context.

6. *What is the required accuracy?*

Another major factor influencing the type of viscometer to choose is the required accuracy. Here some of the simplest models (e.g., capillary and falling ball) compare quite well on the basis of accuracy with more expensive techniques, assuming a sufficiently skilled and careful operator. However the old truism that increased accuracy leads to increased expense does generally hold within a given class of viscometer. As discussed in point 5 above, labor costs may be significant in regards to the cost/accuracy decision.

7. *Are there standard methods associated with your industry or fluid?*

Viscosity measurements for many substances, for many industries, and for the use of many types of viscometers are the subject of government or industrial standards. For example, the ASTM standards governing viscosity measurement are discussed at length in Section 31.3. Likewise many industries or industrial processes are closely tied to particular viscosity measurement techniques, even if these are out-moded. In such cases there may be a considerable body of industrial or process control knowledge that is not readily translatable to more standard viscosity measurements (e.g., the use of the "Stein–Hall Cup" measurement with starch based adhesives used in corrugated box manufacturing). In such cases sticking with the "standard method" may be the most desirable approach.

8. *Is temperature control needed? Is viscosity as a function of temperature needed?*

The viscosities of liquids and gases are a strong function of temperature, and this should always be kept in mind when collecting and reporting viscosity data. Some viscosity measurement techniques lend themselves more readily to maintaining temperature control of the fluid during the measurement (e.g., the Haake falling ball viscometer has a built-in temperature bath capability, for other types that capability must be added *ad hoc*). Likewise some viscometers (e.g., Brookfield rotational viscometer with small sample adapter) lend themselves to measuring the viscosity of a fluid over a wide range of temperatures.

9. *Quantity of fluid needed for the measurement.*

This is an important factor to consider when dealing with scarce or expensive fluids (e.g., blood). Viscosity measurement techniques can vary by more than an order of magnitude in the amount of liquid required to make a measurement.

10. *Specialized needs.*

If your process involves specialized needs or requirements, that is, measurements at high pressure or measurements at temperature extremes there are viscometers available specifically for those purposes.

32.1 INTRODUCTION

Tribology as a subject is relatively new, but the practice of tribological principles is older than recorded history. Tribology is defined as the science and technology of interacting surfaces in relative motion and of related subjects and practices. It deals with the technology of lubrication, control of friction, and prevention of wear. Successful design of machine elements depends essentially on the understanding of tribological principles. During contact of two nominally flat surfaces, contact occurs at discrete spots due to surface roughness and adhesion occurs due to intimate contact. When one solid body moves over another it experiences the resistance to motion called friction. The surface damage or material removal that takes place in a moving contact is termed as wear. Surface coatings and treatments are provided to monitor friction and to control wear. The most effective way of friction and wear control is by using proper lubricants either liquid, solid or gas. The lubricant properties and the mechanisms of lubrication constitute the essence of optimum performance and reliability of bearings. The recent emergence of proximal probes and high capability computational techniques has stimulated systematic investigations of interfacial problems with high resolution in micro and nano components leading to the development of the new field of micro/nano tribology.

Tribology is different from other science branches, for example, fundamental physics where theoretical predictions are made long before the experimental validation of the same. Tribology uses a more empirical methodology based on experimental observation and theoretical concepts follow the findings later. A classical example of experimental observation leading to the development of basic tribological concept of a hydrodynamic pressure field operating in a lubricated bearing is Tower's friction experiments. The railway axle bearings were fitted with numerous oil holes in order to supply oil to the bearing. But during operations, oil leaked through the holes and even wooden plugs were unable to prevent the leakage. Tower fitted pressure gauge at the oil holes to find that the oil pressure was capable to support the bearing load. Figure 32.1 is a schematic representation of the partial bearing used by Tower. Tower's results led to the development of hydrodynamic theory of lubrication by Osborne Reynolds.

Most tribological phenomena, for example, friction, wear, and frictional heating, are not intrinsic material properties. These depend on a number of competing factors. For example, to evaluate load capacity of a hydrodynamic bearing one needs to consider viscous heating of the lubricant, cavitation and turbulent lubricant flow, elastic deformation of bearing structure and so on. Friction and wear being chaotic processes, these are described in terms of specific experimental findings that are systematically analyzed to get an engineering model of friction, wear, and lubrication. Tribological investigation

FIGURE 32.1 Schematic representation of the partial bearing used by Tower.

may be categorized into two groups: fundamental research for understanding of basic mechanisms of friction and wear; and applied research for resolving specific industrial friction and wear issues. On both counts, tribological measurements mainly include surface roughness, friction, wear, test environment, material characteristics, and lubricant characteristics. Wear particle analysis and industrial tribology form an important part of tribological measurement.

32.2 MEASUREMENT OF SURFACE ROUGHNESS

The surfaces of any engineering component contain a vast number of peaks and valleys and it is not possible to measure the height and location of each of the peaks. So what is done is to take measurements from a small and representative sample of the surface so chosen that there is a high probability for the surface lying outside the sample to be statistically similar to that lying within the sample. Over the years different methods have been devised to study the topography of surfaces. A brief outline of some of the methods is presented here.

32.2.1 Surface Profilometer

The most common method of studying surface texture features is the stylus profilometer, the essential features of which are illustrated in Figure 32.2. A fine, very lightly loaded stylus is dragged smoothly at a constant speed across the surface under examination. The transducer produces an electrical signal, proportional to displacement of the stylus, which is amplified and fed to a chart recorder that provides a magnified view of the original profile. But this graphical representation differs from the actual surface profile because of difference in magnifications employed in vertical and horizontal directions. Surface slopes appear very steep on profilometric record though they are rarely steeper than 10° in actual cases. The shape of the stylus also plays a vital role in incorporating error in measurement. The finite tip radius (typically $1\text{--}2.5\text{ }\mu\text{m}$ for a diamond stylus) and the

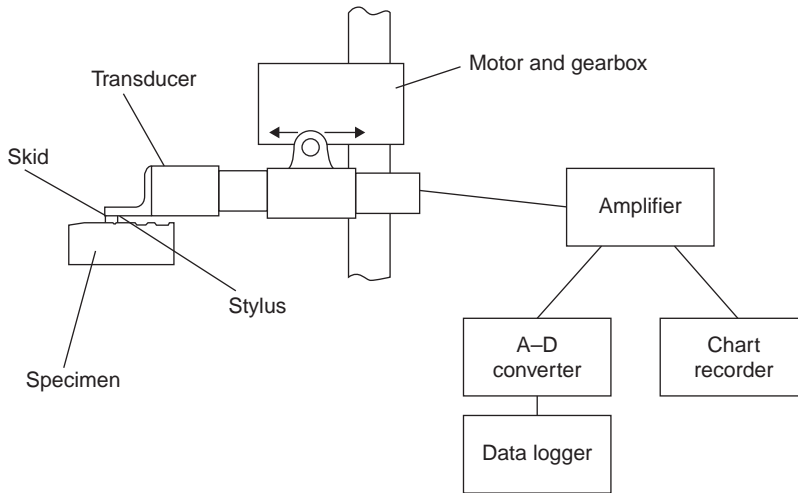

FIGURE 32.2 Component parts of a typical stylus surface-measuring instrument.

included angle (of about 60° for pyramidal or conical shape) results in preventing the stylus from penetrating fully into deep and narrow valleys of the surface and thus some smoothing of the profile are done. Some error is also introduced by the stylus in terms of distortion or damage of a very delicate surface because of the load applied on it. In such cases noncontacting optical profilometer having optical heads replacing stylus may be used. Reflection of infrared radiation from the surface is recorded by arrays of photodiodes and analysis of the same in a microprocessor result in the determination of the surface topography. Vertical resolution of the order of 0.1 nm is achievable though maximum height of measurement is limited to a few microns. This method is clearly advantageous in case of very fine surface features.

32.2.2 Optical Microscopy

In this method, the surface of interest is held to reflect a beam of visible light and then these are collected by the objective of the optical microscope. An image of the surface is produced and is analyzed at very high rates of resolution (up to $0.01\ \mu\text{m}$) by optical interferometers. Depth of field achievable is up to $5\ \mu\text{m}$. But success of the method depends on the reflective property of the material, which limits the use of the same.

Optical methods may be divided into two groups: geometrical methods and physical methods. Geometrical methods include light-sectioning and taper-sectioning methods. Physical methods include specular reflection; diffuse reflection, speckle pattern, and optical interference.

In *light-sectioning method*, the image of a slit is thrown onto the surface at an incident angle of 45° . The reflected image appears as a straight line if surface is smooth and as an undulating line if the surface is rough. In *taper-sectioning method*, a section is cut through the surface to be examined at an angle of θ , thus effectively magnifying the height variation by a factor of $\cot\theta$ and is subsequently examined by an optical microscope. The surface is supported with an adherent coating that prevents smearing of the contour during

the sectioning process. The taper section is lapped, polished, and lightly heat tinted to provide good contrast for optical examination. The process suffers from the disadvantages like destruction of test surface and tedious specimen preparation.

In *specular reflection method*, gloss or specular reflectance that is a surface property of the material and function of reflective index and surface roughness, is measured by gloss meter. Surface roughness scatters the reflected light and affects the specular reflectance. Thus a change in specular reflectance provides a measure for surface roughness.

Diffuse reflection method is particularly suitable for on-line roughness measurement during manufacture since it is continuous, fast, non-contacting and non-destructive. This method employs three varieties of approaches. In total integrated scatter (TIS) approach, one measures the total intensity of the diffusely scattered light and the same is used to generate the maps of asperities, defects and particles rather than micro-roughness distribution. The diffuseness of scattered light (DSL) approach measures a parameter that characterizes the diffuseness of the scattered radiation pattern and relates the same to surface roughness. In angular distribution (AD) approach, the scattered light provides roughness height, average wavelength or average slope. With rougher surfaces, this may be useful as a comparator for monitoring both amplitude and wavelength surface properties.

In *speckle pattern method*, surface roughness is related to speckle, which is basically the local intensity variation between neighbouring points in the reflected beam when a surface is illuminated with partially coherent light. The principle of laser speckle roughness measuring system is schematically shown in Figure 32.3.

The *optical interference technique* involves looking at the interference fringes and characterizing the surface with suitable computer analysis. Common interferometers include the Nomarski polarization interferometer and Tolanski multiple beam interferometer.

32.2.3 Advanced Techniques for Surface Topography Evaluation

A further improvement in the resolution of surface topographic examination is possible by the use of electron microscopes. Two basic types of electron microscopes are available: scanning electron microscopes and transmission electron microscopes. In scanning

FIGURE 32.3 Schematic of the principle of laser speckle roughness measuring system.

electron microscopy (SEM) a focused beam of high-energy electrons is incident on the surface at a point resulting in the emission of secondary electrons. These are then collected and fed to an amplifier to send an electric signal to a cathode ray tube (CRT). The electron beam is scanned over the surface to have a complete picture. The CRT screen gives a topographical image of the entire area of interest. Depth of field is up to $1000\text{ }\mu\text{m}$, which acts as a primary advantage of this method over optical method. The requirement on size of the specimen to be placed within the vacuum chamber of the instrument raises a drawback of the method. This can be overcome by preparing a replica of the surface.

In transmission electron microscopy (TEM), the focused beam of high-energy electrons is made to transmit through a very thin specimen. Then the deflection and scattering of the electrons is recorded to analyze the surface topography. Preparation of a specimen thin enough to transmit electrons plays a vital role. Sometimes a replica of the surface retaining all the texture features but of a material having greater electron transparency is produced for the same purpose.

Recently, a different type of electron microscopy called scanning tunneling electron microscopy (STM) is in use. It incorporates the electron-tunneling phenomenon through an insulating layer separating two conductors. The sharp pointed tip of a probe forms one electrode and the surface of the specimen the other. The probe is moved by a highly precise positional controller to keep the tunneling current at a steady value. The probe provides an image of the surface under examination. The method is superior to the earlier ones in a sense it does not require any vacuum. Only disadvantage is the proper design of the controller mechanism. The principle of the STM is very simple. Just like in a record player, the instrument uses a sharp needle, referred to as the tip, to investigate the shape of the surface. But the STM tip does not touch the surface. The schematic of the method is shown in Figure 32.4. A voltage is applied between the metallic tip and the specimen, typically between a few millivolts and volts. The tip touching the surface of the specimen results in a current and when the tip is far away from the surface, the current is zero. The STM operates in the regime of extremely small distances between the tip and the surface of only $0.5\text{--}1.0\text{ nm}$, which are typically $2\text{--}4$ atomic diameters. At these distances, the

FIGURE 32.4 Schematic of STM.

electrons can jump from the tip to the surface or vice versa. This jumping is necessarily a quantum mechanical process known as “tunneling” and hence the name scanning tunneling microscope. The STMs usually operate at tunneling currents between a few pico-Amperes (pA) and a few nano-Amperes (nA). The tunneling current depends critically on the precise distance between the last atom of the tip and the nearest atom or atoms of the underlying specimen. When this distance is increased a little bit, the tunneling current decreases heavily. As a thumb rule, for each extra atom diameter that is added to the distance, the current becomes a factor of 1000 lower. Thus the tunneling current provides a highly sensitive measure of the distance between the tip and the surface. The STM tip is attached to a piezo-electric element, which changes its length a little bit, when it is put under an electrical voltage. The distance between the tip and the surface can be regulated by adjusting the voltage on the piezo element. In most STMs, the voltage on the piezo elements is adjusted in a manner that the tunneling current always has the same value, say 1 nA. Thus the distance between the last atom on the tip and the nearest atoms on the surface is kept constant. Using the so-called electronics; the distance regulation is done automatically. The feedback electronics continually measures the deviation of the tunneling current from the desired value and accordingly adjust the position of the tip. While this feedback system is active, two other parts of the piezo elements are used to move the tip in a plane parallel to the surface to scan over the surface. In the scanning process, every time that the last atom of the tip is precisely over a surface atom, the tip needs to be retracted a little bit, while it has to be brought slightly closer when the tip atom is between the surface atoms. This automatically leads the tip to follow a bumpy trajectory, which replicates the atoms of the surface. Then this information about the trajectory is available in the form of the voltages that have been applied by the feedback electronics are then finally visualized in the form of a collection of individual height lines or in the form of grey scale/color scale representation or in the form of some three dimensional perspective views.

More recently AFM (atomic force microscope) is developed to investigate surfaces of both conductors and insulators on an atomic scale. Like the STM, AFM relies on a scanning technique to produce very high-resolution, three-dimensional images of sample surfaces. In AFM, the ultra-small forces (less than 1 nN) present between the AFM tip and sample surface are measured by measuring the motion of a very flexible cantilever beam having an ultra small mass. The AFM combines the principles of the STM and the stylus profiler. The important difference between the AFM and the STM is that in the AFM, the tip gently touches the surfaces. The AFM does not record the tunneling current but the small force between the tip and the surface. The AFM tip is attached to a tiny leaf spring, known as the cantilever, which has a low spring constant. The bending of the cantilever is detected with the use of a laser beam, which is reflected from the cantilever. The AFM thus measures contours of constant attractive or repulsive force. The detection is made very sensitive such that the forces as small as a few pico Newton can be detected. Forces below 1 nN are usually sufficiently low to avoid damage to either the tip or the surface. Since AFM does not rely on the presence of a tunneling current, it can also be used on non-conductive materials. Soon after the introduction of the AFM, it was realized that the same instrument could be used to also measure forces in the direction parallel to the surface, that is the friction forces. When modifications are incorporated for atomic scale and micro scale studies of friction, it is termed as the friction force microscope (FFM) or the lateral force microscope (LFM). The FFM usually detects not only the deflection of the cantilever perpendicular to the surface, but also the torsion of the cantilever, resulting

FIGURE 32.5 Schematic operation of AFM/FFM.

from one lateral force. Schematic of the AFM/FFM commonly used for measurements of surface roughness, friction, adhesion, wear, scratching, indentation and boundary lubrication from micro to atomic scales is shown in Figure 32.5.

In all surface profilometric methods, roughness (small-scale irregularities) and form error (deviation from its intended shape) remain coupled in the recorded data. Form error may be subtracted from the recorded data to provide only the roughness features by different means. The two most common methods used in stylus profilometer are (a) use of datum-generating attachments and (b) use of large radius skids or flat shoes. With these the average local level is used as datum and form error or waviness is not recorded. Other methods include the use of filtering the displacement signal corresponding to waviness. Table 32.1 summarizes the comparison of the different roughness measuring methods.

32.3 MEASUREMENT OF FRICTION

Friction is defined as the force of resistance to motion that occurs when a solid body moves tangentially with respect to the surface of another body that it touch. The friction force acts in a direction opposite to that of motion. Even when an attempt is made to initiate the motion, the friction force exists. The friction force required to initiate the sliding is called the static friction force and that required to maintain sliding is called the kinetic friction force the value of which is usually lower than the former for the same combination of material and other parameters. The basic

TABLE 32.1 Summary and Comparison of Roughness Measurement Methods

Method	Quantitative Data	3-D Data	Resolution at Maximum Magnification, nm		On-Line Measurement Capability	Limitations/Comments
			Horizontal	Vertical		
Stylus method	Yes	Yes	15–100	0.1–1	No	Operates along linear track, contact type can damage sample, slow speed in 3-D mapping
Optical methods						
Light sectioning	Limited	Yes	500	0.1–1	No	Qualitative
Taper sectioning	Yes	No	500	25	No	Destructive, tedious specimen preparation
Specular reflection	No	No	10^5 – 10^6	0.1–1	Yes	Semiquantitative
Diffuse reflection	Limited	Yes	10^5 – 10^6	0.1–1	Yes	Smooth surfaces (<100 nm)
Speckle pattern	Limited	Yes			Yes	Smooth surfaces (<100 nm)
Optical interference	Yes	Yes	500–1000	0.1–1	No	Operates in vacuo, limits on specimen size
SEM	Limited	Yes	10	0.1	No	Operates in vacuo, requires replication of surface
TEM	Limited	Yes	0.5	0.02	No	Operates in vacuo, requires replication of surface
STM	Yes	Yes	0.2	0.02	No	Requires a conducting surface, scans small areas
AFM	Yes	Yes	0.2–1	0.02	No	Scans small areas

FIGURE 32.6 Measuring friction by an inclined plane test rig.

principle of any friction-measuring instrument is to place two specimens together under a specified normal load and in relative motion while the tangential force resisting motion is measured. Many methods of varying specimen geometry, loading condition and resisting force measurement are available. Different researchers use many ingenious set-ups to investigate different specific cases.

32.3.1 Inclined Plane Rig

The simplest arrangement is the inclined plane test shown in Figure 32.6. A specimen is placed on a flat plane whose inclination with the horizontal is gradually increased until the specimen on it starts sliding. If the inclination at this moment be θ , then $\mu_s = \tan\theta$. Obviously, this method is not capable of evaluating friction in continuous sliding.

32.3.2 Pin-on-Disc Rig

In continuous sliding cases, the rig based on pin-on-disc configuration (Figure 32.7) is used. The pin is held stationary under a normal load while the disc is made to rotate. The

FIGURE 32.7 Pin-on-disc friction measuring device.

FIGURE 32.8 Friction-measuring devices: (a) pin-on-cylinder, (b) crossed cylinders, and (c) reciprocating rig.

loading can be provided by simple dead weight or by spring loading or hydraulic or pneumatic pressure. The friction force is measured with the help of the calibrated tangential movement of a capacitive or inductive transducer mounted on the stationary specimen. For a multiple-pass arrangement the pin is held at a constant radial distance from the centre of the disc but in single-pass arrangement it is moved radially during the experiment. Other standard arrangements such as pin-on-cylinder, crossed cylinders, and reciprocating arrangement has been shown in Figure 32.8.

32.3.3 Conformal and Non-Conformal Geometry Rig

The test rigs can be classified into two groups depending on the test geometry: conformal and non-conformal geometry test. In conformal geometry test, the profiles of the two contacting surfaces are matched carefully before the experiment is started. In this case the contact pressure is moderate and normally held constant throughout the experiment. The test may then be used to simulate the situations such as brakes, thrust bearings, plane bearings, face seals, and clutches. On the other hand, in non-conformal geometry test (with spherically profiled pin) contact pressure is initially high because on first loading contact is made at a single point and with time pressure reduces due to development of small wear scars. This can be used to simulate the heavily loaded contacts such as gear teeth or to provide accelerated tests of friction and wear of a number of candidate material pairs for specified applications.

32.3.4 Environment Control

For accurate investigation the friction test must be carried out in an enclosed environment having simulated environmental conditions. Different friction pairs are susceptible to the presence of liquid lubricants, water vapour, gases and so on. If pin-on-disc tests are carried out in presence of liquid lubricant, the results vary due to poorly controlled hydrodynamic conditions at the interface. Sometimes the small deformations of the rig caused by the thermal loading or pressure loading may give rise to experimental scatter. So many other forms of test rigs have been developed for specific applications involving different environmental conditions. For example, space environments are simulated by the use of high-vacuum condition where the entire test rig is installed inside the vacuum chamber.

32.3.5 Techniques for Friction Force Measurement

Two basic types of device are commonly used for the measurement of friction force, viz., piezoelectric force gauge and strain gauge transducer. Piezoelectric force gauges give a direct measurement of friction force as an electrical impulse that is recorded electronically. Piezoelectric gauges operate by elastic deflection of a piezoelectric crystal and are sensitive to temperature, vibration and corrosive agents. Piezoelectric gauges are also relatively expensive. Strain gauged beams are comparatively cheaper. In this case, friction force is usually measured from the bending of a beam arranged perpendicularly to the direction of the friction force and strain gauges are mounted on the beam to record the deflection of the beam. Strain gauged beams are effective in recording steady friction forces where piezoelectric force gauges are unsuitable. Only difficulty with strain gauged beam is its failure to record rapid change in friction force.

32.4 MEASUREMENT OF WEAR

Wear is the removal of material from one or both of two solid surfaces in relative motion (sliding, rolling, or impact). Wear occurs as a natural consequence and mostly through surface interactions at asperities. Though wear generally refers to material removal, surface damage due to material displacement with no net change in volume or weight is also termed as wear. Wear is a system response and it is not a material property. Interface wear is strongly dominated by operating conditions. Thus the measurement of wear is mainly influenced by the definition of wear that is considered. For the definition of loss of mass, it is possible to measure wear by simply weighing the worn object before and after a wear test. But this does not allow to measure wear if material displaced by wear gets attached to the worn object. Thus there are three basic methods of measuring wear, viz., detection of change in mass, measurement of reduction in dimension of a worn specimen and profilometry of the worn object. Measurement of mass change is usually done using a sensitive analytical balance since mass changes in wear are usually small. Reduction in dimensions of the worn object is usually measured by connecting a displacement transducer to the surface of the worn object that is directly above the wear spot. Linear variable differential transformer (LVDT) transducers or non-contact inductive proximity probes along with an electronic amplifier are commonly used. The other commonly used technique for evaluation of the worn volume from the wear scar is profilometry where either an optical profile projector, or stylus profilometer or a laser scanning profilometer is used. The optical profile projector is based on projecting an image of the object on a screen and measuring the change in dimensions of the worn specimen. In stylus profilometry technique, a picture of the wear scar is taken and compiled by using several evenly spaced traverses of the stylus over the scar. Then wear is determined from the deepest wear scar profile. In scanning profilometry technique, light from a laser is focused on the surface to measure the dimensions of the wear scar. Other specialized techniques for wear measurement are thin layer activation by radioactivity and ultrasonic interference measurements of dimensional changes. Noise emission and thermal emission from a dynamic contact can also be used for recoding changes in wear condition.

Many different experimental arrangements are used to study sliding wear. These are usually carried out either to examine the process by which wear takes place or to simulate practical situations to generate design data on wear rates and coefficients of friction.

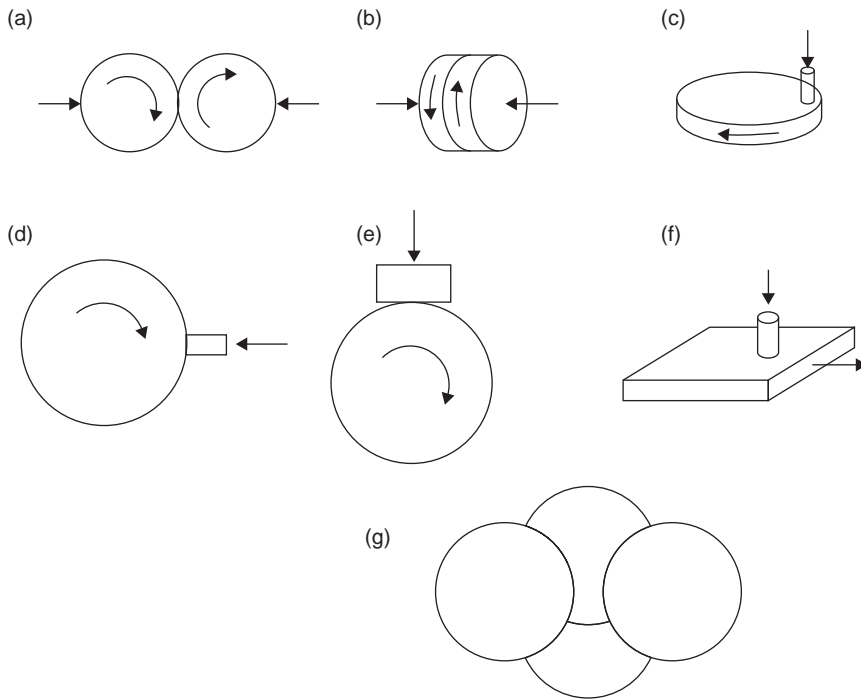

FIGURE 32.9 Sliding wear test arrangements (a) roller/roller, (b) disk/disk, (c) pin on disk, (d) pin on roller, (e) disk on roller, (f) pin on flat, and (g) four ball.

Close control and monitoring of all the variables which may influence wear are essential if the results of a test are to be useful for wider scientific purposes. Figure 32.9 shows the geometrical arrangements in several common types of wear testing apparatus. For adhesive wear between identical materials, the two surfaces are made of same material. For abrasive wear testing, one of the surfaces, generally the larger one, is made of abrasive material. Changes in geometries and arrangements are done for testing of different mechanisms of wear. For two-body abrasive wear, commercial bonded-abrasive paper or cloth is usually used for the counter-face, carrying evenly distributed grit particles of narrow size distribution, bonded to the substrate by a strong resin. In simulating three body abrasion, silica (quartz) particles of a narrow size distribution and from a specified source are fed at a constant rate into the contact region. Figure 32.10 shows schematic diagrams of four types of testing methods for erosive wear. In jet impingement method (a), particles are accelerated in a fluid stream along a nozzle to strike the target material, which is held some way from the end of the nozzle at a fixed angle. In re-circulating loop test (b), a two-phase flow of particles and fluid is driven around a loop of pipe-work where the specimen is kept completely immersed in the flow. In centrifugal accelerator (c), a continuous stream of particles, generated by circular motion of a rotor, strikes the stationary specimens arranged around the rim after rotor. In whirling arm rig (d), two specimens at the ends of a balanced rotor move at high speed through a slowly falling stream of particles, striking them at the peripheral speed of the rotor.

FIGURE 32.10 Schematic of erosive wear test arrangements: (a) jet impingement method, (b) recirculating loop, (c) centrifugal accelerator, and (d) whirling arm rig.

32.5 MEASUREMENT OF TEST ENVIRONMENT

Many experiments often omit the measurement of environmental factors such as temperature, humidity, and oxygen and lead to apparent conflict in experimental data. Careful measurement and control of these environmental factors is necessary for tribology experiments.

32.5.1 Temperature Measurement

In a dynamic contact situation, most of the frictional energy input is generally used up in plastic deformation which is directly converted to heat in the material close to interface with a consequent rise in temperature. Since the heat is produced as a continuous process, temperature gradients will develop in the contacting bodies with the highest temperature occurring at the point of heat release (heat source), that is, the contact surface. In the absence of lubricants, this heat is conducted into the two sliding bodies through contact spots. Contact between two bodies may be approximated as a single contact or as multiple contacts depending on the stress situation. For high contact stress situation, the real area of contact approaches the apparent area of contact and a single contact may be assumed to occur during sliding. Contact of two very smooth surfaces, even at low load, may be assumed as a single contact. For a low contact stress-sliding situation, most engineering contacts of interest are of this type, asperity interaction results in numerous high, transient temperature flashes of as high as several hundred degrees Celsius over a very small area within a few nanoseconds to a few microseconds. As the sliding continues, these temperature flashes shift from one place to another. Measurement of temperature rise over isolated

micro contacts is very difficult. A number of techniques have been used to measure the transient temperature rise in a sliding contact, but with limited success.

Techniques for interface temperature measurement include thermocouples, thin film sensors, radiation detector, metallographic observation, and liquid crystals. Thermocouples are most commonly used but do not measure true flash temperature. Radiation detectors come close to true measurement while liquid crystals and metallographic observations provide a rough estimate of flash temperature.

32.5.2 Thermocouples

A thermocouple uses wires of two dissimilar metals connected together at the two ends and gives rise to a thermal electromotive force (EMF) which depends on the difference in the temperature between two junctions, while one junction is kept at a known reference temperature (cold), the temperature of the other measuring junction (hot) can be obtained from measured EMF using a calibration chart. Two types of thermocouples are in use; embedded thermocouples and dynamic thermocouples. In embedded type, a small hole is drilled through the stationary component of a sliding pair and a small thermocouple is held within the hole such that its measuring junction rests just beneath the sliding surface. In dynamic variety, a thermocouple junction is created at the sliding interface of the contacting bodies. Schematics of the both the types are shown in Figure 32.11. While embedded type cannot measure true flash temperature because of its position and finite mass of measuring junction, the dynamic variety gives a good measure of an average surface temperature rise. Dynamic thermocouples are found to give higher values of measured temperatures and faster transient response than embedded thermocouples. The major disadvantage with dynamic type is that it can only be used for metallic pairs of dissimilar metals and requires electrical contact with a moving body.

32.5.3 Thin Film Sensors

Thin film temperature sensors are used on surfaces to measure temperature rise on a small region and on a very small mass. One of the first of its kind was the thermistor used to measure surface temperature on gear teeth. The resistance of titanium being sensitive to temperature and pressure, measurement of any change in resistance indicates the change in temperature and pressure. Magneto resistive (MR) sensors are used to measure interface flash temperature at magnetic head–medium interfaces. Thin film thermocouples produced by vapour deposition techniques are also used for measurement of sliding interface temperatures.

32.5.4 Radiation Detectors

All materials emit thermal radiation that depends on the surface temperature and structure of the material. It is concentrated in the infrared region if the temperature of the material lies between 10 and 5000 K. Knowing the radiation characteristics of the material and radiant heat transfer properties of particular geometry configuration, temperature of the material may be determined. This method has been successfully used to measure the transient flash temperatures. However, it requires one of the bodies to be transparent to the radiation to be detected and sapphire is a useful material

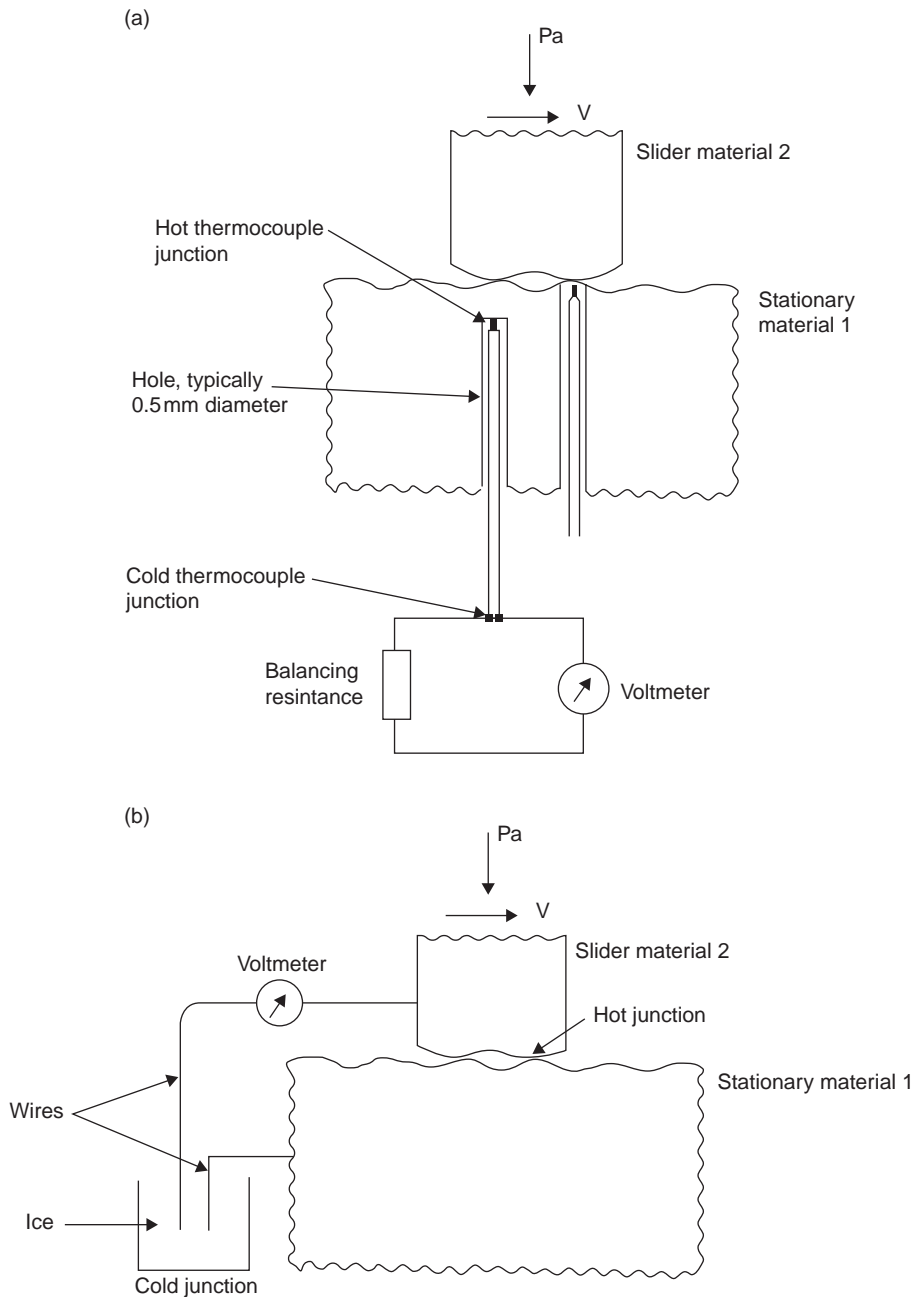

FIGURE 32.11 Schematics of thermocouples: (a) embedded type and (b) dynamic type.

in this respect. Different radiation measurement techniques have been successfully used to measure surface temperatures. These methods include photography, pyrometry, photon detection, and thermal imaging. In infrared detection technique, an infrared (IR) radiometric microscope is used for local surface temperature measurements

where the detector is equipped with optics to limit the field of view to a small spot size in order to permit a small spatial resolution. In photon detection technique, a photo multiplier is used to collect photons emitted by a hot contact spot. The response time of the photo multiplier being very small (less than 30 ns), the technique can be used for detecting flash temperatures of very short duration (2 μ s or less). In thermal imaging technique, a charged couple device (CCD) camera with an IR pass filter is used. The infrared radiation emitted at the contact surface is detected through the sapphire material by the CCD camera, which is linked to a computer-based image processing system. The IR-pass filter permits only IR radiation to reach the CCD camera. The video signal is then processed for thermal imaging and the contact temperature rise may be obtained by suitable transformation through calibration.

32.5.5 Metallographic Observation

Microstructure of many materials undergoes changes due to surface and near surface frictional heating. Using scanning electron microscopic examination of the cross-section of the sliding body in a perpendicular plane to sliding direction, these changes can be detected and may give a rough estimate of the temperature rise. For some material, this can be done by micro hardness measurements. In metal cutting, the flash temperatures during contact can be determined from the micro structural changes in the metal chips, but with limited accuracy. The major limitation of the method is that the micro structural changes may occur due to plastic deformation in surface or near surface regions, in addition to being due to temperature rise.

32.5.6 Liquid Crystals

Cholesteric liquid crystals are also used in surface temperature measurements because these crystals undergo changes in colour with very small change in temperature. When a surface of a body is coated with a specific liquid crystal and subjected to body temperature changes, the colour change occurring in the liquid crystal material estimates the temperature change. Liquid crystals can be sprayed or applied by brush. These are used to measure bulk temperature of bodies rather than flash temperatures.

32.5.7 Humidity Measurement

The routine measurement of humidity and its control at a constant level is necessary as it has a strong influence on friction and wear. Conventionally wet and dry bulb thermometers are used for humidity measurement during tribological studies.

32.5.8 Measurement of Oxygen and Other Gases

The variation in concentration of oxygen and other gases in the atmosphere affect the friction and wear processes to a large extent. Thus there is a need to observe their concentration during tribological tests for effective conclusion of the tests. For this purpose, gas chromatography is commonly used. Gas chromatography is a technique for separating different components of a mixture for analysis by diffusing a gaseous or vaporized sample through a column of liquid. This is based on the principle that different substances are transported at different speeds through a medium. A carrier gas, usually

nitrogen, hydrogen or helium transports the sample through the chromatograph. The mixture of sample and carrier gas is transferred to a long capillary tube filled with liquid, usually a hydrocarbon fluid like silicone oil or squalene, which acts as the separating medium. The components of the sample pass through the capillary tubes at different speeds and are then detected on leaving the capillary to obtain the composition of the sample. Oxygen analysis electrodes are readily available for direct measurement of oxygen concentration in water.

32.6 MEASUREMENT OF MATERIAL CHARACTERISTICS

Tribological behaviour of any material depends on its material characteristics. Each basic type of material, metal, polymer or ceramic, requires different specification of material properties. For metals, the chemical composition and metallurgical phases are significant. For polymers, the organic components, additives and degree of crystallinity are essential. For ceramics, apart from composition, grain size and material toughness are usually important parameters. Accurate measurements of hardness and microhardness are essential for analysis of surface contact and deformation in friction and wear. The materials are in general characterized using four quantities: (a) hardness, that describes the resistance to plastic deformation, (b) Young's modulus and the elasticity limit, that describe the materials' elastic properties, (c) toughness, that accounts for the relative brittleness of the material, and (d) residual stresses, that play an important role in the resistance to wear and cracking.

32.6.1 Hardness

Hardness tests use indenters to make an impression on a sample of a material under a normal load (F) and measure the surface area (S) of the residual impression left after removal of the load. Then hardness is expressed as F/S . Indenters can be of various shapes. For the Vickers test, a square-based pyramid is used while for the Brinell test, spherical indenters are used. For the Rockwell test, either conical or spherical indenters are used while Shore hardness tests use two types of cones.

In Vickers test, the indenter used is a diamond square-based pyramid with an angle of 136° between opposite faces as shown in Figure 32.12.

Vickers hardness is given by the formula:

$$HV = 1.854 \frac{F}{D^2}$$

where F is the applied load (kg) and D is the diagonal of the residual indentation (mm).

Brinell hardness is determined using tungsten carbide spherical indenters of 10, 5, 2.5 or 1 mm in diameter (shown in Figure 32.13). Brinell hardness can be expressed as:

$$HB = \frac{0.204F}{\pi D \left(D - \sqrt{D^2 - d^2} \right)}$$

where F is in N and both the diameter of the spherical indenter (D) and the diameter of the residual impression (d) are in millimetres.

FIGURE 32.12 Vickers hardness test: (a) Vickers indenter and (b) residual square indentation of diagonal D .

In Rockwell hardness test, the depth of the residual impression, h , is measured instead of its diameter. First a preliminary (minor) load of 98 N is applied and it forces the indenter into the surface to a depth of l (say). This depth of penetration is not taken into account in hardness measurement but used as the zero penetration reference point. Then a major normalized load is applied to the surface for a few seconds leading to a total depth of penetration t (say). The major load is then reduced to the minor load and the depth of the residual impression h is measured in millimeters. In Rockwell B test, a steel spherical indenter of diameter 1.58 mm is used with a normal load of 980 N. In Rockwell C test, the load is 1470 N and the indenter is a conical diamond indenter with radius of curvature of 0.2 mm and apex angle of 120° . Rockwell B and Rockwell C hardness can be expressed as:

$$\text{HRB} = 130 - \frac{h}{0.002}$$

FIGURE 32.13 Brinell hardness test: (a) indenter, and (b) residual impression.

and

$$\text{HRC} = 100 - \frac{h}{0.002}$$

The Shore hardness test is suitable specifically for polymers and is conducted with an apparatus called a durometer and a calibrated spring that generates a known force on the indenter. The penetration depth is recorded and the corresponding value of Shore hardness is obtained in a scale of 0–100 with these values corresponding to maximum penetration and zero penetration respectively. For Shore A test, a truncated cone with an apex angle of 35° is used while for Shore D test, a sharp cone with an apex angle of 30° is used.

32.6.2 Young's Modulus and the Elasticity Limit

For an isotropic material, Young's modulus is the constant of proportionality between the stress applied to a specimen rod and its elastic deformation. Generally uniaxial tensile tests are carried out to determine Young's modulus as well as the elasticity limit. However, the same can be determined from indentation tests also.

32.6.3 Fracture Toughness

Different modes of fracture can occur within a brittle material. Brittleness is characterized using a parameter known as fracture toughness (denoted K_{IC}), that describes the resistance of the material to fracture propagation. K_{IC} is generally determined from impact tests on a single-edge notch bend specimen. It can also be obtained using Vickers indentation tests by measuring the length of the radial crack during indentation.

32.6.4 Residual Stresses

Machining methods and surface production processes incorporate strains on the surface layers of materials that in turn induce internal residual stresses. These may be either tensile or compressive. Tensile stresses are dangerous as they help fracture propagation while compressive stresses are beneficial and often added deliberately to harden the surface of a material in order to increase its resistance to wear. Measurement of residual stresses is done either by destructive techniques or non-destructive techniques. The destructive method relies on the cutting-away of some stressed material and measuring of the resulting deformation in the adjacent material that has occurred due to the relaxation of the residual stresses. Non-destructive method relies on the analysis of the changes of the physical and crystallographic properties of the material due to residual stresses. These include the ultrasound method that uses the effect of residual stresses on the variation of speed of ultrasound waves, the Barkhausen technique that uses the interaction between elastic strain and magnetization in ferromagnetic materials, method of X-ray diffraction and so on.

32.6.5 Chemical Composition of a Surface

Chemical composition of a surface can be determined using a number of methods. Generally, a primary particle beam (electronic, optical or ionic) is directed at the surface under investigation and it produces the emission of secondary particles (photons, electrons or

FIGURE 32.14 Principle of spectroscopic surface analysis.

ions). The characterization of these secondary particles allows the identification of the composition of the surface under study (Figure 32.14). The most widely used techniques include Energy dispersive X-ray analysis (EDX), X-ray photoelectron spectroscopy (XPS), Auger electron spectroscopy (AES), Glow discharge optical emission spectroscopy (GDOS), Rutherford backscattering spectroscopy (RBS), Secondary ion mass spectroscopy (SIMS), Infrared (IR) spectroscopy. In EDX, primary particle is electron and secondary particle is photon. EDX helps in elemental analysis of materials to a depth of a few microns but this is not suitable for light element analysis. EDX is generally used in analysis of precipitation and segregation in metallurgical materials, characterization of thermal oxide films, hard coatings. In XPS, primary particle is photon and secondary particle is electron. It helps in elemental analysis of materials along with the information of the environment of the atoms and nature of chemical bonds. In AES, both primary and secondary particles are electrons. It helps in elemental analysis of the top few-atom layers of a solid. It is generally used for analysis of adsorbed layers, thermal or anodic oxide films, thin deposits and so on. In GDOS, primary particle is ion and secondary particle is photon. It can provide simultaneous elemental analysis of dozens of elements and in-depth sample analysis over large areas. In RBS, both primary and secondary particles are ions. In this technique, the analysis of the energy of backscattered helium ions after elastic collision with the sample surface atoms allows the determination of their mass. In SIMS, both primary and secondary particles are ions. It provides elemental and isotropic analysis of all elements in the periodic table. It can be used to obtain ionic images providing elemental distribution. In IR spectroscopy, both primary and secondary particles are photons. This is primarily used for the analysis of organic materials and allows the determination of functional groups present in the material and the nature of the different bonds.

32.7 MEASUREMENT OF LUBRICANT CHARACTERISTICS

Characterization of a lubricant is an essential part of any study related to lubricated wear and friction. Lubricant characterization requires both chemical and physical parameters. Hence different techniques of rheometry and chemical analysis are used for this purpose. Significance of lubricant parameters varies widely depending on the tribological function for which the same is used. For hydrodynamic and elasto-hydrodynamic lubrication, the parameters of significance are viscosity, Barus pressure–viscosity coefficient, temperature dependence of viscosity, limiting shear stress, glass transition, compressibility, thermal conductivity and so on. For boundary lubricants, the significant parameters are composition and concentration of surfactants and corrosive compounds, temperatures of lubricant failure, corrosivity, solubility, and diffusivity of dissolved gases. Sample of a used

lubricant can provide much information regarding the prevailing wear taking place within the tribological system or the quality of lubrication. Also the oxidation or chemical decomposition of a lubricant can easily be detected from the actual lubricant sample.

32.7.1 Analysis of Chemical Changes

Chemical changes occurring in lubricants are directly analyzed using Infra-Red Spectroscopy (IR Spectra). The only difficulty in this technique is the interpretation of complex spectra obtained from degraded lubricants. Specialized numerical analysis of IR spectra is done to extract proper analytical information from overlapping absorption peaks. The most popular one used to detect small changes in the IR spectra is Fourier Transform IR (FTIR) Spectroscopy. Typical IR spectra are displayed as a standard graph of IR transmittance or absorbance within the sample against wave number of the IR radiation.

32.7.2 Viscosity Measurement

The viscosity of lubricants can be measured by many methods based on different principles. Most commonly used instruments typically fall into four categories depending on geometry: Capillary, rotational, and falling sphere and efflux viscometers.

The capillary viscometer is based on measuring the rate at which a fluid flows through a small diameter tube and this takes the form of measuring the time taken to discharge a given quantity of liquid for an applied pressure difference and tube dimensions. In capillary viscometers a direct measurement of absolute viscosity is not possible and kinematic viscosity is measured. The kinematic viscosity is given as: $\nu = ct$ where c is a constant for a given viscometer and t is the time required for a given volume of liquid to flow through the tube. By using some liquid of known viscosity and density, the time required for a given volume to flow through the capillary is determined and the constant for the instrument is found. The sketch of one such viscometer is shown in Figure 32.15.

In rotational viscometers the absolute viscosity of oil is measured. Three different types of rotational viscometers are used: cylindrical, cone-plate type, and parallel plate type. The cylindrical type is in the form of two concentric cylinders of which one rotates in the oil whose viscosity is to be measured. The viscosity measurements are made either by applying a fixed torque and measuring the speed of rotation, or by driving the rotating element at a constant speed and measuring the torque required. The cone-plate and parallel-plate rotational viscometers are the variations of the same technique. For viscosity measurements of non-Newtonian fluids, rotational viscometers involving shearing of the fluid are used. These instruments are usually calibrated with fluids of known viscosity and the viscosities of test samples are taken from the calibration chart. Basic arrangement of cylindrical and cone-plate rotational viscometers are shown in Figure 32.15.

In falling sphere viscometer, the time taken for a ball to fall through a measured height of fluid in a tube is measured. The time required is a measure of absolute viscosity. Other variations of this type are also available. In rolling-sphere viscometer, a ball rolls down an inclined tube filled with test fluid. The falling co-axial cylinder viscometer consists of two coaxial cylinders with their axes vertical. The outer cylinder is clamped and the clearance space between the cylinders is filled with the test fluid. In operation, the inner cylinder is released and falls under gravity. The viscosity

FIGURE 32.15 Different viscometers: (a) u-tube viscometer, (b) rotating-cylinder viscometer, (c) cone and plate viscometer, (d) falling-sphere viscometer, (e) band viscometer, and (f) efflux viscometer.

is determined from the speed of descent of the cylinder whose motion is opposed by the shear stresses induced in the test fluid. Another variety is the band viscometer where a thin band is located in a narrow gap between two parallel shear blocks filled with the test fluid. The band is released to fall under gravity, its motion being opposed by the shear stresses induced in the test fluid. The viscosity is determined from the

speed of descent of band. These types of instruments are useful for non-Newtonian measurements and for high viscosity fluids.

In efflux viscometers the viscosity is measured by the time taken for a given volume of liquid to discharge under gravity through a short tube orifice placed in the base of the instrument. Three types are common: Redwood, Saybolt, and Engler. The first one is commonly used in the U.K. while the second one is mainly used in the Europe and U.S.A. In all these three instruments, the viscosities are quoted in terms of the efflux time, for example, Redwood sec, Saybolt sec or Engler sec. These measurements are then converted to kinematic viscosity using conversion tables.

32.7.3 Lubricant Oxidation Tests

Hydrocarbon lubricants oxidize readily as a result of low temperature acidification. Thus it is important to know the remaining useful life (RUL) of lubricant before the uncontrolled oxidation of the base oil occurs. This is done by conducting laboratory oxidation stability tests where the lubricant is oxidised under various conditions of temperature, pressure, and catalysts. Then lubricant characteristics such as viscosity, antioxidant depletion, total acid number, sludge content and so on are evaluated to measure oil degradation and oxidation stability, and finally to determine the remaining useful life of the lubricant. Lubricant oxidation stability tests can be grouped into three categories: bulk oxidation tests, micro-scale oxidation tests, and non-standard tests. The bulk oxidation test is done to see if excessive oil oxidation takes place when lubricating oil is stored in a storage tank. These methods include open vessel tests, bomb oxidation tests and so on. Micro-scale oxidation tests involve small amounts of lubricant and are carried out to accurately simulate oxidation of oil when it is present as a thin layer so that all parts of the oil are in close contact with atmospheric oxygen. These methods include thin layer oxidation tests, gel permeation chromatography and so on. Non-standard tests are done to reduce the test duration in comparison to standard tests. These methods include differential scanning calorimetry, differential thermal analysis, thermogravimetric balance, chemiluminescence tests and so on.

32.8 WEAR PARTICLE ANALYSIS

Wear particles are produced during almost every tribological operation and are an important source of information about wear processes. The composition, size, and morphology of wear particles are indicative of the wear mechanism involved in their formation. Wear particle analysis helps to assess the condition of the machinery and reliability in mechanical systems. Two basic types of analysis are widely used. One is based on the analysis of the chemical composition of the lubricant to reveal the presence and quantity of metallic wear particles in hydrocarbon based lubricating oil. The other method involves an extraction of wear particles from a used lubricant and then assessment of their number, size, shape, and morphology.

32.8.1 Chemical Analysis of Particles in Lubricant

The common method used to analyze the chemical composition of particles present in lubricating oil is flame spectroscopy. This is based on the principle of emission or

absorption of characteristic colour by individual chemical element when heated in a flame or arc. Systematic analysis of the colours so produced by a lubricant sample provides a complete data of the chemical elements present therein. The concentration of different elements can also be assessed. The technique of flame spectroscopy is commonly known as Spectroscopic Oil Analysis Program (SOAP) which is used in machine condition monitoring. SOAP is used to specify whether to continue operating a machine or to go for any maintenance based on the concentration of contaminant metals and water in the lubricating oil beyond acceptable limits. In tribological experiments on lubricated wear, SOAP is used to determine if oil is functioning at desired conditions. SOAP provides the information about very small wear particles that remain suspended in the oil but fails to capture large wear particles. Thus as the size of the wear particles increases the SOAP accuracy decreases and it becomes insensitive to particles larger than 10 μm .

32.8.2 Analysis Based on Separation of Wear Particles

To avoid the limitations of SOAP analysis, a technique called 'Ferrography' is developed. In this method, wear particles are separated from the lubricating oil according to their size based on the application of a strong magnetic field. A sample of lubricating oil or oil diluted by solvent is allowed to flow over an inclined glass slide suspended above a magnetic field. The fluid sample flows by gravity along the slide. The combination of viscous and magnetic forces acting on the wear particles helps in separation and settlement of the particles on the glass slide. Large particles of iron and steel get deposited near the entry region due to strong attraction of the magnetic field and fine particles are deposited away from the entry region on the slide. Then the slide containing the thin streak of wear particles is subjected to either analytical ferrography or direct reading ferrography. In the former method, the slide is examined under a microscope to study the morphology of wear particles. In the other method, the change in transmission of light through wear particles deposited in a glass tube is measured.

The shape and surface morphology of wear particles provide the information of how the wear particles are formed. Wear particle morphology is in general described by two sets of parameters: particle boundary descriptors like aspect ratio, shape factor, convexity, curl, roundness, fractal dimension and so on and surface topography descriptors like perspective view, colour stereo, contour map image and so on.

32.9 INDUSTRIAL MEASUREMENTS

Measurements in an industrial context are performed to confirm the performance of a component or system. This is usually different from scientific tribological measurement where the basic objective is to develop a model of friction, wear or related phenomena. Industrial measurements are primarily empirical and differ from scientific investigation in respect to specification. Industrial testing usually relates to commercial products, where the test specification is either confidential or incompletely specified. For example, oil additives are marketed without publicly available specification. In many cases, complexity of the phenomena occurring inside the system hinders direct tribological investigation in a simple tribometer. The interaction

between the lubricating oil and combustion cycles of an internal combustion engine is extremely difficult to simulate with the help of a tribometer. Thus direct testing of the engines and gearboxes is the only means to evaluate the performance of the system. Similarly metalworking involves many frictional situations that cannot be simulated in a tribometer and the same requires special tests that are significantly different from common tribological testing with respect to the controlling factors. In metalworking the significant parameters are surface finish, precision, tool life, power consumption and so on. The complexity of service conditions inside a synovial joint in orthopaedic implants is always a challenge to tribologists and designers of tribometers. All these fields of testing ranging from lubricants to orthopaedic implants are known as 'industrial tribology' where the major concern is to overcome the difficulties in identifying the controlling parameters to have a comprehensive understanding of the system.

32.10 SUMMARY

Tribologists for generations have faced a unique problem; predictions and designs are based on continuum and scale independent phenomenon. Though tribological interactions often occur in very small scales and volumes, the observations are related to large-scale dimensions and volumes. As an example, Bowden and Tabor's junction growth model may be cited. It is a very small volume phenomenon at the asperity level that involves molecular level interactions. But due to unavailability of instrumentation that makes it possible to observe directly the phenomenon and the related small volume deformations, the model was based on continuum plasticity theory to provide a phenomenological view of adhesive wear and friction. The situation has undergone a dramatic change in last two decades. With a virtual revolution in materials technology and electronics; reliable measurements down to nano- and Pico metric levels are now possible. This advancement coupled with recent advances in non-continuum modelling at the molecular level has opened up a new horizon for the tribologists and scientists. These advances have opened up the new field of nanotribology. It involves experimental and theoretical investigations of interfacial processes on scales ranging from the atomic/molecular to micro-scale that occur during adhesion, friction, wear, indentation, and thin film lubrication at sliding surfaces.

33.1 WHAT IS CORROSION MONITORING?

Corrosion monitoring refers to corrosion measurements performed under industrial or practical operating conditions. In its simplest form, corrosion monitoring may be described as acquiring data on the rate of material degradation. However, such data are generally of limited use and need to be converted into useful information for inclusion in a corrosion management program. This requirement has led to the evolution of corrosion monitoring tools toward real-time data acquisition, process control tools, knowledge-based systems, and smart structures. Corrosion monitoring is more complex than the monitoring of most other process parameters because

- There are a number of different types of corrosion (see Chapter 2 for more details).
- Corrosion may be uniform over an area or concentrated in very small areas (pitting).

- General corrosion rates may vary substantially, even over relatively short distances.
- There is no single measurement technique that will detect all of these various conditions.

Before embarking in a corrosion monitoring program, it is therefore helpful to review historical data and consider the types of corrosion problems that need to be investigated. It is also advisable to use several complementary techniques rather than rely on a single monitoring method.

Real-time monitoring of pipelines, vessels, and other static equipment enables a near instantaneous appraisal of the corrosivity of produced and transported fluids. If the corrosion activity increases as a result of process nonconformities, the corrosion information can be viewed alongside process variables such that cause-and-effect can be determined and rapid action can be taken to stifle the progress of any associated problem. The same approach can be used to demonstrate the effectiveness of remedial actions or preventive treatments.

Some modern corrosion monitoring technologies are particularly apt at revealing the highly time-dependent nature of corrosion processes. The integration of these corrosion monitoring technologies in existing systems can thus provide early warnings of costly corrosion damage.

An extensive range of corrosion monitoring techniques and systems has evolved, particularly in the last two decades, for detecting, measuring, and predicting corrosion damage. The development of efficient corrosion monitoring techniques and user-friendly software have permitted us to field new techniques that were until recently perceived to be mere laboratory curiosities. Noteworthy catalysts to the growth of the corrosion monitoring market has been the expansion of oil and gas production under extremely challenging operational conditions (e.g., the North Sea), cost pressures brought about by global competition, and the public demand for higher safety standards. In several sectors, such as oil and gas production, sophisticated corrosion monitoring systems have gained successful track records and credibility, while in other sectors their application has made only a limited progress.

33.2 THE ROLE OF CORROSION MONITORING

Correct and effective corrosion monitoring strategies should be used as a proactive tool to assist with operating a plant or any other system more effectively, thereby prolonging its life and gaining optimum throughput. Fundamentally, four strategies are available to an organization in its dealings with corrosion:

1. Ignoring it until a failure occurs.
2. Inspection, repairs, and maintenance at scheduled intervals.
3. Using corrosion prevention systems (inhibitors, coatings, resistant materials etc.).
4. Applying corrosion control selectively, when and where it is actually needed.

The first strategy represents corrective maintenance practices, whereby repairs and component replacement are only initiated after a failure has occurred. Corrosion monitoring is completely ignored in this reactive philosophy. Obviously, this practice is unsuitable for safety critical systems and in general is inefficient from maintenance cost considerations, especially during life extension of aging engineering systems.

The second strategy is one of preventive maintenance. The inspection and maintenance intervals and methodologies are designed to prevent corrosion failures, while achieving 'reasonable' system usage. Corrosion monitoring can assist in optimizing these maintenance and inspection schedules. In the absence of information from a corrosion monitoring program, such schedules may be set too conservatively with excessive downtime and associated cost penalties.

Alternatively, if set too infrequently, the inspection and maintenance intervals may represent an excessive corrosion risk with associated cost and safety consequences (cf. Figure 3.10). Furthermore, without input from corrosion monitoring information, preventive inspection and maintenance intervals will be of the "routine" variety, without accounting for the time dependence of critical corrosion variables. In the oil and gas industry, for example, the corrosivity at a well-head can fluctuate significantly over the lifetime of the production system, between benign to highly corrosive. In oil refining plants, the corrosivity can vary with time, depending on the grade or hydrogen sulfide content of crude that is processed.

The application of corrosion prevention systems is obviously crucial in most corrosion control programs. However, without corrosion monitoring information, their application may be excessive and costly. For example, a certain inhibitor dosage level on a particular system may combat corrosion damage, but real-time corrosion monitoring might reveal that a lower dosage would actually suffice. Ideally, the inhibitor feed rate should be continuously adjusted based on real-time corrosion monitoring information.

In an ideal corrosion control program, inspection, and maintenance would be applied only where and when they are actually needed. In principle, the information obtained from corrosion monitoring systems can be of great assistance in reaching this goal. However, it is sometimes difficult for a corrosion engineer to get management's commitment to investing funds in such initiatives. The importance of corrosion monitoring in industrial plants and other engineering systems should be presented as an investment to achieve some of the following goals:

- Improved safety.
- Reduced downtime.
- Production of early warnings before costly serious damage sets in.
- Reduced maintenance costs.
- Reduced pollution and contamination risks.
- Longer intervals between scheduled maintenance.
- Reduced operating costs.
- Life extension.

Experience has shown that the potential cost savings resulting from the implementation of corrosion monitoring programs generally increase with the sophistication level (and cost) of the monitoring system.

33.3 CORROSION MONITORING SYSTEM CONSIDERATIONS

Corrosion monitoring systems vary significantly in complexity, from simple coupon exposures or handheld data loggers (Figure 33.1) to fully integrated plant process surveillance units with remote data access and data management capabilities.

Corrosion sensors (probes) are an essential element of all corrosion monitoring systems. The nature of the sensors depends on the various individual techniques used for monitoring, but often a corrosion sensor can be viewed as an instrumented coupon. A single high-pressure access fitting for insertion of a retrievable corrosion probe can be used to accommodate most types of retrievable probes. With specialized tools (and brave specialist operating crews!) sensor insertion and withdrawal can be possible under pressurized operating conditions.

The signal emanating from a corrosion sensor usually has to be processed and analyzed. Examples of signal processing include filtering, averaging, and unit conversions. Furthermore, in some corrosion sensing techniques, the sensor surface has to be perturbed by an input signal to generate a corrosion signal output. In older systems, electronic sensor leads were usually employed for these purposes and to relay the sensor signals to a signal-processing unit. Advances in microelectronics have facilitated the sensor signal conditioning and processing by the introduction of microchips that have become an integral component of sensor units (Zollars et al., 1997; Kelly, 1997). Wireless data communication with such sensing units is also a product of the microelectronic revolution. Figure 33.2a and b illustrates a recent wireless monitoring system developed to provide an early warning that a protective coating is degrading (Davis et al., 2005). Such a direct

measurement contrasts with corrosivity sensors that monitor indirectly the problem by monitoring ambient environments.

Irrespective of the sensor details, a data acquisition system is required for on-line and real-time corrosion monitoring. On several plants, the data acquisition system is housed in mobile laboratories, which can be made intrinsically safe. A computer system often performs a combined role of data acquisition, data processing and information management system. In data processing, a process is initiated to transform corrosion monitoring data (low intrinsic value) into process relevant information (higher intrinsic value). Complementary data from other relevant sources, such as process parameter logging and inspection reports, can be acquired together with the data from corrosion sensors, for use as input to a management information system.

Numerous real-time corrosion monitoring programs in diverse branches of industry have revealed that the severity of corrosion damage is rarely uniform with time. Rather, serious corrosion damage is usually sustained in time frames where operational parameters have suffered upsets. These undesirable operational windows can only be identified with the real-time monitoring approach.

In general, it can be said that no individual technique alone is suitable for monitoring corrosion under complex industrial conditions. Therefore, a multitechnique approach is often preferred. In many cases, this approach does not require a higher number of sensors, but rather only an increased number of sensor elements for a given probe and access fitting.

Another important consideration is that, irrespective of the technique, most instrumented sensors only provide semiquantitative corrosion damage information. It is thus sensible to correlate monitoring data from these sensors to long-term coupon exposure programs and actual plant damage. Unfortunately, nonspecialists may put too much faith in the numerical corrosion rate displayed by a commercial corrosion monitoring device. An example of a widely available technique is linear polarization resistance (LPR), which many commercial monitoring systems use to measure corrosion rates, commonly displayed as millimeters/year or milli-inches/year (mpy).¹ Such systems are used extensively in industry for monitoring the effectiveness of water treatment additives and various other applications. However, from fundamental considerations, the derived LPR corrosion rate is only valid if the following assumptions are met, which is rarely the case in actual operational conditions:

- There is only one simple anodic reaction.
- There is only one simple cathodic reaction.
- The anodic and cathodic Tafel constants are known and invariant with time.
- The corrosion reactions proceed by a simple charge-transfer mechanism under activation control, which essentially implies that the corroding surface is clean without corrosion product build-up, scale deposits, or solids settled out of solution.
- Corrosion proceeds in a uniform manner (whereas the vast majority of industrial corrosion problems are related to localized attack).

¹ Table 2.2 provides the conversion factors between commonly used corrosion rate units for all metals and Table 2.3 describes these conversion factors adapted to iron or steel (Fe) for which $n = 2$, $M = 55.85 \text{ g mol}^{-1}$, and $d = 7.88 \text{ g cm}^{-3}$.

- The solution resistance is negligible (some instruments make a solution resistance compensation but this is not necessarily accurate).
- The corrosion potential has reached a steady state value.

The following sections describe in more specific details the various elements that should be considered when deciding on a corrosion monitoring program.

33.3.1 What Is the Monitoring Objective?

The first and most essential step of a corrosion monitoring program is to define the monitoring objective, a step often forgotten. If corrosion monitoring is done for corrosion control the purpose is to assure that asset life is not jeopardized by too many high corrosion rate events. The main objective of corrosion monitoring is in this case to limit the “corrosion events,” without completely using the corrosion allowance of a system before the end of its design life. The main factors that govern the design of a monitoring system in this case are (Thomas and Terpsta, 2003) available corrosion allowance; uncontrolled corrosion rates; event rates; corrosion rate detection sensitivity and response rate; and required service life.

If corrosion monitoring is used for corrosion control, it is thus essential that the corrosion mechanism and the corrosion rates during times of noncompliance be relatively well known. Corrosion monitoring can also be used in a corrosion control context to establish the corrosion mechanism of a system or optimize the corrosion control, for example, testing the efficiency of corrosion inhibitors, adjusting the corrosion inhibitor injection rate, or studying corrosion mechanisms. Such measurements can either be carried out on instrumented sections of the actual system or in a side stream.

Corrosion monitoring could also be needed in a broader context of integrity management to ensure that the operating envelope of a system is not exceeded. The time horizon of ongoing integrity activities can be much shorter than the plant lifetime, by virtue of the definition of integrity. This can be satisfied by ensuring that integrity is maintained up to the next inspection date and reassessed for another period.

33.3.2 Corrosion Monitoring Locations

An important decision in setting up a corrosion monitoring system is the selection of the monitoring points or sensor locations. As only a finite number of points can be considered for obvious economical reasons, it is usually desirable to monitor the “worst-case” conditions, at points where corrosion damage is expected to be most severe. Often, such locations can be identified by reasoning with basic corrosion principles, analysis of in-service failure records and in consultation with operational personnel. For example, the most corrosive conditions in water tanks are usually found at the water–air interface. Corrosion sensors could be attached to a floating platform to maintain these conditions independently of water level changes in order to monitor corrosion under these conditions.

In any monitoring situation, the ideal probe placement is most often not possible. Invariably, the flush or protruding electrode probes require to be placed in the most corrosive environment (e.g., at a 6 o’clock position in a pipeline, at the bottom of a vessel, or at a solution accumulation point in a separator tower). Almost equally invariably, the

available location is entirely at odds with these requirements. Although certain steps can be taken to provide the application with a modified design (e.g., a protruding electrode probe installed at the 12 o'clock position with a long body to extend to the aqueous phase), this is without question a compromise on the part of the technology provider (Eden et al., 2003).

It is obviously imperative that corrosion sensors be positioned to reflect the state of the actual component or system being monitored. If this requirement is not met, all subsequent signal processing or data analysis is negatively impacted and the value of information greatly diminished or even rendered worthless. For example, if turbulence is induced locally around a protruding corrosion sensor mounted in a pipeline, the sensor will in all likelihood give a very poor indication of the risk of localized corrosion damage to the pipeline wall. In this particular case, a flush mounted sensor should be used instead if the goal is to monitor localized corrosion (Figure 33.3).

In practice, the choice of monitoring points is also dictated by the existence of suitable access points, especially in pressurized systems. It is usually preferable to use existing access points, such as flanges for sensor installations. If it is difficult to install a suitable sensor in a given location, additional by-pass lines with customized sensors and access fittings may represent a practical alternative. One advantage of a by-pass is the

FIGURE 33.3 Flush mounted corrosion sensor in an access fitting. (Courtesy of Metal Samples Company, www.metalsamples.com.)

opportunity of experimenting with local conditions of highly corrosive regimes in a controlled manner, without affecting the actual operating plant.

33.3.2.1 Process Industry The following example illustrates how critical sensor locations have been identified for a distillation column (Dean, 1986). The feed point, overhead product receiver, and bottom product line represent locations of temperature extremes and also points where products with different degrees of volatility concentrate. In many cases however, the highest corrosivity is encountered at an intermediate height in the column where the most corrosive species concentrate. Initially, therefore, several monitoring points would be required in such a column (Figure 33.4). As monitoring progresses and data from these points become available, the number of monitoring points could be optimized further.

33.3.2.2 Oil and Gas Production Gathering Lines Corrosion processes within oil and gas production gathering lines and process piping are usually monitored by the use of metal loss coupons or electrical resistance probes inserted into process fluids through access fittings (Powell et al., 2001). Once exposed to the process fluids for periods ranging from 90 days to 1 year, depending on the system and the corrosivity of the fluids, the coupons are removed and cleaned. A comparison of their initial and final weights is used to determine the general corrosion rate, based on the assumption of uniform corrosion

FIGURE 33.4 Corrosion monitoring points in a distillation column.

throughout the exposure period. Corrosion pitting rates can also be determined on the same coupons by measuring the depth of the deepest pit.

In the same environment, electrical resistance (ER) and LPR probes can yield near real-time measurement of the corrosion rate within the process systems. These techniques provide corrosion rate measurements, such that short-term events that affect the rates can be easily identified. For example, the flowback of an acid stimulation treatment can be detected, provided the data readings are sufficiently frequent. Fortunately, remote data collectors and computers greatly reduce the time needed to record and analyze corrosion probe data.

Coupon monitoring and real-time corrosion monitoring techniques complement each other as they focus on different time intervals and should be integral parts of any comprehensive corrosion monitoring system.

The most important consideration when selecting corrosion monitoring locations within crude oil or wet gas production systems is to find locations near the end of the pipeline where the corrosion coupon or probe will be immersed in any produced water. This placement is typically at the 6 o'clock position on horizontal sections of pipeline because produced water is heavier than crude oil or gas condensates. In Figure 33.5a, the monitoring probe installed at 6 o'clock is in an ideal position to sense corrosion processes.

Figure 33.5b illustrates a gas production line that contains a small quantity of condensate and produced water. The water is swept along the bottom of the pipe for horizontal runs. (Only at high fluid velocity is water swept along the circumference of the pipe.) Hence, monitoring locations on the side of the pipeline (3 or 9 o'clock) as shown in Figure 33.5b cannot accurately measure the corrosion rates associated with the aqueous phase at the bottom of the pipeline.

Unfortunately, many pipeline and facility designers have installed monitoring locations on the sides of the pipelines rather than the bottom. Although the side locations may provide easier access for coupon crews, these coupons or probes cannot provide accurate data unless the pipelines are essentially full of water.

FIGURE 33.5 (a) Probe at 9 o'clock. The intrusive probe is incorrectly positioned and cannot monitor corrosion associated with the water phase. This probe would yield invalid results because it is in the gas or oil phase. (b) Probe at 6 o'clock. The flush-mounted probe is best positioned to monitor corrosion, even when there are small volumes of produced water, as in wet gas or some three-phase pipelines.

Hence, operator convenience must not come at the expense of obtaining valid results when selecting coupon or probe monitoring locations.

It is best to design and install the coupon or probe access fittings during the initial fabrication and installation of pipeline systems rather than retrofitting. Although “hot taps” can be conducted safely, they require additional cost, preparation, and integrity checks.

Another consideration is the quantity of water within the pipeline. This determines whether intrusive or flush mounted coupons or probes are the better choice. For example, if an intrusive probe is installed within a wet gas pipeline, the sensing element extends well above the bottom pipe wall and cannot give valid readings. If, however, the pipeline contains three-phase production with a large water cut, inserting an intrusive probe to position the sensing element within the produced water might work. However, a flush mounted probe is generally the better choice because it is less dependent on the quantity of produced water. For pipelines carrying water, linear polarization probes may be used. If hydrocarbons are present, however, they will coat the sensing element and increase the noise/signal ratio. Thus, electrical resistance probes are recommended whenever hydrocarbons are present.

When natural gas is produced, small quantities of water and condensates may typically be produced. Quantities vary, but volumes are usually 160 L of water and up to 16,000 L of hydrocarbon condensate per 30,000 standard cubic meters. The produced water, being heavier than the gas or condensates, is generally swept along the bottom of the pipelines by the flow of gas. The water may accumulate in dead legs or low spots along the pipelines until the volumes are such that the gas will be able to push the fluids further down the pipelines.

Intrusive probes should be located where they can remain in place for extended periods, rather than having to be removed periodically to support pigging and other routine operations. Thus, an intrusive probe should be installed upstream of any pig launcher and downstream of any pig receiver so as not to block the path of the pig. Where this is not possible, flush-mounted probes should be used.

33.3.3 Probe Design and Selection

The probe design is another important consideration in corrosion monitoring since the probe element interfaces directly with the process environment and must be both suitable for the installation location and enable to make representative corrosion measurements. All too often, the quality and relevance of the corrosion data measured can be severely compromised by inappropriate probe design. In this context, knowledge of the probe surface condition is particularly crucial during the initial design and obviously remains important for the duration of the exposure period.

Other factors to consider relate to surface roughness, residual stresses, corrosion products, surface deposits, preexisting corrosion damage, and temperature that can all have an important influence on corrosion damage and need to be taken into account for making representative probes. By considering these factors, it can be desirable to manufacture corrosion sensors from a precorroded material that has experienced actual operational conditions. Heating and cooling may also be applied to corrosion sensors, using special devices, for their surface conditions to reflect certain plant operating domains. Sensor designs, such as spool pieces in pipes and heat exchanger tubes, flanged sections of

candidate materials or test paddles bolted to agitators, also represent efforts to make these sensors representative of actual operational conditions.

The choice of a specific monitoring probe should also be based on the anticipated corrosion rates within the system, as well as on the required sensitivity. When conducting a short-term corrosion test, probes with high sensitivity are desired. For long-term monitoring, however, a thicker probe element with a longer measurement lifetime may be desired.

For rapid flow conditions or if there are concerns related to suspended solids, the sensing elements should be protected with a velocity shield. An ER probe can also be used to measure an “erosion rate” associated with production of sand or other solids. For this purpose, a noncorroding metal element should be selected (Powell et al., 2001).

33.3.3.1 Flush-Mounted Electrode Design The flush-mounted electrode design is most appropriate for use in applications, such as oil and gas flowlines where pigging operations are necessary. While the design is suited to this application operational need, it greatly limits the electrode exposed surface area and the accuracy of the measurements, particularly in low conductivity environments or with low sensitivity instrumentation. As with most measurement processes there is a trade-off between available area for measurement and the opportunity to actually measure corrosion events of low statistical probability (Eden et al., 2003).

Great care must also be taken in the manufacture of this type of probe as the opportunity exists to artificially create unwanted physical phenomena, such as crevices. A crevice created between the outer circumference of an electrode and the surrounding insulating material could provide a focal point for localized corrosion activity and introduce a significant error in the measured data. This effect would be reduced by using larger surface area electrodes.

While this type of probe can be supplied with electrodes of sufficient material to last the lifetime of the component into which it is installed, the monitoring program undoubtedly will benefit from the ability to replace the probe on a regular basis for visual inspection and to confirm the measured data.

33.3.3.2 Protruding Electrode Design The protruding electrode design has more broad-ranging applications than the flush mounted design. A major benefit of this design is the possibility to use replaceable electrodes, as this provides a cost-effective solution. The possibility of crevice corrosion is also less important as the exposed length of an electrode increases the ratio of exposed surface area to the region where a crevice might occur, that is, the circumference of the electrode. However, this design relies on the complete exposure of the electrode surface to the corrosive environment, and so issues may arise in situations where the flow regime within the monitored system becomes turbulent or if the water cut is reduced significantly during operation (Eden et al., 2003).

33.3.3.3 Probes to Suit the Application Each corrosion monitoring application has its specific needs and requirements. The following sections describe a few probe designs that have been developed for specific degradation mechanisms and environments.

Stress Corrosion Cracking Probe Corrosion probes have been developed that enable the working electrode of a three-electrode arrangement to be prestressed to yield stress in

order to match the operating condition of a pipe or vessel. In the following example, corrosion monitoring and control of the double-shell tanks (DSTs) at Hanford had historically been provided through a waste chemistry sampling and analysis program. In this program, waste tank corrosion was inferred by comparing waste chemistry samples taken periodically from the DSTs with the results from a series of laboratory tests done on tank steels immersed in a wide range of normal and off-normal waste chemistries (Edgemon, 2005).

This method has been effective, but is expensive, time consuming, and does not yield real-time data. The Hanford Site near Richland, Washington, has 177 underground waste tanks that store ~253 million liters of radioactive waste from 50 years of plutonium production. In 1996, the Department of Energy Tanks Focus Area launched an effort to improve Hanford's DST corrosion monitoring strategy and to help address questions concerning the remaining useful life of these tanks. Several new methods of on-line localized corrosion monitoring were evaluated. The electrochemical noise (EN) technique was selected for further study based on numerous reports that showed this technique to be the most appropriate for monitoring and identifying the onset of localized corrosion.

Based on a series of studies, a three-channel prototype field probe was designed, constructed and deployed in August 1996. Following the demonstration of the prototype for approximately a year, a longer more advanced eight-channel system was designed and installed in September 1997. Figure 33.6 shows the installation of this system. Unlike the previous prototype, the in-tank probe on this system reached from tank top to tank bottom exposing two channels of EN electrodes in the sludge at tank bottom, four channels in the tank supernate, and two channels in the tank vapor space. Four additional systems of similar design have been installed into other DSTs.

Like most EN based corrosion monitoring systems, the active Hanford systems monitor EN on channels composed of three nominally identical electrodes immersed in the tank waste. Each system is composed of an in-tank probe and ex-tank data collection hardware. The in-tank probe is fabricated from a ~17-m long piece of 2.5-cm diameter

FIGURE 33.6 Installation of first full-scale probe into a double-shell tank (DST) at the Hanford site. (Courtesy of HiLine Engineering & Fabrication.)

FIGURE 33.7 Detail of the Hanford site 25-cm² bullet and 47-cm² C-ring channel electrodes. (Courtesy of Glenn Hedgemon, HiLine Engineering & Fabrication.)

stainless steel tubing. Eight three-electrode channels are distributed along the probe body. Electrodes are fabricated from UNS K02400 steel that has been heat treated to match the tank wall heat treatment. Four channels on each probe are formed from sets of bullet-shaped electrodes (25 cm² per electrode). Four channels are formed from sets of thick-walled C-rings (44 cm² per electrode). Figure 33.7 shows two channels on the most recent probe. The unstressed bullet-shaped electrodes are used for pitting and uniform corrosion detection. The working electrode on each C-ring channel is notched, precracked and stressed to yield prior to installation to facilitate the monitoring of SCC should tank chemistry conditions change to allow the onset of cracking. The other two C-rings on each C-ring channel are not stressed to match the operating conditions of the vessel. Bullet and C-ring channels alternate up the length of the probe. Current DST waste levels in monitored tanks immerses three channels of bullet-shaped electrodes and three channels of C-ring electrodes.

In this way, the working electrode is allowed to behave in a manner most representative of the material in-service, thus providing corrosion information reflecting the real-life situation of the plant equipment. The exposure of single or multiple corrosion probes can enable informed decisions to be made regarding the choice of a material or of a stress relief process.

Corrosion in Hydrocarbon Environments In hydrocarbon environments there must be an electrolytically conductive phase present, which is generally provided by an aqueous phase or by polar solvents, for corrosion to occur. Examples may be flowlines in oil and gas applications or pipelines in chemical process environments where it may not be straightforward to introduce a complex probe system.

A circumferential spool probe has been developed specially for this application to allow a maximum contact of the electrodes with the process environment in “true” flowing conditions along flowlines or pipelines, especially in multiphase oil and gas applications.

The basic ring principle of these sensors allows elements to be made by “salami” slicing a pipe and reassembling pairs of the resulting rings, separated by insulation, to remake

FIGURE 33.8 The principle of ring pair corrosion monitoring. (Courtesy of Cormon Ltd.)

a pipe section capable of retaining line pressure. Each electrically isolated ring is measured using pick up wires attached to the outer face. If wires are attached at equally spaced intervals around the ring the instrumentation can be configured to measure the overall metal loss and the loss in the segment between each pick-up point Figure 33.8.

One of each pair of rings is kept from contact with the process stream by means of a high integrity, thin-film, ceramic coating. The coated ring acts as the reference to the exposed sample ring.

A number of pairs of rings may be used enabling the study of different materials including weldment and HAZ material if preferential weld corrosion is an issue. In addition to the temperature data from the elements, it is a simple matter to include pressure measurement in the device. Together these may add considerably to the understanding of the behavior of the fluid in the line.

Standard rings have the same wall thickness as the original line so no problem should arise with element life in relation to the service life of the line. The thicker wall rings do have a lower speed of response that may not always meet the requirement, especially if real-time adjustment to chemical treatment is proposed. In this case, a combination of two concentric rings may be used to provide a fast response from a thin element inside a thicker supporting ring.

The potentially limited life of the element is balanced by the ability to maintain low corrosion rates through active control, thereby extending the life of the asset and the sensor. The spool sensor is, therefore, a very versatile measurement tool for looking at the character and degree of corrosion of various materials in conditions that are a true representation of line flow. It is capable of being finely tuned to perform the required task with great precision.

The sensor housing uses a double pressure barrier principle. The sensor rings, spacers, and isolators are held in compression by a clamp arrangement producing an inner-pressure tight cylinder. This cylinder is mounted in the outer housing using a pair of

FIGURE 33.9 A ring pair corrosion monitoring system being deployed at sea during the installation of a submerged pipeline. (Courtesy of Cormon Ltd.)

elastomer seal rings to complete the primary containment. The outer housing is a pressure tight assembly in its own right, sealed using flanges, ring type joints, and a spacer ring. Electronics, housings, power consumption, and telemetry are similar in most respects to those for intrusive probes. Figure 33.9 illustrates a monitoring system being deployed with a pipeline as it is submerged in sea.

Coupled Multielectrode Array Systems and Sensors The use of multielectrode array systems (CMAS) for corrosion monitoring is relatively new. The advantages of using multiple electrodes include the ability to obtain greater statistical sampling of current fluctuations, a greater ratio of cathode-to-anode areas that enhances the growth of localized corrosion once initiated, and, depending on the design, the ability to estimate the pit penetration rate and to obtain macroscopic spatial distribution of localized corrosion (Yang et al., 2002).

Figure 33.10 shows the principle of the CMAS in which a resistor is positioned between each electrode and the common coupling point. Electrons from a corroding or a relatively more corroding electrode flow through the resistor connected to the electrode and produce a small potential drop usually of the order of a few microvolts. This potential drop is measured by the high-resolution voltage-measuring instrument and used to derive the current of each electrode. The CMAS probes can be made in several configurations and sizes, depending on the applications. Figure 33.11 shows some of the typical probes that were reported for real-time corrosion monitoring.

The data from these CMAS probes are the large number of current values measured at a given time interval from all the electrodes. In a CMAS probe system, these data are reduced to a single parameter so that the probe can be conveniently used for real-time and online monitoring purposes. The most anodic current has been used as a one-parameter signal for the CMAS probes. Because the anodic electrodes in a CMAS probe simulate the anodic sites on a metal surface, the most anodic current may be considered as the corrosion current from the most corroding site on the metal.

FIGURE 33.10 Multielectrode array multiplexed current and/or potential measurement. (Adapted from Yang and Sridhar (2003).)

The value based on three times of the standard deviation of currents is another way to represent the corrosion current from the most corroding site on the metal. Because the number of electrodes in a CMAS probe is always limited and usually far fewer than the number of corroding sites on the surface of a metal coupon, the value based on the statistical parameter, such as three times the standard deviation of current, was considered to be more appropriate than the single value of the most anodic current. The standard deviation value may be from the anodic currents or from both the anodic and cathodic currents.

FIGURE 33.11 Typical CMAS probes used for real-time corrosion monitoring. (Courtesy of Corr Instruments, LLC.)

In a less corrosive environment or with a more corrosion-resistant alloy, the most anodic electrode may not be fully covered by anodic sites until the electrode is fully corroded. Therefore, the most anodic electrode may still have cathodic sites available, and the electrons from the anodic sites may flow internally to the cathodic sites within the same electrode. The total anodic corrosion current, I_{corr} , and the measured anodic current, I_{a}^{ex} may be related by Equation (33.1).

$$I_{\text{a}}^{\text{ex}} = \varepsilon I_{\text{corr}} \quad (33.1)$$

where ε is a current distribution factor that represents the fraction of electrons resulting from corrosion that flows through the external circuit. The value of ε may vary between 0 and 1, depending on parameters such as surface heterogeneities on the metal, the environment, the electrode size, and the number of sensing electrodes. If an electrode is severely corroded and significantly more anodic than the other electrodes in the probe, the ε value for this corroding electrode would be close to 1, and the measured external current would be equal to the localized corrosion current.

Because the electrode surface area is usually between 1 and 0.03 mm², which is ~ 2 to 4 orders of magnitude less than that of a typical LPR probe or a typical electrochemical noise (EN) probe, the prediction of penetration rate or localized corrosion rate by assuming uniform corrosion on the small electrode is realistic in most applications. CMAS probes have been used for monitoring localized corrosion of a variety of metals and alloys in the following environments and conditions:

- Deposits of sulfate-reducing bacteria.
- Deposits of salt in air.
- High-pressure simulated natural gas systems.
- H₂S systems.
- Oil–water mixtures.
- Cathodically protected systems.
- Cooling water.
- Simulated crevices in seawater.
- Salt-saturated aqueous solutions.
- Concentrated chloride solutions.
- Concrete.
- Soil.
- Low-conductivity drinking water.
- Process streams of chemical plants at elevated temperatures.
- Coatings.

Atmospheric Corrosion Monitoring For atmospheric corrosion monitoring, the required electrolyte for a probe to generate an electrochemical signal may either be a fine mist or a discontinuous film made by condensing humid air. The high resistivity of such an electrolyte means that the probe electrodes must be close while still electrically insulated to function properly. In addition, a further complication is the extremely low

FIGURE 33.12 Electrochemical probe manufactured from an uncoated aluminum alloy in the form of closely spaced elements.

electrochemical activity normally produced by atmospheric corrosion, which means that the following requirements must be met to produce useful results:

- High sensitivity of the measuring instrumentation.
- Minimal IR drop throughout the monitoring system.
- Relatively large electrodes to maximize the opportunity to record corrosion signals.

Figure 33.12 shows schematically a probe configuration to achieve such measurements in a low conductivity condensing environment for monitoring aircraft corrosion. One such corrosion surveillance system was installed on an unpressurized transport aircraft. Electrochemical probes in the form of closely spaced probe elements were manufactured from an uncoated aluminum alloy. All but one of the probes were located inside the aircraft, in the areas that were most prone to corrosion attack and difficult to access. Another probe was located outside the aircraft, in its wheel bay (Roberge et al., 1996). In flights from inland to marine atmospheres, a distinct increase in corrosivity was recorded by potential noise surveillance signals during the landing phase in the marine environment (Figure 33.13). However, the strongest localized corrosion signals were recorded at ground level in a humid environment (Figure 33.14).

Another example of an atmospheric corrosion probe is shown in Figure 33.15. This sensor was fabricated using microcircuit technology in which a thin polyamide film was electroplated with two different metals (gold and cadmium) in a pattern to maximize the galvanic current produced in the presence of an even moderately corrosive environment. With this sensor the galvanic current produced by the thin-film bimetallic elements is integrated with a coulometer as a function of time. The data are then stored in a memory chip for future download when queried through a radio frequency (rf) data-gathering transceiver (DGT) or transponder to a laptop computer.

33.3.3.4 Location of Monitoring Hardware Many industrial plants have intrinsic safety requirements that impose important restrictions on corrosion monitoring systems. To ensure flexibility on large plants, some organizations have adopted the strategy of using a “mobile” corrosion monitoring laboratory that meets their safety regulations. Such a laboratory housing the corrosion monitoring instrumentation can be conveniently moved to

FIGURE 33.13 Temperature, pressure, and electrochemical signals as a function of time during a flight to a marine environment in South Africa.

different locations as required in order to overcome the problems associated with excessive lengths of sensor leads. Such an arrangement additionally provides a protective environment for measuring equipment and data storage hardware, which could otherwise be damaged in corrosive atmospheres.

Mobile laboratories may also be used for corrosion measurements on treated water circuits. A schematic of the water handling facility to carry out microbiologically influenced corrosion (MIC) field tests is shown as an example in Figure 33.16 (Roberge and Sastri, 1994). This facility was used for the growth and monitoring of naturally forming biofilms in five separate slip-streams. Each line accommodated 40 sample coupons and was equipped with an individual injector system that allowed testing of the effect of biocides on active biofilms in a fully equipped trailer (Figure 33.17).

FIGURE 33.14 Electrochemical signals as a function of time in a marine environment in South Africa.

33.3.3.5 Sensitivity and Response Time The usefulness of a corrosion monitoring system strongly depends on how well it can deliver warnings of unwanted corrosion conditions. For measuring techniques this translates into two closely related properties:

1. The sensitivity to detect a change in corrosion rate.
2. The time it requires to detect such a change (i.e., the response time).

By virtue of the measuring principle of many systems, sensitivity and response time have an inverse relation to each other. In order to compare corrosion monitoring systems on the basis of their sensitivity, it is important to distinguish between the accuracy of the measurement and the sensitivity to measure a change in the corrosion rate. The sensitivity to

FIGURE 33.15 Thin-film sensor for atmospheric corrosion monitoring. (Courtesy of Kingston Technical Software.)

FIGURE 33.16 Schematic of the water handling facility at the MIC field testing facility.

measure corrosion rate is the combined result of measurement accuracy and the elapsed time (Thomas and Terpsta, 2003).

Sensitivity (S) and response time (R) of a certain technique are closely related, and can be conveniently displayed in a single graph, as shown in Figure 33.18. It is most convenient to display such S – R curves on a log–log graph. The example in this figure requires a 1–7 days response time while requiring sensitivity in the order of $1\text{--}20\text{ mm/year}^{-1}$

FIGURE 33.17 Oil recovery microbial test lines to evaluate biocide programs. (Courtesy Kingston Technical Software.)

FIGURE 33.18 A corrosion monitoring system sensitivity (1–20 mm/year)/response time (1–7 days) application window for a given system performance threshold (solid line).

corrosion rate measurement. The S – R -curve of a specific technique lies below the window, hence will satisfy each requirement for this application. In Table 33.1, typical applications are given with their characteristics. These applications are depicted in Figure 33.19 for their respective S – R windows.

A monitoring system can also be limited to measure accurately over long time scales because of inherent instability of the monitoring system. This might be the result of deterioration of the sensor, or drift in the recording instrumentation. For systems that have to measure with high sensitivity and over a long interval it is recommended to perform routine verifications and calibrations of the monitoring equipment.

TABLE 33.1 Sensitivity and Response Time of Typical Corrosion Monitoring Applications

Application	Sensitivity Range (mm year ⁻¹)	Response Time	System Characteristics
Corrosion tests	0.1–100	1 h–5 days	Continuous
Inhibition control	0.1–20	0.5–2 days	Continuous optimization
Corrosion control (upsets)	1–100	1 h–2 days	Continuous monitoring (upsets)
Corrosion control performance demonstration	1–10	1 week– 1 month	Continuous/interval measurement
Inspection planning	0.2–10	1 month– 0.5 year	Interval
Inspection	1–20	3 months– 10 year	Interval

FIGURE 33.19 Application windows depicted in the S-R plot. The size range of the application windows is given in Table 33.1.

33.3.3.6 Data Communication and Analysis Requirements It is important, at the onset of a corrosion monitoring program, to define the full data communication chain from signaling unacceptable corrosion to the implementation of a remedial action. The times for each step in the chain should be in balance, that is, it is obviously not very useful to invest in a system with a response time of 1 day if it requires weeks to process the information and/or months to implement follow-up remedial measures. The following individuals may be involved in the communication process (Thomas and Terpsta, 2003):

1. Process plant operator, to collect data.
2. Corrosion monitoring specialist (corrosion or inspection engineer), to process data.
3. Corrosion engineer, to assess the information and determine follow up.
4. Operations or maintenance engineer, to plan and implement remedial action.

The response time from “sensor-to-desk” for the steps 1–3 determine the actual response time obtained from a corrosion monitoring system. For a highly critical monitoring task, the data might go directly to the party responsible for remedial action, for example, to the control room, for action by an operator.

The perceived importance of the monitoring system and strategy has to be mirrored by commitment of all individuals involved in integrity management, that is, the asset holder, usually operations, but also maintenance and inspection staff, corrosion engineering, production chemists, and frequently the chemical treating contractor. It is essential that the approach is agreed and implemented by a team that includes these individuals, who

together decide not only how corrosion should be controlled, but also how the corrosion monitoring should be implemented.

33.3.3.7 Define System Reliability Note that if the monitoring system is an active operational component, a high demand is put on its reliability. For example, large economic losses could be incurred if the monitoring system used to control the inhibitor concentration of a system with a high-uninhibited corrosion rate would fail. For such an application, a quantitative reliability study of the monitoring system may be warranted (Thomas and Terpsta, 2003).

If a monitoring system has a passive role, for example, if it is used to verify that corrosion conditions have been within expected limits, a more qualitative analysis of possible failures might be adequate. It may well be that there are other sources of information to estimate corrosion progress besides monitoring, or it may be necessary to have more than one system in place to warn if extreme degradation is possible.

33.3.3.8 Availability and Cost The final choice of the corrosion monitoring system will be influenced by availability of the tools and their cost. Some methods and in particular the installation and implementation of the overall corrosion monitoring system can be quite costly. In view of the implications of excessive corrosion and loss of integrity, the choice should be based on the total cost of ownership of the equipment (Thomas and Terpsta, 2003).

33.3.3.9 In a Nutshell An effective corrosion monitoring system or device should exhibit the following characteristics (Zintel et al., 2001):

- *User Friendly*: The monitoring system must be simple to install, simple to use, and simple to interpret by system operators. At least some interpretation functions must be sufficiently developed so that the system can be interfaced to alarms and controllers for chemical treatment additions or on-line cleaning systems.
- *Rugged*: The monitoring system must be able to withstand the normal use and abuse if it is deployed in an industrial environment.
- *Sensitive*: The monitoring element or probe must be sensitive to the onset of a corrosion problem and provide a definitive indication in real-time that may be used as a process control variable or to evaluate the effectiveness of a control measure.
- *Accurate*: False positives and negatives or any indications caused by interferences from effects, such as flow, erosion, and fouling, can be detrimental in many ways. Erroneous readings may seriously affect the credibility and straightforward usefulness of a corrosion monitoring program.
- *Maintainable*: Probes are expected to foul in service. A minimum time between servicing operations of several months to several years may be required for most applications. Periodic servicing and calibration should be simple and easy to perform.
- *Cost Effective*: The cost of the monitoring system must be significantly less than the cost of the downtime that is avoided or the treatment costs that are saved. The speed and accuracy of the technique are also factors in the cost effectiveness of the monitoring system.

33.3.4 Corrosion Monitoring Techniques

Assessment of corrosion in field conditions is complex due to the wide variety of applications, process conditions, and fluid phases that exist in industrial systems. As discussed in Chapter 3, the expectations of a corrosion monitoring program will vary greatly between organizations that have well-established proactive corrosion management programs and other organizations where corrosion damage is simply a nuisance. Many of the possible corrosion monitoring and inspection techniques available have been recently organized by a group of experts and interested users in different categories as shown in Tables 33.2 and 33.3 (Techniques for Monitoring Corrosion and Related Parameters in Field Applications, 1999).

In the report produced by this group, a direct technique is one that measures parameters directly affected by the corrosion processes while an indirect technique provides data on parameters that either affect, or are affected by the corrosivity of the environment or by the products of the corrosion processes. Additionally, a technique can be described as being intrusive if it requires access through a pipe or vessel wall in order to make the measurements. Most commonly intrusive techniques make use of some form of probe or test specimen, which include flush mounted probe designs. Some indirect techniques can

serve to monitor various parameters on-line in real-time while others provide information off-line after samples collected from process streams or other operational locations are further analyzed following an established method.

The following sections will generally follow the organization used in that report with the notable exceptions of visual inspection and the direct nonintrusive techniques that are usually described as either nondestructive evaluation (NDE), nondestructive testing (NDT), or nondestructive inspection (NDI) techniques.

33.3.4.1 Direct Intrusive Techniques

Physical Techniques Physical corrosion monitoring techniques determine corrosion damage by measuring changes in the geometry of exposed coupons or test specimens. There are many properties of a test specimen that may change to some degree as a result of corrosion, such as its mass, electrical resistance, magnetic flux, reflectivity, stiffness, or any other mechanical properties. When the physical property is measured by electronic means, the test specimen can remain *in situ* and frequent readings are possible. However, frequent readings are less easy to implement if the test specimen needs to be removed from the process to have its physical property measured.

MASS LOSS COUPONS Mass loss coupons are usually designed to monitor the damage rate occurring on existing equipment, to evaluate alternative materials of construction, and sometimes to determine the effects of process conditions that cannot be reproduced in the laboratory. This simple and low cost method of corrosion monitoring consists in exposing small specimens in the environment of interest for a specific period of time and subsequently removing them for weight loss and more detailed examination. Even though the principle is relatively simple, numerous potential pitfalls exist, which can be avoided by following the recommendations of a comprehensive standard guide, such as ASTM G-4 (Standard Guide for Conducting Corrosion Tests in Field Applications, 2001).

Various means of introducing coupons of materials of construction into operating equipment have been devised. For equipment operating under considerable pressure, special attachments are available from corrosion equipment suppliers. A single high-pressure access fitting for insertion of a retrievable corrosion probe (Figure 33.20) can be used to accommodate most types of retrievable probes (Figure 33.21). As mentioned earlier, specialized tools exist for sensor insertion and withdrawal under pressurized operating conditions (Figure 33.22).

Mass loss coupon testing provides several specific advantages over laboratory coupon testing. A large number of materials can be exposed simultaneously and ranked in actual process streams with actual process conditions. A slip-in rack, for example, can be inserted into and removed from equipment with a retractable coupon holder full (Figure 33.23). A rod-shaped coupon holder is contained in the retraction chamber, which is flanged to a full-port gate valve. The other end of the retraction chamber contains a packing gland through which the coupon holder can pass. Coupons mounted on the rod in the extended position are drawn into the retraction chamber. The chamber is bolted to the gate valve, which is then opened to allow the coupons to be slid into the process stream. The sequence is reversed to remove the test coupons. It is essential that the rod or handle be equipped with a restraining chain or other device to prevent the blowout of the specimen holder when retracting the specimens in a system under pressure.

Because many coupons can be exposed simultaneously, they can be tested in duplicate or triplicate (to measure scatter), and be fabricated to simulate such conditions as welding, residual stresses, or crevices. These variations can provide the engineer with increased confidence in selecting materials for new equipment, maintenance, or repair (Dean, 2003).

Coupons can be designed to detect such phenomena as crevice corrosion, pitting, and dealloying corrosion. The environment of interest can be the full process flow at a location where the conditions are deemed to be suitably severe to give a meaningful representation. Alternatively, coupons can be exposed in a side stream that can be

FIGURE 33.20 High-pressure access fitting for insertion of a retrievable corrosion probe. (Courtesy of Metal Samples Company, www.metalsamples.com.)

FIGURE 33.21 A single high-pressure access fitting can be fitted with different types of retrievable corrosion probes. (Courtesy of Metal Samples Company, www.metalsamples.com.)

FIGURE 33.22 Retrieval tool for removing corrosion probes under pressure. (Courtesy of Metal Samples Company, www.metalsamples.com.)

isolated from the main process stream. The design of the coupon should match the objective of the test, that is, simple flat sheets for general corrosion or pitting, welded coupons for local corrosion in weldments, stressed, or precracked test specimens for SCC problems (Techniques for Monitoring Corrosion and Related Parameters in Field Application, 1999).

Length of Exposure and Limitations In general, the length of exposure is typically as long as possible to allow for initiation of localized corrosion and adequate evaluation of service conditions. A minimum exposure of 3 months has normally been used for evaluation of pitting and crevice corrosion. For general corrosion, ASTM G-31 describes a minimum test duration in hours that is ~ 50 divided by the expected corrosion rate in millimeter per year (Standard Practice for Laboratory Immersion Corrosion Testing of Metals, 2004).

For example, when the corrosion rate is estimated to be $\sim 0.05 \text{ mm year}^{-1}$, the exposure period should be at least 1000 h. This can vary according to whether the coupons are exposed in well-controlled situations, such as laboratory tests or in the field. The use of

FIGURE 33.23 Illustration of retractable coupon holder (Dean, 2003).

coupons is, however, subject to the following limitations (Techniques for Monitoring Corrosion and Related Parameters in Field Applications, 1999; Dean, 2003):

- The technique only determines average rate of metal loss over the period of exposure.
- Coupon testing cannot be used to detect rapid changes in the corrosivity of a process.
- Localized corrosion cannot be guaranteed to initiate before the coupons are removed even with extended test durations.
- Reinsertion of a used coupon is generally not recommended.
- Short exposure periods normally yield unrepresentative average rates of metal loss. This is often the result of higher metal loss during initial acclimation to the process environment.
- Corrosion rate calculated from coupons may not reflect the corrosion of the plant equipment due to factors, such as multiphase flow, where the aqueous phase is much more corrosive than the organic or vapor phase, or turbulence from mixers, elbows, valves, pumps, and other items that accelerate the corrosion in a specific location in the equipment removed from where coupons were exposed.
- Procedures for mass-loss coupon analysis can be quite labor intensive.
- Another limitation of coupon testing is the simulation of erosion–corrosion and heat-transfer effects. Careful placement of the coupons in the process equipment can slightly offset these weaknesses.
- Coupons may be misleading in situations where the corrosion rate varies significantly over time because of unrealized process factors.

Contamination of the process fluid can also be an issue for corrosion monitoring for particular industries (e.g., food processing, medical, and electronic equipment manufacturing industries).

Uniform Corrosion Coupons The most common coupon shape for the evaluation of uniform corrosion is rectangular because most alloys are available in plate or sheet form.

Other shapes are used when there are restrictions on available product forms or when a specific material condition is required. Coupon identification must be legible and permanent. The simplest, and preferred, method of identification is stencil stamping (Dean, 2003).

Coupon finish represents a significant contribution to the overall cost. The least expensive finish that is consistent with the monitoring requirements should be selected. For example, an inexpensive surface finish is acceptable where carbon steel coupons are used routinely to monitor additions of inhibitor in water treatment programs. This may be achieved by punching or shearing, followed by glass bead blasting. On the other hand, when it is necessary to rank alloys in a process environment, the coupons must be finished with ground or machined parallel edges and sanded faces. Ideally, the surface finish of the coupon should match the finish of the equipment. However, this is hardly achievable for several reasons including the aging and scaling of real surfaces when exposed to process conditions.

Coupons that are cut by punching or shearing have cold-worked edges. The effects of cold work extend back from the cut edge a distance equal to the material thickness. These affected areas can be removed by grinding or machining. Cold-worked edges may affect the corrosion rate in some cases, and the residual stresses it induces may cause SCC in some materials. Extensive edge preparation can be a major contributor to the cost of a coupon.

Galvanic-Corrosion Coupons Pairs of test coupons can be coupled electrically to study the effects of galvanic corrosion. The relative areas exposed usually vary from 1:1 to 10:1 or greater. A major concern with electrically coupled coupons is maintaining electrical continuity for the entire exposure period. Corrosion product films can wedge mechanically joined coupons apart, thereby eliminating the electrical contact and any galvanic corrosion effect. ASTM G-71 provides valuable information on galvanic corrosion testing in both field and laboratory environments (Dean, 2003; Standard Guide for Conducting and Evaluating Galvanic Corrosion Tests in Electrolytes, 2003).

With metals that can become embrittled by hydrogen absorption (e.g., titanium, zirconium, tantalum, and hardenable steels) the cathodic or protected member of the galvanic couple may be subject to the greater damage. However, the typical mass loss measurements would not reveal such damage.

Crevice-Corrosion Coupons Equipment crevices are quite common in complex systems. These crevice sites can easily trigger the onset of localized corrosion in even benign process environments. Many metals perform differently in crevices as opposed to unshielded areas. The various techniques that can be used for crevice corrosion testing include rubber bands, spot-welded lap joints, and wire wrapped around threaded bolts. Each crevice test creates particular crevice geometry between specific materials and has a particular anode/cathode area ratio.

The two most widely used crevice geometries in field coupon testing employ insulating spacers to separate and electrically insulate the coupons. Spacers are usually either flat washers or multiple-crevice washers. Either type of spacer can be made of materials ranging from hard ceramics to soft thermoplastic resins. ASTM G-78 and G-48 provide valuable information on crevice corrosion specimen design and should be consulted before attempting a crevice corrosion test (Standard Guide for Crevice Corrosion Testing of Iron-Base and Nickel-Base Stainless Alloys in Seawater and Other Chloride-Containing Aqueous Environments, 2001; Standard Test Methods for Pitting and Crevice Corrosion

Resistance of Stainless Steels and Related Alloys by Use of Ferric Chloride Solution, 2003). In this ASTM G-78 test, washers make a number of contact sites on either side of the specimens (Figures 33.24 and 33.25a and b). The number of sites showing attack in a given time can be related to the resistance of a material to initiation of localized corrosion, and the average or maximum depth of attack can be related to the rate of propagation.

Stress-Corrosion Cracking Coupons Typical sources of sustained tensile stress that cause SCC of equipment in service are the residual stresses resulting from forming and welding operations and the assembly stresses associated with interference fitted parts, especially in the case of tapered, threaded connections. Therefore, the most suitable coupons for plant tests are the self-stressed bending and residual-stress specimens. Convenient coupons are the cup impression, U-bend (Standard Practice for Making and Using U-Bend Stress-Corrosion Test Specimens, 2003), C-ring (Standard Practice for Making and Using C-Ring Stress-Corrosion Test Specimens, 2001), tuning fork, and welded panel (Standard Practice for Preparation of Stress-Corrosion Test Specimens for Weldments, 1999). All these methods of stressing coupons produce a decreasing load as the cracks form and begin to propagate. Therefore, complete fracture is seldom observed, and careful examination is required to detect cracking.

Heat-Transfer Coupons For heat-transfer effects, specially designed coupons are required that simulate effects, such as those found in heating elements or condenser tubes.

FIGURE 33.24 A schematic representation of the washer (a) and a washer assembly (b) for conducting an ASTM G 78 crevice susceptibility test.

FIGURE 33.25 Crevice forming assembly in a beaker immersion test (a); components of the assembly and S30400 washer coupons after thirty days in a solution containing 4% NaCl and 8% FeCl₃ (b).

Coupons range in design from thermowell-shaped devices to sample tubes in a test heat exchanger. Thermowell-shaped devices are heated or cooled on the inside and project into the process stream (Standard Guide for Conducting Corrosion Tests in Field Applications, 2001). Heat-transfer tests can also be conducted in the laboratory. In this environment, the coupon forms part of the wall of the test vessel, and can therefore be heated or cooled

from one side. Because of the cost involved, heat-transfer coupon tests are usually carried out on only one (or perhaps two) alloys that have been selected from a larger group (Dean, 2003).

Welded Coupons Because welding is a principal method of fabricating equipment, the use of welded coupons is often desirable. Aside from the effects of residual stresses, the primary concern is the behavior of the weld bead and the heat-affected zone (HAZ). In some alloys, the HAZ becomes sensitized to severe intergranular (sometimes called knife-line) attack, and in certain other alloys, the HAZ is anodic to the parent metal. When possible, it is more realistic to remove welded coupons from production-sized weldments than to weld the small coupons (Dean, 2003).

Because the thermal conditions in both the weld metal and the HAZ are a function of the number of weld passes, the metal thickness, the weld position, and the welding technique, it is not usually considered good practice to use welded coupons to assess the possibility of sensitization from welding. It is generally better to carry out a sensitizing heat treatment on an unwelded coupon before it is tested and then look for evidence of intergranular corrosion or cracking.

Sensitized Metal Sensitization is a metallurgical change that occurs when certain noble alloys (e.g., austenitic and ferritic stainless steels, nickel base alloys) are heated under specific conditions. This may result in the precipitation of carbides or other intermetallic phases at grain boundaries that may reduce the corrosion resistance. Any heat-inducing process may cause sensitization, a process that is time and temperature dependent. There is a specific temperature range over which each particular alloy sensitizes rapidly.

Welding is the most common cause of sensitization. However, welded coupons may not exhibit sensitization because they may have been given insufficient weld passes when compared to actual process equipment. As a result, they spend insufficient time in the sensitizing temperature range, and susceptibility to intergranular corrosion may not be detected.

An appropriate sensitizing heat treatment guarantees that any corrosion susceptibility induced by welding or heat treatment is detected. The optimal temperature and time ranges for sensitization vary for different alloys. For example, 30 min at 650°C is usually sufficient to sensitize S31600 stainless steel. Some of the corrosion-resistant aluminum magnesium alloys containing 3–6% Mg, (e.g., 5××× series) are also subject to sensitization when heated at temperatures in the range of 65–175°C (Standard Test Method for Determining the Susceptibility to Intergranular Corrosion of 5××× Series Aluminum Alloys by Mass Loss After Exposure to Nitric Acid (NAML Test), 2004).

Coupon Cleaning and Evaluation The test coupons should be cleaned as soon as possible after removal from a test. The procedures for cleaning and weighing, which depend on the test material and the extent of corrosion, are described in ASTM standard G-1 (Standard Practice for Preparing, Cleaning, and Evaluating Corrosion Test Specimens, 2003). Examination of corrosion coupons after cleaning and weighing should reveal the forms of corrosion that may be expected in equipment made of the coupon material. Coupons are examined with the unaided eye, and then at increasing magnifications, up to 30–50×, with a binocular microscope. A scanning electron microscope (SEM) has often proved to be an extremely useful tool for detecting superficial localized defects (Dean, 2003).

In some cases, coupons must be bent and/or sectioned and metallographically examined to reveal certain types of corrosion damage. There are special localized corrosion effects that may not only jeopardize the determination of realistic corrosion rates, but also signal other serious types of behavior. Once the coupons have been cleaned thoroughly through repetitive cleaning processes, the corrosion or penetration rate can be estimated from a mass loss plot (Figure 33.26) (Standard Practice for Preparing, Cleaning, and Evaluating Corrosion Test Specimens, 2003; Hausler, 2005). The rate is estimated by Equation (33.2).

$$R = \frac{K(m_1 - m_2)}{A(t_1 - t_2)\rho} \quad (33.2)$$

where R is the penetration (corrosion) rate (millimeter per year); A is the exposed area (centimeter square); m_1 and m_2 are the initial and final masses (g), with m_2 being the intercept made by extrapolating line BC to the y axis in Figure 33.26; t_1 and t_2 are the starting and ending times (hours); ρ is the density (grams per centimeter cube); and K is a constant for unit conversion.

One question that arises when estimating the reproducibility of immersion test results is the amount of uncertainty that each measurement of the observables (e.g., time, mass loss, and area) contributes to the total uncertainty in Equation (33.2). This error defines the minimum uncertainty in the penetration rate that is possible during a given experiment. Such minimum uncertainty would be possible when (Freeman and Silverman, 1992):

- There is no localized corrosion.
- The penetration is uniform across the coupon surface.
- The projected and actual surface areas are the same.

FIGURE 33.26 Cleaning procedure of corrosion coupons for weight loss determination yields scale weight, total corrosion weight loss, and error due to cleaning procedure (Standard Practice for Preparing, Cleaning, and Evaluating Corrosion Test Specimens, 2003; Hausler, 2005).

- Weights are unaffected by corrosion product removal.
- Areas have not changed during the exposure.
- The penetration rate is independent of time.

Accurate weight determination is essential to minimize the uncertainty. The balance should have an accuracy of at least 0.1 mg and weighing each coupon at least three times to obtain an average would decrease the uncertainty somewhat.

Assuming that the environment remains unchanged, the longer the coupons are exposed to the environment the smaller will be the error. As discussed earlier, adhering to the ASTM Standard G-31 recommendation is a good rule-of-thumb to minimize the error. However, the ability to control the environment may limit the test duration so that the long test times needed for accurate measurement of low corrosion rates may not be achievable.

ELECTRICAL RESISTANCE Acceptance of the electrical resistance (ER) corrosion monitoring method grew quickly after the correlation with corrosion rates was established in the 1950s (Dravnieks and Cataldi, 1954; Freedman et al., 1958). The principle of the widely used ER technique is quite simple, that is, the electrical resistance of a sensing element increases as its cross sectional area is reduced by corrosion damage. The electrical resistance of a metal or alloy element is given by Equation (33.3):

$$R = r \frac{L}{A} \quad (33.3)$$

where L is the probe element length (cm); A is the cross-sectional area (centimeter square); and r is the specific resistance of the probe metal (ohm centimeter).

Reduction or metal loss in the element cross section A due to corrosion will be accompanied by a proportionate increase in the element electrical resistance (R). Since temperature influences the electrical resistance of the probe element, ER sensors usually measure the resistance of a corroding sensor element relative to that of an identical shielded element (Figure 33.27). Commercial sensor elements are in the form of plates, tubes, plates, or wires (Figure 33.28).

FIGURE 33.27 Illustration of an electrical resistance probe (Dean, 2003).

FIGURE 33.28 Commercial sensor elements to carry out ER measurements. (Courtesy of Metal Samples Company, www.metalsamples.com.)

Reducing the thickness of the sensor elements can increase the sensitivity of these sensors. However, improved sensitivity involves a trade-off against reduced sensor lifetime. The ER probe manufacturers provide guidelines showing this trade-off for different sensor geometries (Figure 33.29). These probes usually have a useful life up to the point where their original thickness has been halved with the exception of wire sensors. For ER wire sensors the lifetime is lower, corresponding to a quarter original thickness loss.

FIGURE 33.29 The ER probe element selection guide. (Adapted from Metal Samples.)

It is obvious that erroneous ER corrosion results will be obtained if conductive corrosion products or surface deposits form on the sensing element. Iron sulfide formed in sour oil-gas systems or in microbial corrosion and carbonaceous deposits in atmospheric corrosion are relevant examples. The same restriction also applies to electrically conductive environments, (e.g., molten salts or liquid metals).

To obtain the corrosion rate, a series of measurements are made over a period of time, and the results are plotted as a function of exposure time. The corrosion rate can be determined from the slope of the resulting plot (Standard Guide for On-Line Monitoring of Corrosion in Plant Equipment (Electrical and Electrochemical Methods), 2001).

There are several advantages to the ER corrosion monitoring method. Because probes are relatively small, they can be installed easily and the system wired directly to a control room location or to a portable resistance bridge at the probe location. For systems that are wired directly to control rooms, a computer system can be used to obtain the data and to transform the results in corrosion rate values. On the other hand, it is time consuming and sometimes impossible to take measurements at the probe site with a portable bridge. The temperature-compensation device reacts slowly, and it can be a source of error if the temperature varies when the measurement is taken (Dean, 2003).

Corrosion rate measurements obtained in short periods of time can also be inaccurate because the method measures only the remaining metal, which produces significant errors by estimating small differences between large numbers. Measurement resolution is typically 1 part in 1000 of the total measuring range of the probe, and the probe range is typically from 0.05 to 0.64 mm. Measured resistance changes are small so that thermal, stress, or electrical noise can affect the signal, necessitating hardware and software filtering.

The ER results provide a good measure of metal loss by general corrosion. However, the probes are less sensitive to effects of localized attack, which increase the element resistance on only a small area of the element, except near the end of probe life on loop element probes, where the localized attack completely corrodes through the element, increasing its resistance to infinity. Special probes have been prepared for sensitivity to crevice corrosion by creating multiple crevices on the measurement element, such as beads on wire loop probes.

INDUCTIVE RESISTANCE PROBES Following advances in electronics, signal processing, and measuring techniques, this new metal loss monitoring technology is a derivative of ER corrosion sensing. This corrosion monitoring technology has been developed to combine very high-resolution measurement with long probe life and the capability of intrinsically safe operation in hydrocarbon process plant environments (Denzine and Reading, 1998).

The thickness reduction of a sensing element is measured by changes in the inductive resistance of a coil embedded in the sensor (Figure 33.30). Sensing elements with high magnetic permeability intensify the magnetic field around the coil; therefore thickness changes affect the inductive resistance of the coil. Sensitivity has been claimed to be several orders of magnitude higher than with comparable ER probes.

The measurements are virtually unaffected by other process variables, such as temperature, hydrostatic pressure, impact loading (slugging), or flow regimes. The system is also immune to extraneous industrial noise, specifically electromagnetic induction, and thermally induced electromotive force voltages. The inductive resistance sensor elements have very high geometric and physical symmetry providing sensor surfaces with identical metallurgy and microstructures.

Electrochemical Techniques In view of the electrochemical nature of corrosion, it is not surprising that measurements of the electrical properties of the metal solution interface are so extensively used across a wide spectrum of corrosion science and engineering activities, from fundamental studies to monitoring and control in service. Electrochemical monitoring methods involve the determination of specific interface properties that can be divided into three broad categories:

FIGURE 33.30 Subsea inductive resistance probe (a); probe element (b); spool instrument package for subsea (c). (Courtesy of Cormon Ltd.)

FIGURE 33.30 (Continued)

- *Corrosion Potential Measurements:* The potential at a corroding surface arises from the mutual polarization of the anodic and cathodic half-reactions constituting the overall corrosion reaction. Corrosion potential is intrinsically the most readily observable parameter and understanding its relation to the thermodynamics of a system can provide very useful information on the state of a system;
- *Reaction Rate as Current Density:* Partial anodic and cathodic current densities cannot be measured directly unless they are purposefully separated into a bimetallic couple. By polarizing a metal immersed in an aqueous environment, it is possible, with the use of simple assumptions and models of the underlying electrochemical behavior, to estimate net currents for both the anodic and cathodic polarizations from which a corrosion current density can be deduced;
- *Surface Impedance:* A corroding interface can also be modeled for all its impedance characteristics, therefore revealing subtle mechanisms not visible by other means. Electrochemical impedance spectroscopy (EIS) is now well established as a powerful technique for investigating corrosion processes and other electrochemical systems.

Corrosion potential or current produced by naturally occurring or externally imposed conditions can be measured with a variety of electrochemical techniques. Conversions of the measurements into corrosion rates or other meaningful data use equations or algorithms that are specific to each technique. The conversion of the measured current density into a corrosion rate, for example, can be made by using Faraday's law (Tables 33.4 and 33.5) and other empirically determined constants and factors specific to the system. Some techniques use analysis of the interface with direct current (dc) methods. Other techniques use alternating current (ac) methods to provide further characterization of the corrosion interface and the conductivity of the process fluids.

TABLE 33.4 Conversion Between Current, Mass Loss, and Penetration Rates for All Metals^{a,b}

	mA/cm ²	mm/year	mpy	g m ⁻² day ⁻¹
mA/cm ²	1	3.28 M/nday	129 M/nday	8.95 M/n

mpy	0.00777 nday/M	0.0254	1	0.0694 day
g m ⁻² day ⁻¹	0.112 n/M	0.365/day	14.4/day	1

^ampy, milliinch per year; *n*, number of electrons freed by the corrosion reaction; *M*, atomic mass; *d*, density.

^bNote: The table should be read from left to right, that is, 1 mA/cm², (3.28 M/nday) mm/year, (129 M/nday) mpy, (8.95 M/n)/g m² day.

Limits of operation for field work are more serious than those experienced in a laboratory environment, mostly for reasons of practical probe geometry. For example, capillary salt bridges (e.g., Luggin capillary) commonly used in laboratory setups to reduce the interference of solution resistance are definitively too delicate or cumbersome for field use (Techniques for Monitoring Corrosion and Related Parameters in Field Applications, 1999).

The widespread use of electrochemical polarization techniques, dc or ac, does not mean that they are without complications. The main complications or obstacles in performing polarization measurements can be summarized in the following categories:

- *Effect of Scan Rate:* The rate at which a potential or current is scanned may have a significant effect on the resulting polarization (Van Orden, 1998). The goal is for the polarization scan rate to be slow enough to minimize surface capacitance charging, otherwise some of the current being generated may serve to charge the surface capacitance with the net result that the measured current can be greater than the current actually generated by the corrosion reactions alone.
- *Effect of Solution Resistance:* The distance between the reference electrode and the working electrode is purposely minimized in most measurements to limit the effect of the solution resistance. In solutions that have extremely high resistivity (e.g., concrete, soils, and organic solutions), this effect can be an extremely significant.
- *Changing Surface Conditions:* Corrosion reactions take place on the metallic surface exposed to the environment and that surface can be modified by changing process conditions. This can have a strong effect on the polarization curves (Van Orden, 1998).
- *Determination of Pitting Potential:* In analyzing polarization curves the presence of a hysteresis loop between the forward and reverse scans often indicates that localized corrosion (e.g., pitting or crevice corrosion) is in progress. This observation has led to the

FIGURE 33.31 Hypothetical linear polarization plot.

creation of special potentiodynamic techniques to reveal the severity of localized corrosion problems. However, it can be a serious hindrance for monitoring uniform corrosion.

LINEAR POLARIZATION RESISTANCE (LPR) In this popular electrochemical technique, a small potential perturbation (typically 10–20 or even 30 mV) is applied to the sensor electrode of interest and the resulting current is measured. The ratio of the potential to current perturbations is known as the polarization resistance, which, according to Equation (33.4), is inversely proportional to the uniform corrosion rate. More specifically, the polarization resistance of a metal is defined as the slope of the potential-current density ($\Delta E/\Delta i$) curve at the free corrosion potential (Figure 33.31), yielding the polarization resistance R_p that can be itself related to the corrosion current (i_{corr}) with the help of the following Stern–Geary Eqs. (32–34):

$$R_p = \frac{B}{i_{\text{corr}}} = \frac{(\Delta E)}{(\Delta i)_{\Delta E \rightarrow 0}} \quad (33.4)$$

where R_p is the polarization resistance²; i_{corr} is the uniform corrosion current; and B is an empirical polarization resistance constant that can be related to the anodic (b_a) and cathodic (b_c) Tafel slopes with Equation (33.5).

$$B = \frac{b_a \cdot b_c}{2.3(b_a + b_c)} \quad (33.5)$$

The Tafel slopes required to perform these calculations can be either determined empirically from polarization plots such as shown in Figure 33.32 or obtained from the literature

²The accuracy of the technique can be improved by measuring the solution resistance independently and subtracting it from the apparent polarization resistance value.

FIGURE 33.32 E of a plot of η against $\log |i|$ or Tafel plot showing the exchange current density can be obtained with the intercept.

(Grauer et al., 1982). Tafel slopes can also be determined by other techniques, such as curve fitting of polarization resistance curves (i.e., nonlinear polarization resistance), by potentiodynamic polarization scans, or by harmonic distortion analysis.

In a plant situation, it is necessary to use a probe as one of those shown in Figure 33.33 such that it enters the vessel in the area where the corrosion rate is desired (Figure 33.34).

FIGURE 33.33 Commercial sensor elements to carry out linear polarization resistance (LPR) measurements. (Courtesy of Metal Samples Company, www.metalsamples.com.)

FIGURE 33.34 Typical linear polarization resistance probe (a) and probe in pipe tee (b) (Dean, 2003).

An electronic power supply polarizes the specimen from the corrosion potential. The resulting current is recorded as a measure of the corrosion rate. Several commercially available probes and analyzing systems can be directly interfaced with remote computer data-acquisition systems. Alarms can also be used to signal plant operators when high corrosion rates are experienced (Dean, 2003; Standard Guide for On-Line Monitoring of Corrosion in Plant Equipment (Electrical and Electrochemical Methods), 2001).

The LPR probes are typically a two or three electrode configuration with either flush or projecting electrodes. With a three electrode system, corrosion measurements are made on the test electrode. Because these measurements take only a few minutes, the need for a stable reference electrode is minimized. For field monitoring, the reference electrode is typically made of stainless steel or of the same alloy as that being monitored on the test electrode. The auxiliary electrode is also normally of the alloy being monitored. The proximity of the reference electrode to the test electrode governs the degree to which compensation for solution resistance is effective. With a two-electrode system, the corrosion measurement is an average of the rate for both electrodes. Both electrodes would then be made of the alloy being monitored (Techniques for Monitoring Corrosion and Related Parameters in Field Applications, 1999).

A combination of LPR and zero resistance ammeter (ZRA) measurements has been used in a special study to evaluate the rate of localized corrosion in a flowing environment by placing a large-area electrode in fast flow conditions and one small electrode in slow flow conditions in a side-stream differential flow cell schematically shown in Figure 33.35 (Yang, 1995, 1998). When the large area electrode and the small electrode were connected together through a ZRA, the large electrode became a cathode and the small electrode an anode, due to differential aeration forcing the small electrode to experience preferential corrosion. As immersion time increased, the small electrode became covered with deposits and its corrosion rate a good representation of an underdeposit or localized corrosion situation.

FIGURE 33.35 Schematic of differential flow cell with a fast flow electrode (FE), a slow flow electrode (SE), a reference electrode (RE), and an inert counter electrode (CE) (Yang, 1995).

There are several limitations to corrosion monitoring with LPR. The corroding environment must be an electrolyte with reasonably low-resistivity. High-resistivity electrolytes produce erroneously low corrosion rates. This need for a sufficiently conductive medium precludes the use of this technique for many applications in oil and gas, refinery, chemical, and other low-conductivity applications.

Another problem with the technique is that the vessel or pipe wall must be penetrated, and this involves concerns regarding leaks, personnel safety, and other problems. The ability to use direct wiring from the probe location to a remote control room is desirable, but the installation of these wiring systems is costly. In addition, LPR measurements do not provide information on localized corrosion, such as pitting and SCC and since the corrosion-rate values obtained with LPR are at best approximate, the method is best suited for use during periods when substantial corrosion-rate changes may occur (Dean, 2003; Standard Guide for On-Line Monitoring of Corrosion in Plant Equipment (Electrical and Electrochemical Methods), 2001).

ZERO RESISTANCE AMMETRY With this electrochemical technique galvanic currents between dissimilar electrode materials are measured with a zero resistance ammeter.³ The design of dissimilarities between sensor elements may be made to target a feature of interest in the system being monitored (e.g., different compositions, heat treatments, stress levels, or surface conditions). The technique may also be applied to nominally identical electrodes in order to reveal changes occurring in the corrosive environment and thus serve as an indicator of changing corrosion rates.

The main principle of the technique is that differences in the electrochemical behavior of two electrodes exposed to a process stream give rise to differences in the redox potential at these electrodes. Once the two electrodes are externally electrically connected, the

³ A zero resistance ammeter is a current to voltage converter that produces a voltage output proportional to the current flowing between its two input terminals while imposing a “zero” voltage drop to the external circuit.

noble electrode becomes predominantly cathodic, while the more active electrode becomes predominantly anodic and sacrificial. When the anodic reaction is relatively stable the galvanic current monitors the response of the cathodic reaction to the process stream conditions. When the cathodic reaction is stable, it monitors the response of the anodic reaction to process fluctuations (Techniques for Monitoring Corrosion and Related Parameters in Field Applications, 1999).

This technique has been found particularly useful to study depolarization effects of the cathode of a galvanic pair of electrodes to obtain feedback of low levels of dissolved gases, particularly oxygen, or the presence of bacteria, which depolarize the cathode of the galvanic pair and increase the coupling current. When used for detection of low levels of oxygen, other dissolved gases may interfere. Calibration against a dissolved oxygen meter is usually required if quantitative values are needed.

The ZRA method can provide a quantitative measure if the number of influencing factors is limited and preferably verifiable through other means. For monitoring the effect of dissolved gases, the conversion of the signal to a gas concentration level is not accurate. When other factors play a role as well, for example, during the formation of biofilm compounds or in the presence of inhibitors, the method cannot really provide a quantitative indication of any kind.

Additionally, results from galvanic probes do not always reflect the actual galvanic corrosion rates, because galvanic corrosion depends on the relative areas and specific geometries of the components, which can easily vary between a probe design and the actual plant components being monitored. The ZRA method cannot distinguish between either activation of the anodic, or the cathodic reaction. For example, an increase in the measured current can result from cathodic activation by increased dissolved oxygen, from anodic activation by increased bacterial activity, or by a combination of these. Separate analysis is sometimes performed if it is necessary to distinguish between these electrochemical components.

POTENTIODYNAMIC—GALVANODYNAMIC POLARIZATION In this technique, a three electrode corrosion probe is used to polarize the electrode that serves as the sensing element. The current or potential response is measured as the potential (potentiodynamic) or current (galvanodynamic) is shifted away from the free corrosion potential. The basic difference with the LPR technique is that the applied polarization can be of several hundred millivolts (Figure 33.36). While the technique is used quite commonly in a laboratory environment, it is used only occasionally in the field mostly to estimate the anodic and cathodic Tafel slopes for systems on which the basic corrosion rate theory is based (Figure 33.37). The formation of passive films and the onset of pitting corrosion can also be identified at characteristic potentials, which can assist in assessing the overall corrosion risk.

Potentiodynamic polarization is generally used in aqueous systems while galvanodynamic polarization has been used in systems containing oil, so that current density is controlled. One of the most common uses of the technique is to determine whether crevice corrosion or pitting is a problem and whether general corrosion can be estimated by another technique. It is also often used to estimate the relative susceptibility of various materials to localized corrosion in the process stream (Techniques for Monitoring Corrosion and Related Parameters in Field Applications, 1999).

Ideally, each point on the current–potential graph should be made by allowing a polarization time of tens of seconds to several minutes to permit the complete charging of the double-layer capacitance associated with the metal–fluid interface. Such long-time

FIGURE 33.36 Typical anodic polarization plot for S43000 steel in a 0.05 M H_2SO_4 solution.

intervals also permit the electrode surface to oxidize or reduce all of the surface deposits and to polarize to the applied potential. In practice, the applied current or applied potential, whichever is the controlling variable, is changed continuously in an analog form at some preset rate (potentiodynamic or galvanodynamic) or in a digital form of small discrete steps at some preset rate (potential staircase or galvanic staircase).

In either case, the faster the rate of change of the applied signal, the greater is the lag of the measured signal behind the true steady-state values desired. This compromise

FIGURE 33.37 Generalized polarization diagram showing the various potential regions of a passivable metal and the Tafel extrapolation lines.

between a practical and reasonable time to complete a scan and the degree of lag from measured-to-ideal response is a key question with this technique, particularly so in the field where the tested environment is continually changing and cannot usually be controlled as it can be in a laboratory.

A potentiodynamic polarization variant is cyclic voltammetry which involves sweeping the potential in a positive direction until a predetermined value of current or potential is reached, then the scan is reversed toward more negative values until the original value of potential is reached. In some cases, this scan is done repeatedly to determine changes in the current–potential curve produced with scanning.

Another variation of potentiodynamic polarization is the potentiostaircase method. This refers to a technique for polarizing an electrode in a series of potential steps where the time spent at each potential is constant, while the current is often allowed to stabilize prior to changing the potential to the next step. The step increase may be small, in which case, the technique resembles a potentiodynamic curve (Van Orden, 1998).

Electrochemical potentiodynamic reactivation (EPR) is another polarization method that evaluates the degree of sensitization of stainless steels, such as S30400 and S30403 steels. This method uses a potentiodynamic sweep over a range of potentials from passive to active (called reactivation).

However, probably the most popular variant is the cyclic polarization test. This test is often used to evaluate the pitting susceptibility of a material. The potential is swept in a single cycle or slightly less than one cycle usually starting the scan at the corrosion potential. The voltage is first increased in the anodic or noble direction (forward scan). The voltage scan direction is reversed at some chosen current or voltage toward the cathodic or active direction (backward or reverse scan) and terminated at another chosen voltage. The presence of a hysteresis between the currents measured in the forward and backward scans is believed to indicate pitting, while the size of the hysteresis loop itself is often related to the amount of pitting.

This technique has been especially useful to assess localized corrosion for passivating alloys such as S31600 stainless steel, nickel-based alloys containing chromium, and other alloys, such as titanium and zirconium. Though the generation of the polarization scan is simple, its interpretation can be difficult (Silverman, 1998).

In the following example, the polarization scans were generated after 1 and 4 days of exposure to a chemical product maintained at 49°C. The goal of these tests was to examine if S31600 steel could be used for short-term storage of a 50% commercial organic acid solution (aminotrimethylene phosphonic acid) in water. A small amount of chloride ion (1%) was also potentially present in this acidic chemical.

In this example, the potential scan rate was 0.5 mV/s and the scan direction was reversed at 0.1 mA/cm². Coupon immersion tests were run in the same environment for 840 h. The S31600 steel specimens were exposed to the liquid, at the vapor–liquid interface, and in the vapor phase. The reason for the three exposures was that in most storage situations, the containment vessel would be exposed to a vapor–liquid interface and a vapor phase at least part of the time. Corrosion in these regions can be very different from liquid exposures. The specimens were also fitted with artificial crevice formers.

Figure 33.38 shows the polarization scan generated after 1 day and Figure 33.39 shows the polarization scan generated after 4 days of exposure. The important parameters considered were the position of the “anodic-to-cathodic” transition relative to the corrosion potential, the existence of the repassivation potential and its value relative to the corrosion potential, the existence of the pitting potential and its value relative to the

FIGURE 33.38 Polarization scan for S31600 steel in 50% aminotrimethylene phosphonic acid after one day of exposure (the arrow indicates scanning direction).

corrosion potential, and the hysteresis (positive or negative). The interpretation of the results is summarized in Table 33.6.

The presence of the negative hysteresis would typically suggest that localized corrosion may be a problem depending on the value of the corrosion potential relative to the

FIGURE 33.39 Polarization scan for S31600 steel in 50% aminotrimethylene phosphonic acid after four days of exposure (the arrow indicates scanning direction).

TABLE 33.6 Features and Values Used to Interpret Figures 33.38 and 33.39

Feature	Value in Figure 33.38	Value in Figure 33.39
Repassivation potential–corrosion potential	0.12 V	0.0 V
Pitting potential–corrosion potential	0.22 V	0.12 V
Potential of anodic-to-cathodic transition–corrosion potential	0.12 V	0.0 V
Hysteresis	Negative	Negative
Active-to-passive transition	No	No

characteristic potentials present in these polarization plots. After the first day of exposure, pitting was not expected to be a problem because the pitting potential was far away from the corrosion potential. The currents generated were much higher than those normally associated with S31600 steel in a passive state. These observations suggested that there was a risk of initiation of corrosion, particularly in localized areas where the pH can decrease drastically (Silverman, 1998).

After 4 days, the risk of localized corrosion increased. At this time, the repassivation potential and the potential of the change from anodic-to-cathodic current were equal to the corrosion potential. The pitting potential was only ~ 0.1 V more noble than the corrosion potential and the hysteresis still negative. The risk of pitting had increased to become a concern.

Coupon immersion tests confirmed the long-term predictions. Slight attack was found under the artificial crevice formers in the complete liquid exposure.

The practical conclusion of this in-service study was that, since localized corrosion often takes time to develop, a few days of exposure to this chemical product could be acceptable. However, it was recommended to avoid long-term exposure since both pitting and crevice corrosion would be expected for longer exposure periods.

While this example was an interesting study, the potentiodynamic techniques are generally not considered for on-line or real-time monitoring because the electrodes have to be replaced after only one or two test runs. The high anodic potentials used in the tests simply corrode the sensing elements and permanently changes their surface. Correcting the ohmic(IR) drop due to the solution resistance may also be particularly important with this technique because of the relatively high currents used compared with other electrochemical techniques. The IR induced error can be much smaller in highly conductive environments.

ELECTROCHEMICAL IMPEDANCE SPECTROSCOPY With electrochemical impedance spectroscopy (EIS), the sensing element is polarized by the application of an alternating potential that in turn produces an alternating current response. For corrosion monitoring, the frequency range of the applied ac polarization is typically between 0.1 and 100 kHz with a polarization level within 10 mV of the corrosion potential. Full frequency scans provide phase shift information that can be utilized in combination with equivalent circuit models to obtain useful information on the system complex interface.

Amongst the numerous equivalent circuits that have been proposed to model electrochemical interfaces only a few really apply to a freely corroding system. The circuit shown in Figure 33.40a is the simplest equivalent circuit that can describe a metal–

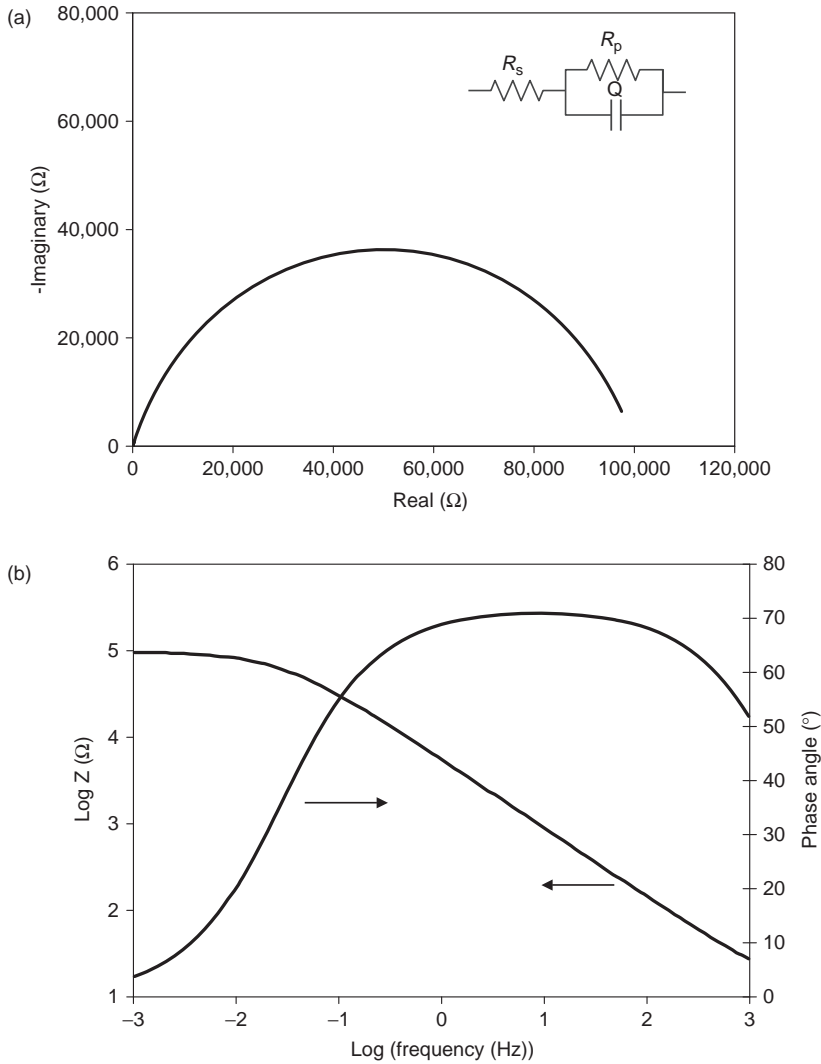

FIGURE 33.40 (a) Complex plane and RC model circuit with simulated data, where $R_s = 10 \Omega$, $R_p = 100 \text{ k}\Omega$, and Q decomposes into $C_{dl} = 40 \mu\text{F}$ and $n = 0.8$. (b) Bode plot corresponding to the same simulated data.

electrolyte interface. Its behavior is described by Equation (33.6).

$$Z(\omega) = R_s + \frac{R_p}{1 + (j\omega R_p C_{dl})^\beta} \quad (33.6)$$

where R_s is the solution resistance, R_p is the polarization resistance, ω is the ac polarization frequency, and C_{dl} is the double layer capacitance.

The term Q in Figure 33.40a describes the “leaky capacitor” behavior corresponding to the presence of a constant phase element (CPE) (Boukamp, 1989). Figure 33.40a also illustrates the complex plane presentation of this EIS model circuit in which $R_s = 10\ \Omega$, $R_p = 100\ \text{k}\Omega$, and Q is a function of $C_{dl} = 40\ \mu\text{F}$ and $n = 0.8$. Figure 33.40b shows how the same data would appear in a Bode plot format.

The high-frequency response is used to determine the component of solution resistance (R_s) included in the measurement. The polarization resistance (R_p) can then be determined by subtracting the R_s value from the low-frequency measurement. To convert the polarization resistance into a corrosion rate involves an empirical measurement of the Tafel slopes that have to be determined by other techniques, such as potentiodynamic polarization and harmonic distortion analysis, or again obtained from the literature (Grauer et al., 1982).

The measurement cycle time depends on the frequency range used, especially the low frequencies. A single frequency cycle at 1 mHz, for example, takes 15 min. A high-to-low frequency scan going to such a low frequency would take $>2\ \text{h}$. In order to make routine corrosion monitoring with EIS certain simplifications are needed to maximize the use of high frequency data and drastically shorten the measurement time. It is also important to simplify the data processing and analysis to make the technique user friendly for field corrosion monitoring. However, the need for a field instrument that can be easily deployed has always been an impediment for on-line corrosion monitoring with EIS.

In order to simplify the analysis of field EIS results, a method was developed that consists of finding the geometric center of an arc formed by three successive data points on a complex impedance diagram (Figure 33.41) (Roberge and Sastri, 1994; Roberge, 1992). This technique was designed as an improvement over the two point method based on the comparison of high- and low-frequency data points for which the impedance would be

FIGURE 33.41 Schematic of the extrapolation method to obtain the polarization resistance from EIS data.

proportional to the R_s at the high frequency point and the summation of R_s and R_p at the low frequency point (Haruyama and Tsuru, 1981). In real-world situations, one difficult assumption to satisfy with the two point method is that data points should contain negligible imaginary components (i.e., 0 phase shift), a condition usually hard to achieve in a meaningful manner at low measuring frequencies.

The three point analysis technique was further developed by permuting the data points involved in the projection of centers in order to obtain a population of projected centers. This improvement has permitted to automate the data analysis while providing some information concerning the adherence of the results with the RC behavior described by Equation (33.6), what is assumed for the evaluation of the parameters associated with uniform corrosion. The technique was extensively tested in a laboratory environment before being applied in field tests with the same laboratory equipment (Roberge and Sastri, 1994).

Very recently, a full-spectrum relatively low cost EIS corrosion monitoring system has been developed, which is wireless, small (5-cm diameter, 1.2-cm height), requires nominally 10-mW power during its 200-s measurement period, and has an electronic identifier, which allows for a single data logger to monitor multiple devices in the same general vicinity (Figure 33.2a and b) (Davis et al., 2005).

The wireless EIS sensor determines the impedance at 15–20 independent frequencies, by measuring amplitude and phase at each frequency (Figure 33.42). It computes corrosion rate, conductivity and coating impedance, and transmits the result wirelessly to a data logger. The miniature and wireless features make it suitable for embedding in concrete or placing in hidden and inaccessible locations, for example, in HVAC systems. Its minimal power consuming aspect lends itself useful for long-term monitoring of coating integrity.

The miniature EIS system has been tested in various environments, namely, concrete, water, and under coatings (Figure 33.43a and b). In addition, it was also tested against a

FIGURE 33.42 Magnitude of impedance of a coating versus frequency. Low-frequency impedance values show good correlation with long-term exposure behavior. (Courtesy of Guy D. Davis, DACCO SCI, Inc.)

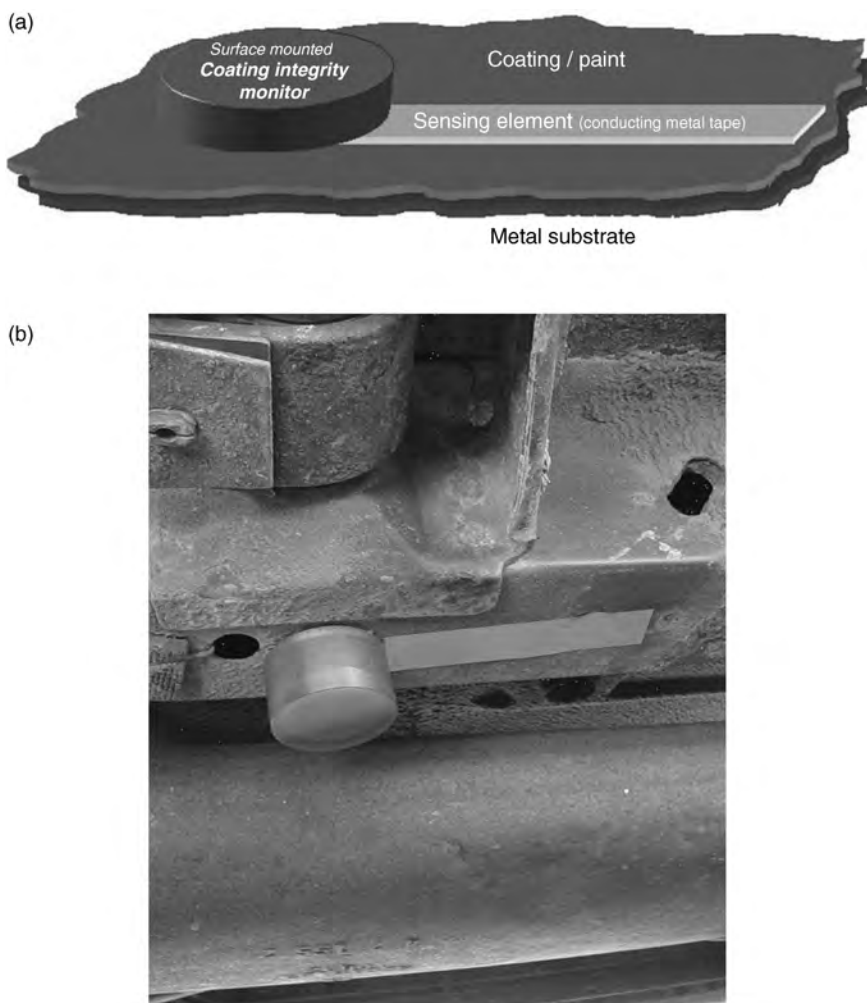

FIGURE 33.43 (a) Schematic of the Coating Health Monitor (CHM) with a tape sensing element mounted on a coated metal and (b) actual sensor tape electrode and electronics housing mounted on the frame of a commercial vehicle. (Courtesy of Guy D. Davis, DACC SCI, Inc.)

simple resistor capacitor circuit and validated with two different commercial instruments. The miniature EIS system successfully monitored the corrosivity of water contaminated with chloride, concrete in contact with water containing salt, and health and integrity of coatings on metals. These results correlated well with data obtained using conventional bench-top EIS and LPR instruments. However, unlike the conventional instruments, the wireless EIS sensor is small, requires very little power to operate and can be hermetically sealed. Therefore, it can be embedded in structures and immersed in liquids without much concern about drawing wires and cables.

HARMONIC DISTORTION ANALYSIS With this technique, a low-frequency sinusoidal potential is applied to a three-electrode measurement system, and the resulting current is measured.

As the corrosion process is nonlinear in nature, a potential perturbation by one or more sine waves should generate responses at more frequencies than the frequencies of the applied signal. Current responses can be measured at zero, harmonic, and intermodulation frequencies.

Measuring the dc at frequency “zero” is called the Faraday rectification (FR) technique. The FR technique can be used for corrosion rate measurements if at least one of the Tafel parameters is known. The corrosion rate and both Tafel parameters can be obtained with one measurement by analyzing the harmonic frequencies. The speed with which the Tafel slopes can be determined (typically <1 min) is a particular attraction of the technique (Bosch et al., 2001).

With harmonic distortion analysis (HDA), a single, low-frequency and low-distortion, sinusoidal voltage is applied to the corroding interface. As a quality check, three different frequencies are used to verify the repeatability of the technique. The amplitude is in the range of 10–30-mV peak to peak. The frequency used is typically 0.1–10 Hz. Other frequencies can be used depending on the corrosion process.

The theoretical analysis for the computation of Tafel slopes and corrosion current makes no assumptions about solution resistance effects and measurements cannot be performed unless the system is free of significant electrical noise in the frequency range of the applied measurement potential, or one of its harmonic frequencies (Techniques for Monitoring Corrosion and Related Parameters in Field Applications, 1999).

In principle, analyzing the primary frequency and the harmonics makes it possible to extract all the information to calculate Tafel slopes and corrosion rate. In practice, this has been used in a very limited number of applications to date. A serious limitation of the existing nonlinear techniques is that their application has been restricted mainly to activation controlled corrosion processes, for example, corrosion rate measurements in acid media with and without inhibitors.

Besides FR, variations of harmonic distortion analysis developed have been called nonlinear EIS (NLEIS), harmonic analysis (HA), harmonic impedance spectroscopy (HIS), and electrochemical frequency modulation (EFM). These techniques all analyze nonlinear response of a corrosion system after perturbation with a mono -or biharmonic signal, and on this basis allow extraction of the required kinetic parameters of the corrosion process. Except for the FR method, all other HAD techniques allow the simultaneous determination of corrosion current and both Tafel coefficients (Jankowski, 2003).

ELECTROCHEMICAL NOISE (EN) ANALYSIS Fluctuations of potential or current of a corroding metallic specimen are a well known and easily observable phenomenon. Electrochemical noise analysis (ENA) as a corrosion tool has increased steadily since Iverson's paper in 1968 (Iverson, 1968) and the number of industrial applications of electrochemical noise monitoring has grown significantly in recent years. The study of EN has been found to be uniquely appropriate for monitoring the onset of events leading to localized corrosion and understanding the chronology of the initial events typical of this type of corrosion.

The EN technique differs in many ways from the other electrochemical techniques described so far. One important difference is that ENA does not require that the sensing element be polarized in order to generate a signal. However, it is also possible to measure current noise under an applied potential, or measure potential noise under an applied current. The potential and current between freely corroding electrodes (in many cases <1 μ V and <1 nA) are measured with sensitive instrumentation. A measurement frequency of 1 Hz is usually appropriate to provide meaningful data. For simultaneous measurement of

electrochemical potential and current noise, a three-electrode sensor is required. In field corrosion monitoring, the three sensor elements are usually made of the same material.

While the measurement of electrochemical noise is relatively straightforward, the data analysis can be complex and inconclusive. Even if ENA was first applied in field corrosion monitoring in the late 1960s, an understanding of the method of analysis is still evolving, partly because the technique has been used to look at several types of corrosion. The relationships between potential and current noise are inherently complex to analyze quantitatively because the naturally occurring fluctuations do not have controlled frequencies as are applied, for example, in EIS. For these reasons, much of the investigations with EN have been centered on frequency analysis of the data. There are still varying conclusions about the accuracy and effectiveness of the technique in its own right (Techniques for Monitoring Corrosion and Related Parameters in Field Applications, 1999).

Electrochemical Noise Analysis The analysis of EN, begun a few decades ago, has only been recently introduced as a credible corrosion monitoring technique. In this context, the pioneering work of Eden *et al.* has been instrumental in introducing the idea of a corrosion cell with two working electrodes (WE), where both current and voltage fluctuations can be measured (Eden *et al.*, 1986). The remaining question was how to establish the data interpretation on a firm basis. Because EN measurements on a single corroding electrode are not sufficient to evaluate corrosion rates, most applications in the field are based on the use of cells with two identical electrodes (same material, same size, same surface preparation), connected through a zero-resistance ammeter (ZRA) so as to have both working electrodes set at a common corrosion potential (Huet *et al.*, 2001).

There are many cases, particularly in field applications where the use of low-noise reference electrodes commonly used in laboratories would be impractical. In these cases, one can use a third electrode made of material similar to the other two working electrodes. Obviously, such a reference electrode would contribute to the noise of the system. It turns out, however, that in such an arrangement the noise impedance Z_n is equal to a fraction of the total noise impedance (Z), that is, $\sqrt{3}|Z|$, so that a simple correction is sufficient to correct the problem. However, a more serious concern is that the noise signals depend on the three electrodes having the same impedance and contributing the same noise. As every corrosion worker knows, initially identical electrodes tend to diverge in behavior with time. Experience has shown that this is particularly troublesome in the case of localized corrosion for which it could introduce significant errors difficult to correct.

There are basically three categories of ENA: visual examination, sequence-independent methods that treat the collection of voltage or current values without regard to their position in the sequence of readings (moments, mean, variance, standard deviation, skewness, and kurtosis), and those that take the sequence into account (autocorrelation, power spectra, fractal analysis, stochastic process analysis) (Cottis *et al.*, 2001).

Visual examination of the time record trace can give indications as to the type of corrosion processes that are occurring. The following example illustrates how a simple examination of EN measurements could reveal the corrosivity of various points of an industrial gas scrubbing system where highly corrosive thin-film electrolytes may form (Roberge, 2000). These conditions arise when gas streams are cooled to a temperature below the dewpoint. The resulting thin electrolyte layer (moisture) is often highly concentrated in corrosive species.

The corrosion probe used in this example is illustrated in Figures 33.44 and 33.45. A retractable probe with flexible depth was selected, in order to mount the sensor surface

FIGURE 33.44 Corrosion sensor and access fitting used for thin-film corrosion monitoring. (Courtesy Kingston Technical Software.)

flush with the internal scrubber wall surface. The close spacing of the carbon steel sensor elements was designed to work with a discontinuous thin surface electrolyte film. This corrosion sensor was connected to a handheld multichannel data recorder by shielded multi-strand cabling Figure 33.1. As the ducting of the gas scrubbing tower was heavily insulated, no special precautions were taken to cool the corrosion sensor surface.

Potential noise and current signals recorded during the first hour of exposure at the conical base of the gas scrubbing tower are presented in Figure 33.46. According to the operational history of the plant, condensate had a tendency to accumulate at this location where highly corrosive conditions had been noted. The high levels of potential noise and current noise in Figure 33.46 are indicative of a massive pitting attack that is consistent with the operational experience. Note that the current noise is actually off-scale for most of the monitoring period, in excess of 10 mA. The high corrosivity indicated by the

FIGURE 33.45 Close-up of corrosion sensing elements used for thin-film corrosion monitoring. (Courtesy Kingston Technical Software.)

FIGURE 33.46 Potential and current noise records at two locations in a gas scrubbing tower.

electrochemical noise data from this sensor location was confirmed by direct evidence of severe pitting attack on the sensor elements, revealed by scanning electron microscopy (Figure 33.47). In contrast, both current and voltage signals remained relatively constantly small at a position higher up in the tower, where the sensor surface remained mostly dry.

FIGURE 33.47 Scanning electron microscope image of a sensor element surface after exposure at the base of the scrubbing tower clearly showing corrosion pits.

FIGURE 33.48 Electrochemical current noise (large band) and potential noise (lower signal) in a debutanizer overhead piping obtained with the Concerto VT noise system. (Courtesy of CAPCIS Ltd.)

An improvement over this simple analysis is commonly practiced in industry by tracking the width of the potential and current signals as an indication of corrosion activity in the system being monitored. Figure 33.48 illustrates how the decrease in the current band obtained with a monitoring system was interpreted as a reduction in general corrosion activity in a debutanizer overhead piping where the interaction between operational changes and the corrosion mechanism were being investigated.

Most ENA techniques have been developed to relate sometimes subtle features in the noise data records to changes in the corrosivity of a system and particularly on how these changes affect localized corrosion. Three techniques have also been proposed for obtaining the polarization resistance as a measure of uniform corrosion rate if the Tafel constants of the system are known or measured.

The noise resistance (R_n), a sequence-independent method, is the ratio of the standard deviation of potential to the standard deviation of current. The impedance resistance (R_{imp}), a sequence-dependent method, is the ratio of the square root of the potential power to the square root of the current power in the low frequency limit. The potential and current power densities are calculated from power spectrum distribution (PSD) techniques, such as fast Fourier transform (FFT) or the maximum entropy method (MEM) (Cottis and Turgoose, 1999). Finally, the EN transient resistance (R_{tran}) is the ratio of the amplitude of potential to current for single transients (Klassen and Roberge, 2002). The parameter R_{tran} provides the most exact corrosion resistance value, but the data analysis is also the most complicated since the technique hinges on finding transients amenable to a clear interpretation.

While these techniques have been extensively used in controlled laboratory experiments, the high variability of field environments combined with the availability of well established methods such as ER, LPR, or the use of coupons have created the impression that ENA is not an appropriate option for obtaining corrosion rates when uniform corrosion is the prevalent corrosion mechanism.

In contrast, localized corrosion processes, such as pitting and SCC, have characteristic transients in the time record traces that may help to distinguish between various possible types of corrosion. The modern success of ENA is in great part based on this unique property since more traditional on-line techniques are quite ineffective in this area. This success is also due to the fact that most forms of localized corrosion are much more troublesome in the management and operation of many engineering systems than uniform corrosion.

The effect of localized corrosion on EN signals tends to create a deviation from a normal distribution (Poisson distribution) as may be determined from the skewness and kurtosis of the EN signals. If techniques, such as linear polarization resistance (LPR) and harmonic distortion analysis (HDA), are also used, then independent derivation of the general corrosion current (I_{corr}) is possible. The ratio of the current noise (standard deviation of the current) to the general corrosion current may then be used as an improved indicator of localized corrosion activity (Eden, 2000).

Skewness and kurtosis are measures of the probability density of the noise signals in relation to the mean value. Skewness provides an indication of the symmetry of the distribution. A value of zero implies that the distribution is symmetrical whereas a positive skewness implies that there is a tail in the positive direction and a negative skewness a tail in the negative direction. Kurtosis is a measure of the shape of the distribution compared with the normal distribution. A kurtosis of zero implies that the distribution has a shape similar to that of the normal distribution. A positive kurtosis implies a narrower distribution, whereas a negative kurtosis implies a flatter distribution. It was found experimentally that the kurtosis of a signal generated by uniform corrosion was approximately 1.5–2 while a kurtosis value >5 would be indicative of localized corrosion (Eden, 2005).

The localization parameter is the ratio of the standard deviation of the current, σ_I , to the root-mean-square (rms) current (Cottis and Turgoose, 1999). However, the rms current is related to the mean coupling current, which, over an infinite period of time with two similar electrodes is zero. This gives the localization parameter the possibility of having the unfortunate value of infinity. The pitting factor is a modification of the localization parameter (Roberge et al., 1996). The idea is to use a measure of i_{corr} instead of rms current. If one assumes that R_p is representative of the polarization resistance then the pitting factor is equivalent to the ratio of the standard deviation of potential, σ_V , to the Stern–Geary constant (B).

Figures 33.49 and 33.50 illustrate how the corrosion pitting indication and associated system instability were tracked during the debutanizer overhead piping evaluation project mentioned earlier.

The shot-noise charge is a measure of the average charge of a transient based on shot-noise analysis (Cottis and Turgoose, 1999). This is the ratio of $\sigma_I \sigma_V / bB$, where b is the bandwidth of measurement (s^{-1}). The bandwidth is the frequency range from essentially zero to the Nyquist frequency, $1/(2\Delta t)$, where Δt is the sampling period.

Certain characteristics of localized corrosion have been interpreted by analyzing EN data in the frequency domain. The slope of the linear region of the PSD plot of current or potential versus frequency has been interpreted as being related to the shape, amplitude and frequency of elementary transients (Cottis and Turgoose, 1999). The expected slopes can be in the range of 0 to -4 with zero for white noise processes, -0.5 for diffusion controlled processes, -1 for processes having a Gaussian distribution and less than -2 for processes with fluctuations (Eden, 2005). However, the exact value of this slope corresponding to localized corrosion behavior may differ significantly between systems and environments.

FIGURE 33.51 Simultaneous current and potential monitoring using three identical electrodes. (Adapted from Eden (2005).)

Probe Design and Signal Analysis An appreciable level of effort has been directed towards developing electrode arrangements for monitoring localized corrosion with EN, in particular pitting, such as the use of both very small ($\leq 1 \text{ mm}^2$) or very large ($\geq 100 \text{ cm}^2$) electrodes, as well as electrode arrays. A great variety of instrumentation approaches have also been used (Eden, 2005):

- Three identical electrodes, configured as two coupled via a ZRA and one pseudoreference, with simultaneous (Figure 33.51) or sequential (Figure 33.52) measurements of current and potential.
- Three identical electrodes configured in potentiostatic mode (working, reference and auxiliary) with the reference potential set at 0 V (Figure 33.53), with simultaneous measurement of current and potential. This particular arrangement is useful in that the potentiostatic control may be used to perform other controlled polarization measurements such as LPR or HDA.
- Multiple electrode arrays of the test material using scanning techniques to measure current and/or potential between individual or combinations of elements in order to identify locally anodic behavior on one or more of the electrodes (Figure 33.10) (Yang and Sridhar, 2003).
- Single electrode probe consisting of a working electrode with current (Figure 33.54) or potential (Figure 33.55) measured with respect to the structure of interest. As with the three electrode arrangement this may also be used to evaluate polarization response.

Higher levels of electrochemical corrosion activity are generally associated with higher EN levels. Certain electrochemical phenomena, such as the breakdown of passivity during pit initiation show up distinct noise “signatures”, which can be exploited for corrosion monitoring purposes. Pit initiation and growth, for example, can be detected with EN measurements long before it becomes evident by visual examination.

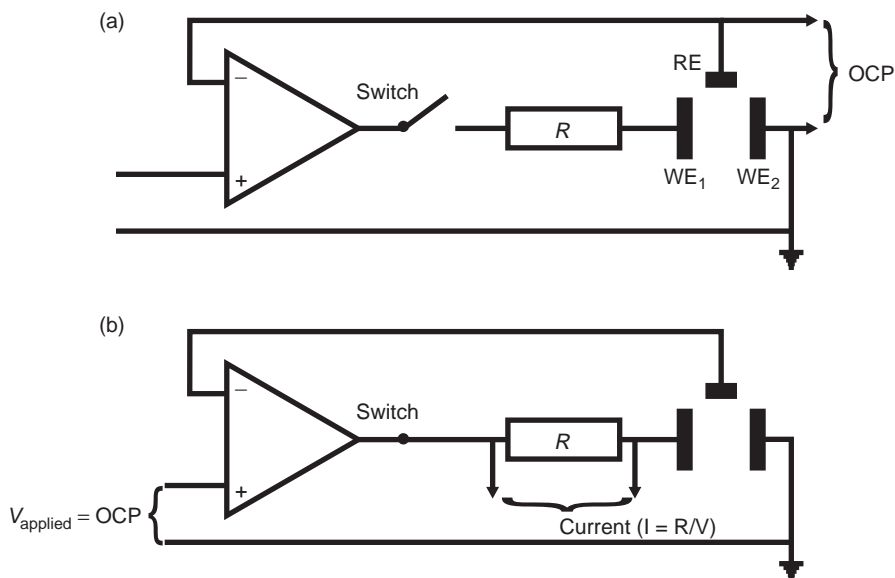

FIGURE 33.52 Sequential current and potential logging of three electrodes: (a) the open circuit potential of WE₂ and (b) switched-on mode of operation. (Adapted from Eden (2005).)

The analysis of EN results obtained between two working electrodes (WEs) with an imposed or naturally developing asymmetry can be carried out by considering Equation (33.7), which indicates that the noise impedance of a cell (Z_n) depends on the impedances of the two WEs, as well as their noise levels, represented by the power density spectra (Ψ_{i_1} and Ψ_{i_2}) obtained by performing the analysis of noise signals with either FFT or with the maximum entropy method (MEM).

$$Z_n(f) = \sqrt{\frac{\Psi_V(f)}{\Psi_I(f)}} = |Z_1(f)Z_2(f)| \sqrt{\frac{\Psi_{i_1}(f) + \Psi_{i_2}(f)}{|Z_1(f)|^2\Psi_{i_1}(f) + |Z_2(f)|^2\Psi_{i_2}(f)}} \quad (33.7)$$

FIGURE 33.53 Three identical electrodes simultaneous current and potential measurement. (Adapted from Eden (2005).)

FIGURE 33.54 Single electrode measurement of current with respect to plant. (Adapted from Eden (2005).)

For the simplest case of two WEs with the same impedance ($Z_1 = Z_2$) the noise impedance is equal to the modulus of the electrode impedance $|Z(f)|$. This result is valid independently of the origin of the noise signals (localized or uniform corrosion, bubble evolution due to the cathodic reaction) and the shape of the impedance plot, even if the noise levels of the two electrodes are different. In such case, noise measurements are equivalent to impedance measurements for which the external signal perturbation has been replaced by the internal noise generated by the corrosion processes (Huet et al., 2001).

However, when the two WEs do not have the same impedance, the noise impedance analysis requires a more cautious interpretation. Depending on the source of the current

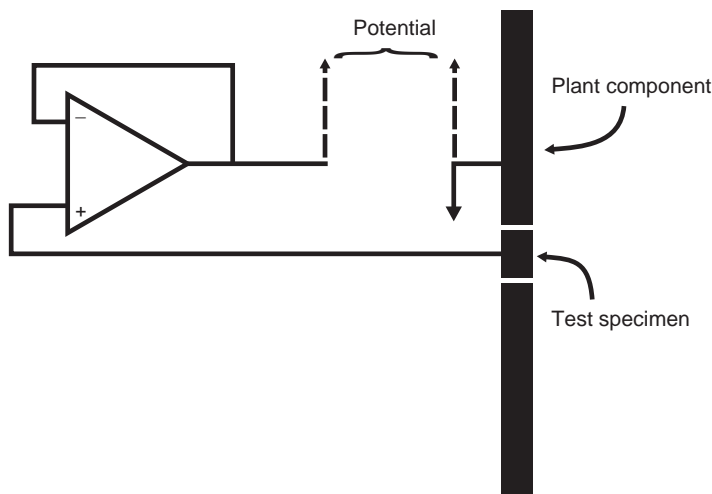

FIGURE 33.55 Single electrode measurement of potential with respect to plant. (Adapted from Eden (2005).)

noise the measured impedance may either be that of a quiet cathode or that of a quiet anode while in intermediate cases the results of the measurement of Z_n would show a mixed behavior and be more difficult to interpret. For example, if hydrogen bubbles are evolving on the cathode while the anode undergoes generalized corrosion, the noise of the cathode is orders of magnitude larger than that of the anode, so that Z_n becomes equal to the impedance modulus of the anode, $|Z_a|$. In these conditions, while the time records appear to show only the cathodic processes, the impedance measured is that of the anode, using the noise of the cathode as input signal.

An opposite case would be a cell where the anode is undergoing pitting, while the cathodic reaction is the reduction of dissolved oxygen or an imposed galvanic situation. Since the anodic noise is preponderant, Equation (33.7) shows that Z_n is equal to the impedance modulus of the cathode, $|Z_c|$. The anodic noise is the internal signal source utilized for the measurement of the impedance of the cathode.

However, this special arrangement can produce current noise signals valid on their own (Klassen et al., 2001; Schmitt et al., 2005). The design of asymmetric corrosion probes opens new possibilities for the evaluation of the susceptibility of a system to localized problems difficult to instrument otherwise: galvanic cells (inhibitors, presence of oxygen), crevice corrosion, stress corrosion cracking, etc. This is surely a very promising area of research since no other field technique has close to the sensitivity and flexibility that ENA could have for the detection of such problems.

33.3.4.2 Direct Nonintrusive Techniques By definition, direct nonintrusive measurement techniques do not require access to the inside of the system being monitored and so avoid the usual risks associated with on-line insertion and retrieval operations of intrusive devices. An important advantage of these techniques over intrusive corrosion monitoring techniques is that the actual plant material is monitored instead of a possibly different test coupon material. Depending on the specific technique and implementation, the area of the plant material monitored is generally larger than on an inserted specimen.

As mentioned earlier, most of the techniques belonging to this category in the NACE International report (Techniques for Monitoring Corrosion and Related Parameters in Field Applications, 1999) are described in Chapter 5 since they are usually described as NDE, NDT, or NDI techniques.

Thin-Layer Activation and Gamma Radiography With thin-layer activation (TLA) and gamma radiography, a technique developed from the field of nuclear science, a small section of material is exposed to a high energy beam of charged particles to produce a radioactive surface layer. For example, a proton beam may be used to produce the radioactive isotope Co-56 within a steel surface. This isotope decays to Fe-56 with the emission of gamma radiation. The concentration of radioactive species is sufficiently low that metallurgical properties of the monitored component are essentially unchanged. The radioactive effects utilized are much lower than conventional radiography and so the health risk concerns. The low levels of radiation present involve modest handling procedures and product quality, other than for human consumables, is not compromised.

Changes in gamma radiation emitted from the surface layer are measured with a separate detector to study the rate of material removed from the surface. The radioactive surfaces can be produced directly on components (nonintrusive) or on separate sensors (intrusive). The measured gamma radiation depends on the quantity of the original

radioactive tracer present and the natural decay of the isotope with time (related to its half-life). The technique has been applied to measure wear, erosion, and corrosion when the corrosion product is removed from the surface. Different components in a system can be irradiated with different isotopes to allow simultaneous measurements of these components. Activation area can be small ($<1 \text{ mm}^2$), which allows monitoring from specific metallurgical areas such as welds and weld heat-affected zones.

The gamma radiation can penetrate typically up to 5 cm of steel with acceptable signal attenuation, so that on-site external monitoring of internally generated activated layers is possible without any physical interconnection between internal and external surfaces. To compensate for the natural isotope decay and the natural background levels, three measurements are used for each reading, namely the activated component, the reference sample of the same isotope (for natural decay), and the background radiation (for naturally occurring radiation in the system and atmosphere) (Techniques for Monitoring Corrosion and Related Parameters in Field Applications, 1999). However, these techniques measure strictly material loss and do not distinguish between erosion and corrosion effects. Additionally, corrosion products still adherent to the material surface are not measured as material loss.

Field Signature Method Field signature method (FSM) is a nonintrusive technique that can monitor corrosion of a pipe wall directly. The original development of this technique was largely directed at oil and gas production. Typical applications involve pin attachment to the external surface of a pipeline, which is normally protected against corrosion, to monitor corrosion damage to the inside of the pipe wall. The technique measures corrosion damage over several meters of an actual structure and can be used for locations where access for traditional intrusive probes is difficult, and for high temperatures ($>150^\circ\text{C}$) where the application of probes and ultrasonic testing (UT) is limited. The technique is useful in difficult access areas because generally no access is required after the initial installation. There are no consumable parts in this system except for the pipe spool itself that may be consumed when used in high corrosion rate conditions.

In FSM, a current is induced in the monitored section of interest, typically 3–10 m apart for a large pipe or a few centimeters for small pipes, and the resulting voltage distribution is measured to detect corrosion damage (Figure 33.56). An array of pins is attached by stud welding, gluing, or spring-loading to make electrical connections externally over the structure.

From a corrosion perspective, the location and type of corrosion to be expected is critical in designing a FSM monitoring matrix. Up to 84 pin pairs can be typically utilized for one location. If monitoring for localized attack, the pin pairs are set up closer together, whereas for uniform corrosion the pin pairs can be spread out to cover a much larger area. A general rule for covering both types of corrosion is to position the pin pairs at three times the pipe wall thickness (Scanlan et al., 2003).

The voltage readings are monitored and compared looking for any nonuniformity that could be due to cracking or pitting in the monitored section (Figures 33.57 and 33.58). Comparison of the average voltage drop with that of a reference element is used to monitor general metal loss. The area monitored is dependent on the pin spacing with a resolution inversely proportional to pin spacing and wall thickness (Techniques for Monitoring Corrosion and Related Parameters in Field Applications, 1999). When a reference element is used, the sensitivity to general metal loss is approximately one part per thousand of wall thickness. The FSM monitoring unit has a lower sensitivity when not permanently

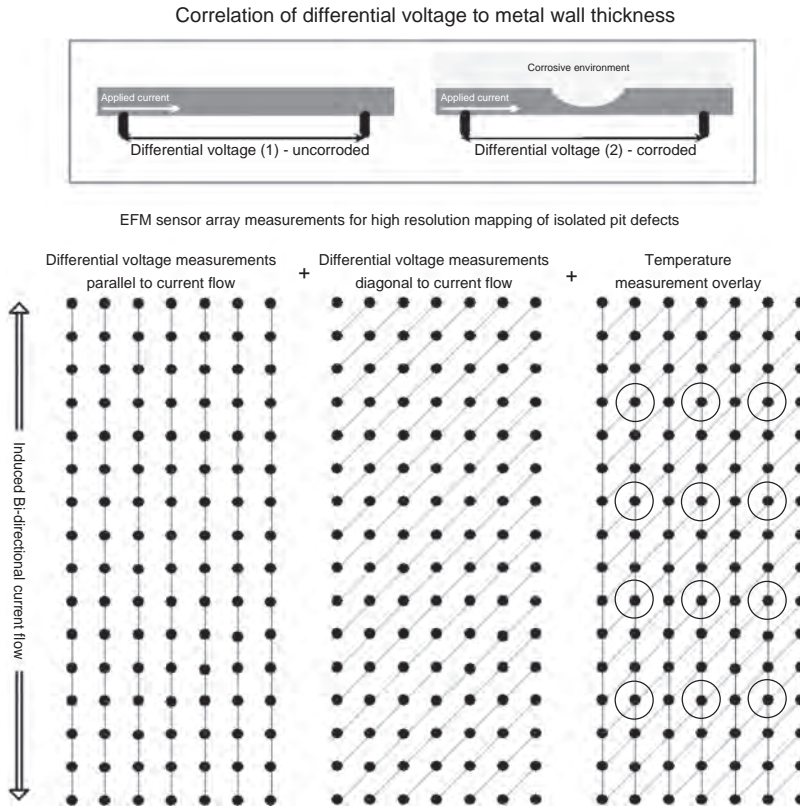

FIGURE 33.56 Schematic of the electric field monitoring sensor array for high-resolution mapping of isolated pit defects with FSM. (Courtesy of Eric Kubian, PinPoint Corrosion Monitoring Inc.)

attached because of the need to relocate the contact pins accurately for voltage measurements.

Once the locations vulnerable to the corrosion mechanism are determined, the process temperature needs to be considered. Two types of FSM systems are available. One is a high-temperature system and the other a low temperature system, with the cut off being $\sim 150^{\circ}\text{C}$ due to hardware requirements. The high-temperature system requires a further junction box located outside the insulation. However, in theory the FSM technique has no temperature limits (Scanlan et al., 2003). Following the installation of the FSM system, attention must be given to data interpretation, which can be quite complex. This technique does not distinguish between internal and external flaws or general material loss.

Acoustic Emission Acoustic emission (AE) is based on measuring acoustic sound waves that are emitted during the growth of microscopic defects, such as stress corrosion cracks. The sensor elements are thus essentially very sensitive microphones, which are strategically positioned on structures. The sound waves are generated from mechanical stresses generated during pressure or temperature changes. Background noise effects have to be

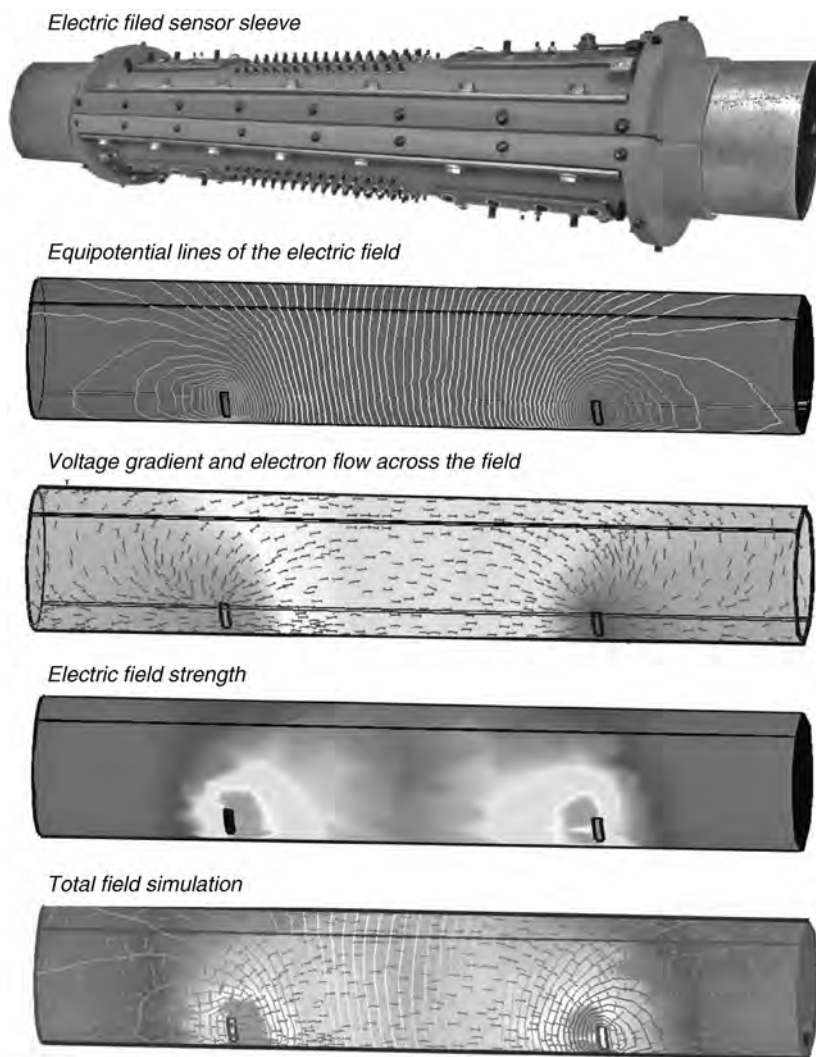

FIGURE 33.57 Electric field sensor sleeve and various representations of the electric behavior between two sensor points when monitoring with FSM. (Courtesy of Eric Kubian, PinPoint Corrosion Monitoring Inc.)

taken into consideration and can be particularly troublesome in on-line measurements. The technique produces large amounts of data and requires relatively sophisticated filtering and analysis.

It is the flaw growth or even plastic deformation that generates the sound waves that are detected by the acoustic sensors. Secondary emissions from crack fretting or breaking of corrosion pockets can also be employed for the detection of flaws. The technique is essentially qualitative in identifying areas with flaws that may be further investigated with other nondestructive techniques, (e.g., ultrasonics) (Techniques for Monitoring Corrosion and Related Parameters in Field Applications, 1999).

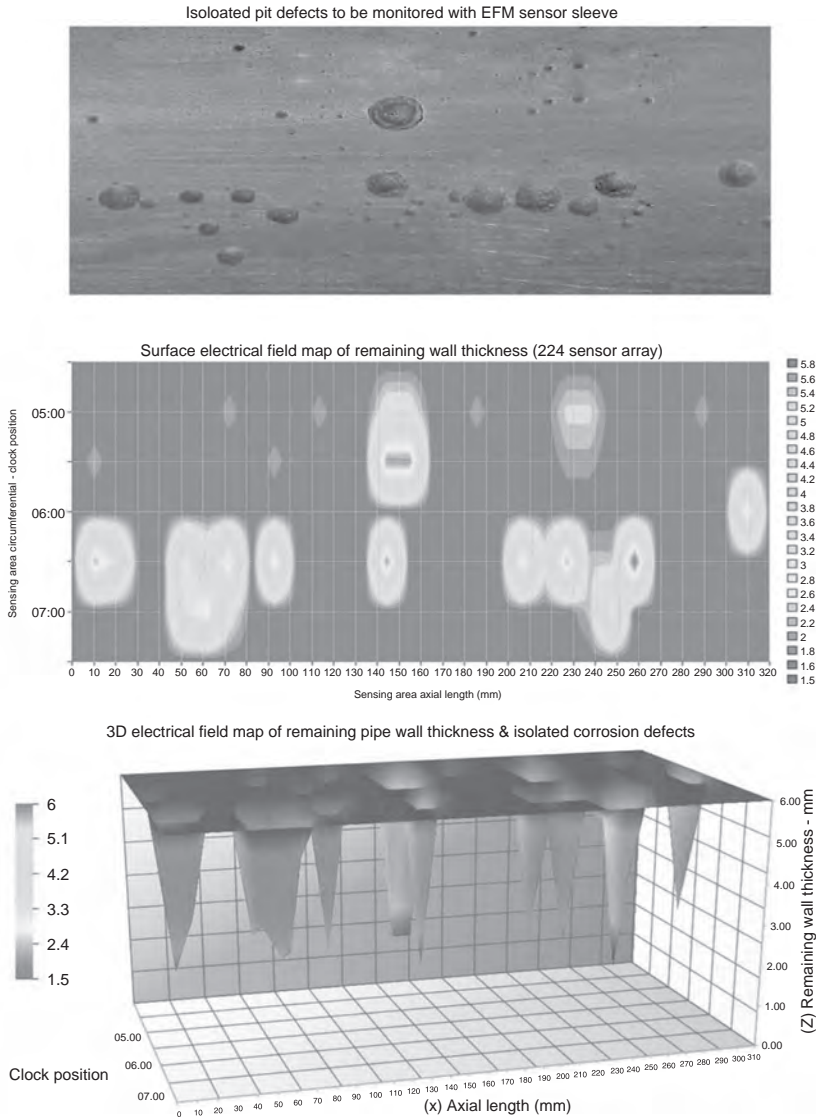

FIGURE 33.58 Example of FSM results plotted as a three-dimensional (3D) map obtained on a pitted pipe using a 224 sensor array. (Courtesy of Eric Kubian, PinPoint Corrosion Monitoring Inc.)

Testing is most commonly done off-line by applying pressure changes, or during shut-down as the temperature is changing, to minimize the background noise effects. On-line testing is also done, but the range of detection is reduced due to background noise. Frequency and gain of the sensors are modified according to the procedure to adjust filtering. Off-line tests are short-term tests to monitor for integrity whereas on-line tests are used to track the operational conditions that promote flaw propagation. A frequency range of 150–175 kHz is used for initial wide coverage in off-line applications. For on-line

applications in which flaw noise is the targeted problem, the frequency used is ~ 1 MHz, which reduces the range of coverage to ~ 0.50 m.

Triangulation can be used to estimate the location of growing flaws. Acoustic energy measured at the sensor depends on the magnitude and distance of the flaw from the sensor. In off-line tests, overpressure only detects flaws that have sufficient energy during the monitoring period to be on the verge of propagation. It does not detect flaws that are not actively growing under the applied stress excursions, even though these flaws may be potential weak points or actively growing under a more severe process excursion.

33.3.4.3 Indirect On-Line Techniques A great variety of techniques have been developed to measure the indirect changes, either in the environment or in the metallic component of interest, that can occur during corrosion processes or that can increase the rate at which these processes are occurring. This variety is reflected in the number of disciplines (e.g., metallurgy, physics, biology, chemistry, nuclear science) involved in the development of these tools designed to track and assess the effects and factors associated with corrosion damage.

Hydrogen Monitoring The principle of the hydrogen probe relies on the fact that one of the cathodic reaction products in nonoxidizing acidic systems is hydrogen which, in its atomic form, can diffuse through the thickness of vessel or pipe walls and recombine into hydrogen molecules at the exterior surface. This “uptake” of hydrogen occurs when the recombination of hydrogen atoms and subsequent release as molecular hydrogen in the environment is inhibited by the presence of some chemical species or poisons (e.g., cyanides, arsenic, antimony, selenium, or sulfur compounds). The generation of atomic hydrogen can be used for corrosion monitoring purposes in both intrusive and nonintrusive ways. In the latter, hydrogen monitoring sensors are attached to the outside walls of vessels and piping. It is the diffusion of atomic hydrogen through the metallic substrate that is of most concern, as it can lead to problems such as hydrogen induced cracking.

Hydrogen monitoring is highly applicable to the oil refining and petrochemical industries with hydrocarbon process streams. The presence of hydrogen sulfide in these industries promotes the uptake of hydrogen into plant components. Several types of hydrogen probe have been developed to monitor hydrogen flux (Figure 33.59) (Kane and Cayard, 1998). These probes are based on one of the following three principles:

1. *Hydrogen Pressure (or Vacuum) Probe:* One version of this probe technology is intrusive and consists in the insertion of a steel tube or cylinder that includes an inner cavity. The pressure in the inner cavity of the tube or cylinder is measured with a pressure gauge. Another version is nonintrusive and consists of a patch-type device, in which a patch or foil is welded or otherwise sealed to the outside of the pipe or vessel to create a cavity. In some implementations, the pressure range from zero absolute to atmospheric pressure, that is, the vacuum region. Other types use positive pressure above atmospheric pressure. Hydrogen passing through the wall of the tube or cylinder is detected as an increase in pressure in the cavity as a function of time. The higher the hydrogen flux, the greater the rate of pressure increase with time (Techniques for Monitoring Corrosion and Related Parameters in Field Applications, 1999).
2. *Electrochemical Hydrogen Patch Probe:* This nonintrusive device is attached to the outer surface of the pipe or vessel to be monitored. The patch probe itself consists of

FIGURE 33.59 Various hydrogen probes, which are inserted into a vessel or pipe, or are external. (Adapted from Kane and Cayard (1998).)

a small electrochemical cell containing an appropriate electrolyte in contact with the component to be monitored (Figure 33.60). Typically, this cell uses the nickel electrode from a nickel cadmium battery with a caustic electrolyte put directly on the pipe. Often the electrolyte is isolated from the outer surface of the pipe or vessel by a thin palladium foil. This foil is also used as an electrode in the detection circuit. The cell is operated at a potential that oxidizes hydrogen as it enters the cell. The current used to maintain this potential is proportional to the hydrogen flux into the cell (Techniques for Monitoring Corrosion and Related Parameters in Field Applications, 1999).

FIGURE 33.60 Schematic of an electrochemical patch probe.

FIGURE 33.61 Schematic of the hydrogen detector using a solid electrolyte proton exchange membrane fuel cell (Vera et al., 2002).

3. *Hydrogen Fuel Cell Probe*: This other nonintrusive technique is also an electrochemical device that consists of a small fuel cell. As shown in Figure 33.61, the cell contains a solid electrolyte membrane, a cathode material, and an anode which consists of a surface catalyzed with palladium. Hydrogen entering the cell is reacted on the activated palladium surface while the cathode material reacts with ambient oxygen (air) causing a current flow in an external circuit between the cathode and anode. This current is directly proportional to the hydrogen flux through the palladium membrane (Vera et al., 2002).

When the relative distribution of atomic hydrogen in a material is constant, the permeating fraction of hydrogen can give relative corrosion rate information. However, the technique is used more commonly to detect high flow rates of the hydrogen passing through the steel that could lead to hydrogen blistering and hydrogen-induced cracking (HIC).

Hydrogen evolution is only one of a few possible cathodic reactions that can occur concurrently with the actual purely anodic corrosion reaction. This technique is not considered suitable to indicate corrosion rates in conditions or environments when any of the other cathodic reactions (e.g., reduction of dissolved oxygen) would be dominant. Currently there is no known absolute correlation between hydrogen diffusion rates and corrosion rates, cracking, or blistering without specific analysis of a piece of the actual steel affected.

Corrosion Potential Measurement of the corrosion potential (E_{corr}) is a relatively straightforward intrusive technique that is widely used in industry for monitoring reinforcing steel corrosion in concrete and structures, such as buried pipelines under cathodic or anodic protection. Changes in corrosion potential can also give an indication of active-passive behavior in stainless steel. However, this technique only indicates a corrosion risk and does not measure corrosion or pitting rates.

The parameter E_{corr} (also known as rest potential, open-circuit potential, or freely corroding potential) is measured relative to a reference electrode, which is characterized by a

stable half-cell potential. Either a reference electrode has to be introduced into the corrosive medium for these measurements, or an electrical connection has to be established to a structure in conjunction with an external reference electrode in contact with the structure with a wet electrolyte.

The success of corrosion-potential measurements depends on the long-term stability of the reference electrode. Such electrodes have been developed for continuous application for measuring corrosion potentials. However, conditions of temperature, pressure, electrolyte composition, pH, and other possible variables can limit the usage of these electrodes for corrosion monitoring service. Special reference electrodes are needed for operating temperatures above about the boiling point of water (100°C).

The use of E_{corr} measurements for in-service corrosion monitoring in process environments is not as widespread as the use of polarization resistance. However, this approach can be valuable in some cases, particularly where an alloy could show both active and passive corrosion behavior in a given process stream. For example, stainless steels can provide excellent service, as long as they remain passive. However, if an upset occurs that might introduce either chlorides or reducing agents into the process stream, these alloys could become active and exhibit excessive corrosion rates. Corrosion-potential measurements would indicate the development of active corrosion that could be confirmed by using LPR, for example (Dean, 2003).

On-Line Water Chemistry Analyses Various types of chemical analyses can provide valuable information to a corrosion monitoring programs. The measurement of pH, conductivity, dissolved oxygen, metallic and other ion concentrations, water alkalinity, concentration of suspended solids, inhibitor concentrations, and scaling indexes all fall within this domain. Several of these measurements can be made on-line using appropriate sensors.

All of the following measurements are used particularly in water treatment, and in general apply only to aqueous environments. Many of these parameters are used in combination to generate various indices, such as the Langelier index,⁴ in order to rate the scaling tendency and corrosivity of waters.

pH The pH^5 of an aqueous environment may be measured with a meter or calculated if certain parameters are established. Water itself dissociates to a small extent to produce equal quantities of H^+ and OH^- ions displayed in the equilibrium described in Equation (33.8).

The term pH was derived from the manner in which the hydrogen ion concentration is calculated. It is the negative logarithm of the hydrogen ion (H^+) concentration as shown in Equation (33.9).

$$\text{pH} = -\log_{10}(a_{\text{H}^+}) \quad (33.9)$$

⁴ See Appendix B for additional information on Langelier, Ryznar, and other scaling indices.

⁵ The pH, originally defined by Danish biochemist Søren Peter Lauritz Sørensen in 1909, is a measure of the concentration of hydrogen ions.

where \log is a base 10 logarithm and a_{H^+} is the activity (related to concentration) of hydrogen ions.⁶

A higher pH means that there are fewer free hydrogen ions. A change of one pH unit reflects a 10-fold change in the concentrations of the hydrogen ion. For example, there are 10 times as many hydrogen ions available at pH 7 than at pH 8. Substances with a $\text{pH} < 7$ are considered to be acidic and substances with $\text{pH} > 7$ are considered to be basic or alkaline. Thus, a pH of 2 is very acidic and a pH of 12 very alkaline. In general, for steel, low pH (or high acidity) produces a particularly corrosive environment. For other alloys this can vary.

The pH is an important corrosion factor for two reasons. First, the H^+ ion can be reduced into hydrogen and thus participate to the overall corrosion processes as the cathodic reaction. Second, the pH influences the solubility of the products of the chemical corrosion reactions, particularly the passivation reactions involving oxides, sulfides, or carbonates. As a measure of alkalinity, pH is a very important component in scaling indices.⁷

Generally, pH measurements have been limited to a maximum temperature of boiling water and to a maximum pressure of ~ 2 MPa, although some special-purpose probes are available for up to 70 MPa.

The pH measurements can be affected by interfering ions, such as lithium, sodium, and potassium ions that can interact with the sensing glass membrane of a pH electrode. However, because lithium ions are normally not found in sample solutions and potassium ions cause little interference, the most significant interference is from sodium ions.

Additionally, fouling of the probe measurement element by hydrocarbons, for example, can reduce or even completely block the probe response to pH changes. Frequent maintenance might thus be required to ensure cleanliness and maintain calibration. Low-conductivity solutions can also be a problem. Even low-ionic-strength pH probes can have problems at conductivities less than $20 \mu\text{S}/\text{cm}$. Some low-conductivity probes inject an electrolyte to correct for high solution resistance.

CONDUCTIVITY In the present context, conductivity is the electrolytic current-carrying capacity of water, which is largely determined by the concentration of ions from dissolved salts and solids (Standard Test Methods for Electrical Conductivity and Resistivity of Water, 2005). When a salt dissociates, the resulting ions interact with surrounding solvent molecules or ions to form charged clusters known as solvated ions. These solvated ions can move through the solution under the influence of an externally applied electric field. Such motion of charge is known as ionic conduction. Ionic conductance, which for the bulk solution is the only conductance present, is the reciprocal of ionic resistance. The dependence upon the size and shape of the conductor can be corrected by using conductivity κ rather than conductance G , as expressed in Equation (33.10) for the simple geometry shown in Figure 33.62.

$$\kappa = \left(\frac{\ell}{A}\right) \frac{1}{R} = G \left(\frac{\ell}{A}\right) \quad (33.10)$$

⁶ The p in Equation (33.9) stands for the German word for “power,” *potenz*, so pH is an abbreviation for power of hydrogen.

⁷ See Appendix B for additional information on Langelier, Ryznar, and other scaling indices.

FIGURE 33.62 Schematic of a conductivity cell containing an electrolyte and two inert electrodes of surface A parallel to each other and separated by distance ℓ .

where ℓ is the length of the conductor, that is, the gap separating the electrodes in Figure 33.62; A is the cross-sectional area of each electrode, assuming that both electrodes have the same dimensions.

Because corrosion is an electrochemical process, an increase in conductivity is generally associated with an increase in corrosivity. However, this does not mean that zero electrolyte conductivity signifies that corrosion is stifled. Extra pure water such as used in nuclear reactors, for example, has proven to be quite corrosive unless small amounts of oxygen or other passivating agents are added to counter this aggressiveness.

Electrochemical reactions at the electrode interfaces can affect the readings and can be dependent on the measurement frequency used. Therefore a frequency of 1 kHz is commonly used as the measurement frequency to avoid this problem. Routine cleaning of the measurement cell has often been necessary to prevent false readings due to bridging of the electrodes, or fouling on the membrane.

DISSOLVED OXYGEN Dissolved oxygen refers to the amount of oxygen dissolved in a liquid, usually expressed as parts per billion (ppb) or parts per million (ppm) in the engineering world or in milligrams per liter (mg/L) in the chemical world. The solubility of oxygen depends on temperature, pressure, and molarity of the solution. Increased pressure increases oxygen solubility while an increase in temperature decreases its solubility (see Chapter 1 for additional details).

Dissolved oxygen can be measured by ion-selective electrodes, or for approximate low levels of oxygen a galvanic probe can be used (Figure 33.63). The oxygen ion-selective electrode has a thin organic membrane covering a layer of electrolyte and two metallic electrodes. Oxygen diffuses through the membrane and is electrochemically reduced at the cathode. There is a fixed voltage between the cathode and anode so that only oxygen is reduced. The greater the oxygen partial pressure, the more oxygen diffuses through the membrane in a given time. The result is a current that is proportional to the oxygen in the sample (Standard Test Methods for Dissolved Oxygen in Water, 2003).

Temperature sensors can be built into the probe to make corrections for the sample and membrane temperatures. The cathode current, sample and membrane temperatures, barometric pressure, and salinity information are used to calculate dissolved oxygen content of the sample in either concentration (ppb or ppm or mg/L) or percent saturation (% sat).

FIGURE 33.63 Two different electrode chemical cell designs to measure dissolved oxygen.

The affinity of oxygen for most structural metals is the cause of many corrosion phenomena. Oxygen is responsible for both corrosive attack and passivation. The approach to controlling corrosion of carbon steel in oil fields and in boilers in North America has generally been to remove all or most of the molecular oxygen by various combinations of physical and chemical means. Bringing oxygen levels <20 ppb or $20\text{ }\mu\text{g/L}$ has a significant effect on corrosion. With an oxygen scavenger, typical levels are <1 ppb or $1\text{ }\mu\text{g/L}$. In some boilers that use high-purity deionized water, no oxygen scavenger is used but instead small amounts of oxygen or hydrogen peroxide are deliberately added to the feed-water to act as a passivating agent under carefully controlled boiler water chemistry conditions.

Generally, dissolved oxygen measurements have been limited to a maximum temperature of 65°C and a maximum pressure of $200\text{--}350\text{ kPa}$. Consumption of oxygen by the probe may also lower the oxygen concentration near the probe, so that a flowing or stirred sample is generally recommended. The electrolyte is also depleted of its active ingredients as it reduces the oxygen and needs to be replaced at regular intervals of a few weeks or months depending on the design and use of the probe. Periodic calibration of the probes is therefore a recommended practice. Nonetheless, poisoning of the electrode can occur. This has precluded the use of the method in many industrial environments such as processes involving heavy hydrocarbon and water.

OXIDATION–REDUCTION (REDOX) POTENTIAL Oxidation reduction (redox) potential is the potential of a reversible oxidation–reduction electrode measured with respect to a reference electrode in a given electrolyte. The measurement system comprises a potentiometer (high-sensitivity and high-impedance voltmeter) connected to a reference electrode and a noble metal sensing electrode. The change in potential of the sensing electrode produced by the oxidizing or reducing species, is measured relative to the reference electrode. This voltage difference is then converted electronically to display on a meter or recorder for real-time on-line measurement.

This technique has also been used to detect the end point of oxidation or reduction reactions during a water treatment to control more closely the addition of oxidizing

biocides, such as chlorine and bromine, which may have a significant effect on increasing the corrosion rates.

Redox potential is also a key measure to evaluate soil corrosivity where the redox potential is essentially related to the degree of aeration. A high redox potential indicates a high oxygen level. Low redox values may provide an indication that conditions are conducive to anaerobic microbiological activity. Sampling of soil will obviously lead to oxygen exposure and unstable redox potentials are thus likely to be measured in disturbed soil.

Process Variables

FLOW REGIME Corrosion usually occurs on the metal surface wetted by the aqueous phase. This wetting action and transport of corrosive agent to the surface can be controlled by the flow regime. In some flow regimes, such as slug flow, high surface shear stresses and extreme turbulence can make corrosion inhibition difficult and increase corrosion rates to several centimeters per year. At higher flow regimes, impingement, cavitation, and erosive conditions created by two-phase flows can be extremely corrosive.

In single-phase flows, the flow regime is typically described as laminar, transition, or turbulent flow as defined by the Reynolds number, which depends on the flow velocity, the pipe diameter, the fluid viscosity, and the fluid density. In multiphase flows the relative pattern of multiple phases is important as defined by mist flow, annular flow, or slug flow. In single-phase environments, the flow regime affects the mass transfer to the metal surface and the shear stresses on the metal surface. These have a direct impact on the corrosion rates at the metal surface (see Chapter 2 for a description of the effects of flow on corrosion).

In multiphase flows the flow regime varies with varying flow rates of each phase, elevation changes, or specific geometry of a line or conduit. Acoustic monitoring and on-line γ -radiography have been used to detect slug flow. Flow characteristics can also be used to provide predictions of corrosion rates based on modeling and other empirical data.

PRESSURE Pressure can affect the proportion of phases present in a vessel or pipe, or the composition of the process fluids. Different phases and constituents can produce quite different corrosive environments. For example, the partial pressure of CO_2 affects the amount of CO_2 dissolved in water, which in turn affects the corrosivity of the fluid due to the presence of carbonic acid. Similarly, the partial pressure of H_2S is a major determining factor in the susceptibility of various alloys to sulfide stress cracking (SSC).

Total pressure measurements can be made on-line, and are a real-time measurement. Determination of partial pressures utilizes knowledge of the composition of the process fluid, the temperature, and the total pressure. This involves sampling of the process fluid. In some gas-liquid systems, pressure affects gas solubility, but the relationships are complex. Consequently, the pressure is usually used only to analyze and predict which phases are present, rather than as an on-line measurement.

TEMPERATURE The temperature of a process fluid can have a direct effect on its corrosion dynamics. These temperature effects can be nonlinear. Low temperature can produce condensation of water or other corrosive liquids. High temperature increases chemical reaction rates and can change the composition of the process. In general, increased temperature increases the chemical reaction rates. The temperature can lead either to vaporization (a dry condition) or condensation (from a dry to a wet condition). Both these changes in state can affect corrosion.

DEWPOINT Dewpoint is the temperature at which a liquid starts condensing from a vapor or gaseous phase. Dewpoint monitoring is important because the region of condensation of water and corrosive fluids in otherwise dry environments has a major impact on corrosion rates. This can be complex in some environments where multiple gases and condensable combinations are present. In atmospheric environments in which the condensing liquid is water, the dewpoint temperature is measured with a wet-bulb thermometer. In a process system, this may not be practical, and a system in which cooling of the flow to the point of condensation on an optical mirror has been used.

The direct effects of dewpoint conditions can be measured with mass-loss coupons or electrical resistance techniques. Electrochemical methods, such as electrochemical noise and multielectrode array systems (CMAS), have also been used in a similar way, either as a time-of-wetness indicator or for corrosion rate measurements, since these electrochemical techniques will function even when surfaces are only partially wetted. Additionally, forced cooling of the corrosion measurement surfaces can be used to generate the appropriate dewpoint on the measurement surfaces.

Fouling Fouling is an accumulation of both organic and inorganic substances from a fluid stream onto the surfaces of the equipment through which the fluid is circulated as well as *in situ* corrosion products and inorganic deposits, such as hardness salts that occur on the metal surface. Fouling is a prime cause of underdeposit corrosion since it can produce highly anodic areas and give rise to hot spots in boilers, for example. Fouling may also restrict flow by causing an increase in pressure drop through the equipment or retard heat transfer by formation of an insulating deposit. Side-stream and in-line intrusive measurement techniques, together with visual inspection, have been used for determination of fouling. One of two techniques has been employed, that is, heat-transfer or pressure-drop monitoring.

33.3.4.4 Indirect Off-Line Measurement Techniques A great variety of chemical analysis techniques have been used over the years to provide operators and providers of corrosion control services some estimates of the effects of corrosion on systems, on the corrosivity of given environments, or on the effective usage of chemical additives. The following sections describe the type of information commonly sought with these techniques (Techniques for Monitoring Corrosion and Related Parameters in Field Applications, 1999).

Off-Line Water Chemistry Parameters

ALKALINITY Alkalinity is considered to be an important measurement when handling waters because carbonate and hydroxide scales are common problems. The alkalinity of a water as determined by titration with standard acid solution to the methyl orange endpoint (pH \sim 4.5) is sometimes abbreviated as “M alkalinity”. Total alkalinity includes many alkalinity components, such as hydroxides (OH^-), carbonates (CO_3^{2-}), and bicarbonates (HCO_3^-).

METAL ION ANALYSIS Some corrosion products are soluble and can be detected by metal ion analysis of the process stream for determining the amount of metal lost that has dissolved in the process stream or the amount that has been carried along in the process stream as corrosion product (e.g., iron, copper, nickel, zinc, and manganese). The analysis

can be done easily, inexpensively, and quickly in the field. The assumption that metal loss occurred over the total surface area or that the concentration of ions in solution is proportional to the corrosion rate is often incorrect, in which case the technique may only provide a trend indication. An increase in the metal ion concentration can indicate an increase in corrosion. However, a low metal ion concentration is not a guarantee of low corrosion, due to the possibility of localized corrosion, deposition of the metal ion due to temperature or pH changes, or a significant time delay before analysis.

Metal ion analysis is most useful when applied in closed systems and if the corrosion products are soluble or relate to particular concentrations of soluble species. In open systems, the relative changes in ion concentrations between locations can provide some useful information. The technique is generally not reliable in fluids containing hydrogen sulfide due to the precipitation of insoluble sulfides from soluble metallic ions, or in alkaline solutions because of precipitation of hydroxides.

Much care should be used in obtaining a representative sample of the aqueous phase, including the sampling point design, because the sampling point can accumulate corrosion products. Obtaining a representative sample from a process stream can also be difficult, because fluid velocity, temperature, and pressure can vary greatly with time unless specific precautions are taken to prevent this.

CONCENTRATION OF DISSOLVED SOLIDS Total dissolved solids (TDS) is the sum of minerals dissolved in water. It is therefore an important parameter for the determination of a scaling index.⁸ Total dissolved solids is determined by evaporating the water from a pre-weighed sample. A calculated TDS value can be determined by adding the various cations and anions from an analysis.

GAS ANALYSIS Gas analysis commonly includes hydrogen, H₂S, or other dissolved gases. This technique is generally done in a laboratory, but can also be done for certain gases in the field to determine potentially corrosive constituent gases, particularly acid gases, that become corrosive when hydrated, for example, when the temperature falls below the dewpoint. However, the technique is limited to very specific gaseous process situations and the equipment for analysis can be relatively expensive to acquire and maintain.

RESIDUAL OXIDANT Ozone and halogens, specifically chlorine, chlorine dioxide, and bromine, are powerful oxidizing agents and are widely used to control microbiological fouling in aqueous systems. Residual halogen can directly oxidize the inhibitors used to protect against corrosion or fouling. Dissolved halogens in aqueous environments can be measured using redox potential or one of a variety of colorimetric techniques.

Halides are salts that come from halogen acids, typically HF, HCl, HBr, and HI. Halides have been directly implicated as a causative agent in SCC and have been indirectly linked to galvanic corrosion by increasing the conductivity of the environment. Halides can be measured using specific ion electrodes or with a colorimetric method.

MICROBIOLOGICAL ANALYSIS Microbiological influenced corrosion is a very pervasive factor in many corrosion situations. Due to the importance of the subject, a special section of

⁸ See Appendix B for additional information on Langelier, Ryznar, and other scaling indices.

this chapter is devoted entirely to the techniques and methods that have been developed to monitor microbes and bacteria that are the most susceptible to cause corrosion damage.

Residual Inhibitor Measurement of corrosion inhibitor residuals in a system provides an indication of the concentrations of inhibitor at various locations of a system. When the reliability of an analytical test method is established and the minimum acceptable inhibitor concentration has been determined, measurement of inhibitor concentrations throughout a system can indicate whether adequate corrosion protection is likely to be achieved at each sample location. Additional inhibitor loss due to reaction with the system hardware or reactions with the environment (e.g., absorption, neutralization, precipitation, adsorption on solids or corrosion products) can be detected and compensated for by dosage selection.

Filming Corrosion Inhibitors: Filming corrosion inhibitors are chemical products used in low concentrations to adsorb on system surfaces and shield them from corrosive agents. Filming inhibitor residual measurements are usually made to ensure that an adequate supply of inhibitor has been introduced in the system to compensate for a reduction of the inhibitor concentration by adsorption and maintenance of inhibitor film;

Reactant Corrosion Inhibitors: Reactant corrosion inhibitors are designed to react with potential corrosive agents in a system to neutralize their harmful effect and combine with constituents in a system to produce *in situ* corrosion inhibitors. Reactant corrosion inhibitor residual measurements are used to ensure that sufficient reactant inhibitors have been injected into the system to provide an excess of reactant. Measurement of residual reactant inhibitor can be taken after the point of introduction of oxidant (oxygen or air entry, e.g.) to ensure that sufficient inhibitor has been injected to perform the reaction while leaving some residual inhibitor.

Reactant corrosion inhibitors can be alkaline neutralization chemicals used to maintain a safe operating pH and, for example, adjust the pH at the point of condensation of acid gases in a distillation system. A typical parameter in determining the effectiveness of such an inhibitor is the ability to measure the pH at appropriate points in a system. Reactant inhibitors can also be used to react with or reduce oxidants in a system and thus remove them from the environment. This type of inhibitor or oxygen scavenger can include sulfites, bisulfites, and hydrazine for example.

Chemical Analysis of Process Samples Chemical analysis of process samples taken at times of high and low corrosion rates can be useful in identifying the constituents that cause the high corrosion rates. From this information, the source of aggressive constituents can be found and corrected or modified. In petroleum production, crude oil and gas condensate samples are typically analyzed for organic nitrogen and acid. Sulfur, organic acid, nitrogen, and salt content are typically measured for refining purposes. These parameters are used in combination to predict the corrosivity of the oil.

In gas handling and gas processing operations, samples of produced and processed natural gas and gas-liquids are typically analyzed to determine hydrogen sulfide (H_2S), carbon dioxide (CO_2), water (H_2O), carbonyl sulfide (COS), carbon disulfide (CS_2), mercaptans (RSH), and/or oxygen (O_2) to predict and assess corrosion potential in producing wells, gas gathering systems, and gas processing operations.

In this monitoring technique, a representative sample of a process stream is taken and kept in a vessel that maintains the original condition of the sample for subsequent analysis. The sampling methods can be quite complex since the samples need to be maintained under the pressure conditions of the process stream. This can be particularly difficult for high-pressure process systems.

SULFUR CONTENT Sulfur is the most abundant element in petroleum other than carbon and hydrogen. Corrosion of carbon steel may become extremely high (~ 100 mm/year!!) when the sulfur $>0.2\%$. It can be present as elemental sulfur, dissolved hydrogen sulfide, mercaptans, sulfides, and polysulfides. The total sulfur content is generally analyzed according to ASTM D 4294. Halides and heavy metals interfere with this method and the capability of a sulfur compound to form H_2S during heating in the refinery process, rather than the total amount of the compound, is believed to correlate with corrosion in the plants.

TOTAL ACID NUMBER Acid content is generally expressed in terms of total acid number (TAN) or neutralization (neut) number. For the purpose of predicting corrosion in crude distillation units in refineries, the TAN threshold is believed to be ~ 0.5 for whole crude and 2.0 for the cuts. In petroleum production, it was found that the corrosion rate is usually inversely proportional to the algebraic product of the nitrogen concentration and the TAN.

With this monitoring technique, an oil sample is dissolved in a mixture of toluene and isopropyl alcohol containing a small amount of water. The solution is then titrated with an alcoholic potassium hydroxide solution (KOH). Both ASTM D 664 and ASTM D 974 can be used to determine the TAN. However, ASTM D 664 yields numbers 30–80% higher than does ASTM D 974.

Inorganic acids, esters, phenolic compounds, sulfur compounds, lactones, resins, salts, and additives, such as inhibitors and detergents, sometimes interfere with the measurement. Universal Oil Products (UOP) Methods 565 and 587 give procedures to remove most of the interfering materials before performing the analysis for organic acids.

NITROGEN CONTENT The total nitrogen is generally analyzed according to ASTM D 3228 for the assessment of the corrosivity of process feedstocks. High nitrogen content indicates corrosion-inhibitive properties of the crude oil or condensate in petroleum production. As already stated, the corrosion rate is inversely proportional to the algebraic product of the organic nitrogen concentration in weight percent and the TAN. In refining, however, when the organic nitrogen concentration exceeds 0.05%, cyanide and ammonia can form, collect in the aqueous phase, and corrode certain materials.

SALT CONTENT OF CRUDE OIL Salt (primarily sodium chloride with lesser amounts of calcium and magnesium chloride) is present in produced water, and this produced water can be dispersed, entrained, and/or emulsified in crude oil. Salt can cause corrosion of refinery equipment and piping by the formation of hydrochloric acid through hydrolysis and heating. Salt precipitates can form scale in heaters and heat exchangers and this can result in accelerated corrosion of equipment. Refineries generally limit salt content of crude oil for processing to 2.5–12 mg/L.

The salt content of crude oil can be determined using ASTM D 3230. The analytical procedure assumes that calcium and magnesium exist as chlorides and all the chloride is calculated as sodium chloride.

33.3.5 Monitoring Microbiologically Influenced Corrosion

An effective biocorrosion mitigation program needs to include corrosion monitoring as a periodic or continual means of assessing whether program goals are being achieved. This is particularly true in industrial water-handling systems with known susceptibility to biocorrosion (e.g., cooling water and injection water systems, heat exchangers, wastewater treatment facilities, storage tanks, piping systems, and all manner of power plants, including those based on fossil fuels, hydroelectric, and nuclear) (Dexter, 2003). Table 33.7 lists potential problem areas by industry (Scott, 2004).

As mentioned in Chapter 1, the interaction of microbial metabolism and corrosion processes can produce localized attack at very high rates. Monitoring techniques that detect the presence of microbes, especially on metallic surfaces, can provide an early indication of incipient MIC or the potential for MIC. A number of methods for the detection of microorganisms, including specific types of organisms and estimates of their numbers and activity, have been developed (Zintel et al., 2001).

The first biocorrosion monitoring systems were focused on assessing the number of microbes per unit volume of water sampled from the system. These data were combined with electrochemical corrosion measurements, using ER or LPR probes in addition to coupon weight loss measurements. The problem with this approach is that the number of free-floating planktonic organisms in the water does not correlate well with the organisms present in biofilms on the metal surface where the corrosion actually takes place. An effective monitoring scheme for controlling both biofouling and biocorrosion should include data gathering of as many of the following types of data as possible (Dexter, 2003):

- Sessile bacterial counts of the organisms in the biofilm on the metal surface done by either conventional biological techniques or optical microscopy.
- Direct observation of the community structure of the biofilm. This can be done on metal coupons made from the same alloy used for the system. Several types of probe systems are commercially available for holding and inserting such coupons into the system. Examination of the biofilm has been done by SEM, epifluorescence optical microscopy, or confocal laser scanning microscopy.
- Identification of the microorganisms found in both the process water and on the metal surface.
- Surface analysis to obtain chemical information on corrosion products and biofilms.
- Evaluation of the morphology of the corrosive attack on the metal surface after removal of biological and corrosion product deposits. Conventional macrophotography, as well as low-power stereomicroscopy, optical microscopy, metallography, and SEM may all be helpful in this regard.
- Electrochemical corrosion measurements.
- Water quality and redox potential measurements.
- Other types of information specific to each operational system, including duty cycle and downtime information, concentrations and timing for addition of biocides and other chemical inputs, local sources and nature of pollutants, and so on.

TABLE 33.7 Where MIC Problems Are Most Likely to Occur

Industry/Application	Potential Problem Sites for MIC	Organisms Responsible
Pipelines—oil, gas water, and wastewater	Internal corrosion primarily at the bottom (6:00) position Dead ends and stagnant areas Low points in long-distance pipes Waste pipes-internal corrosion at the liquid/air interface Buried pipelines-on the exterior of the pipe, especially in wet clay environments under disbonded coating	Aerobic and anaerobic acid producers, SRB, manganese and iron-oxidizing bacteria, sulfur-oxidizing bacteria
Chemical process industry	Heat exchangers, condensers, and storage tanks-especially at the bottom where there is sludge build-up Water distribution systems (See also “Cooling water systems,” “Fire protection systems,” and “Pipelines” in this table)	Aerobic and anaerobic acid producers, SRB, manganese, and iron-oxidizing bacteria In oil storage tanks also methanogens, oil-hydrolyzing bacteria
Cooling water systems	Cooling towers Heat exchangers-in tubes and welded areas-on shell where water is on shell side Storage tanks-especially at the bottom where there is sludge build-up	Algae, fungi, and other microorganisms in cooling towers Slime-forming bacteria, aerobic and anaerobic bacteria, metal-oxidizing bacteria, and other microorganisms and invertebrates
Fire protection systems	Dead ends and stagnant areas	Anaerobic bacteria, including SRB
Docks, piers, oil platforms, and other aquatic structures	Just below the low-tide line Splash zone	SRB beneath barnacles, mussels, and other areas sequestered from oxygen
Pulp and paper	Rotating cylinder machines Whitewater clarifiers	Slime-forming bacteria and fungi on paper making machines Iron-oxidizing bacteria SRB in waste water
Power generation plants	Heat exchangers and condensers Firewater distribution systems Intakes	As above for heat exchangers and fire protection systems Under mussels and other fouling organisms on intakes
Desalination	Biofilm development on reverse osmosis membranes	Slime-forming bacteria

33.3.5.1 Planktonic Organisms Depending on the type of industrial system, planktonic organisms may include, besides bacteria, unattached algae, diatoms, fungi, and other microorganisms present in a system bulk fluids. In most cases, it is planktonic bacteria that are the focus of monitoring for MIC using microbiological detection techniques, since system fluids are generally easier to sample than metallic surfaces. Unfortunately, the levels of planktonic bacteria present in the liquids are not necessarily indicative of MIC problems or their severity (Zintel et al., 2001).

At best, the detection of viable planktonic bacteria may serve as an indicator that living microorganisms are present in a particular system, some of these organisms are capable of participating in the microbial attack. It is generally very important that additional monitoring methods be performed to confirm that actual corrosion due to microbial processes has occurred.

33.3.5.2 Sessile Organisms Microorganisms that are attached to a surface are termed “sessile” organisms. These organisms are most often present as a consortium or community, collectively referred to as a biofilm. Complex assemblages of various species may occur within both planktonic and sessile microbial populations. The environmental conditions largely dictate whether the microorganisms will exist in a planktonic or sessile state.

Sessile microorganisms do not attach directly to the actual surface, but rather to a thin layer of organic matter adsorbed on the surface (Figure 33.64, Stages 1 and 2). As microbes attach to and multiply, a biofilm composed of immobilized cells and their extracellular polymeric substances builds up on the surface.

The growing biofilm increasingly prevents the diffusion of dissolved gases and other nutrients coming from the bulk liquid. These changing conditions become inhospitable to some microorganisms at the base of the biofilm, and eventually many of these cells die. As the foundation of the biofilm weakens, shear stress due to adjacent fluid flow, for example, may cause sloughing of cell aggregations exposing the bare surface to the bulk fluid in localized areas (Figure 33.64, Stage 5). The exposed areas are subsequently recolonized and new microorganisms and their exopolymers are woven into the fabric of the existing biofilm (Figure 33.64, Stage 6). This phenomenon of biofilm instability occurs even when the physical conditions in the bulk liquid remain constant. Thus, biofilms are constantly in a state of flux (Geesey, 1993).

Since MIC occurs directly on metal surfaces, the presence of sessile organisms is an important component to monitor. Monitoring sessile organisms either requires that the system be regularly opened for sampling or that accommodations be made in the system design to allow for regular collection or on-line tracking of attached organisms while the system continues to operate. It should be pointed out, however, that the presence of viable sessile organisms does not always translate into actual attack on the metal surfaces. Again, it is a good idea to use additional methods that directly determine the presence of active MIC.

33.3.5.3 Sampling Samples for analysis can be obtained by scraping accessible surfaces. In open systems or on the outside of pipelines or other underground facilities, this can be done directly. Bull plugs, coupons or inspection ports can provide surface samples in low pressure water systems (Sanders, 1988). More sophisticated devices

FIGURE 33.64 Different stages of biofilm formation and growth. Stage 1: Conditioning film accumulates on submerged surface. Stage 2: Planktonic bacteria from the bulk water colonize the surface and begin a sessile existence by excreting exopolymer that anchors the cells to the surface. Stage 3: Different species of sessile bacteria replicate on the metal surface. Stage 4: Microcolonies of different species continue to grow and eventually establish close relationships with each other on the surface. The biofilm increases in thickness. Conditions at the base of the biofilm change. Stage 5: Portions of the biofilm slough away from the surface. Stage 6: The exposed areas of surface are recolonized by planktonic bacteria or sessile bacteria adjacent to the exposed areas (Geesey, 1993).

are commercially available for use in pressurized systems (Gilbert and Herbert, 1987). In these devices, coupons are held in an assembly that mounts on a standard pressure fitting.

If the biofilm developing on the coupon is to be representative of the behavior in a system it is important for the sampling coupons to be made of a material similar to the system material and that they be flush mounted in the wall of the system to have the same

flow effects as those of the surrounding surface. While pressure fittings allow inserting coupons directly in process units, these fittings can be expensive. Pressure vessel codes and accessibility can also restrict possible locations. For these reasons, sidestream installations are often preferred.

Handling of field samples should be done carefully to avoid contamination with foreign matter including biological materials. Many different types of sterile sampling tools and containers are commercially available. Because many systems are anaerobic, proper sample handling and transport is essential to avoid exposure to oxygen from the air. One option is to analyze samples on the spot with special kits. Where transportation to a laboratory is required, Torbal jars or similar anaerobic containers can be used (Gerhardt, 1981). In many cases, simply placing samples directly in a large volume of the process water in a completely filled screw cap container is adequate.

Processing in the lab should also be done anaerobically using special techniques or in anaerobic chambers designed for this purpose. Because viable organisms are involved, processing should be done quickly to avoid growth or death of cells stimulated or inhibited by changes in temperature, oxygen exposure or other factors (Jack, 1999).

33.3.5.4 Biological Assessment Biological assays can be performed on liquid samples or on suspensions of solid deposits to identify and enumerate viable microorganisms, quantify metabolic or specific enzyme activity, or determine the concentration of key metabolites (Jack, 2002). Table 33.8 summarizes some of the methods that have been used to detect and describe microorganisms in terms of total cells present, viable cell numbers, and metabolic activity. Table 33.8 also identifies assays that can be used to establish the presence of biomass in a field sample, identify the organisms present, and assess the activity of enzymes, such as hydrogenase, that are thought to accelerate corrosion through cathodic depolarization. A more detailed description of these assays and other techniques is provided in the following sections.

Direct Inspection Direct inspection is best suited for the enumeration of planktonic organisms suspended in relatively clean water. In liquid suspensions, cell densities $>10^7$ cells cm^{-3} may cause the sample to appear turbid. Quantitative enumerations using a phase contrast microscopy can be done quickly using a counting chamber that holds a known volume of fluid in a thin layer. Visualization of microorganisms can be enhanced by fluorescent dyes that cause cells to light up under ultraviolet radiation. The technique is usually performed in the laboratory (Techniques for Monitoring Corrosion and Related Parameters in Field Applications, 1999).

Using a stain, such as acridine orange, cells separated by filtration from large aliquots of water can be visualized and counted on a 0.25- μm filter using the epifluorescent technique. Newer stains, such as fluorescein diacetate, 5-cyano-2,3-ditolyltetrazolium chloride, or *p*-iodonitrotetrazolium violet, indicate active metabolism by the formation of fluorescent products (Jack, 1999). Antibody fluorescence microscopy is similar to general fluorescent microscopy, except that the fluorescent dye used is bound to antibodies specific to SRBs. Only bacteria recognized by the antibodies fluoresce. Results can be analyzed within 2 h. The technique detects viable and nonviable bacteria, but it is limited to the type of SRB used in the manufacture of these antibodies (Techniques for Monitoring Corrosion and Related Parameters in Field Applications, 1999).

TABLE 33.8 Inspection, Growth, and Activity Assays for Microbial Populations

Assay	Method	Comments
Microorganisms	<i>Microscopic examination:</i> Cell numbers are obtained with a Petroff-Hausser counting chamber. Fluorescent dyes can light up specific microbes.	Requires a microscope with high magnification, phase contrast, and ultraviolet fluorescence, as appropriate. Cell counts are straightforward, but particulates and fluorescent materials may interfere.
Viable cell counts	<i>Most probable number:</i> Sample is diluted into a series of tubes of specific growth medium. Cell numbers based on growth at various dilutions.	Commercially available kits can be inoculated in the field, but growth takes days to weeks.
SRB APB Other organisms	<i>Dip slides:</i> A tab coated with growth medium is immersed, then incubated 2–5 days. Microbial colonies are counted visually.	
Identification of microorganisms	<i>Fatty acid methyl ester analysis:</i> Methyl esters of fatty acids from field sample are analyzed by gas chromatograph.	Crude numbers of bacteria, yeast, or fungi can be estimated in contaminated crankcase oil or fuels, for example. Commercial kits require minimal cost and expertise.
	<i>Probes based on nucleic acid base sequences:</i> Probes bind to DNA or RNA for specific proteins or organisms.	Fatty acid composition fingerprints specific organisms. The technique is available commercially.
	<i>Reverse sample genome probing:</i> DNA from MIC microbes is spotted on a master filter. Labeled DNA from field samples will bind to that DNA, if the reference organism is present.	Probes require special expertise and lab facilities.
	<i>Protein, lipopolysaccharide, nucleic acid analysis:</i> Established methods, widely available.	The assay answers the question, “Is this organism present?” It can also be used to track changes in a population after chemical treatment but it requires special expertise and equipment.
Biomass		Concentration of cell constituents correlates to level of organisms present in field sample.
Metabolic activity	<i>Adenosine triphosphate (ATP):</i> Fluorometer and supplies commercially available for field use.	ATP level correlates well with microbial metabolism level. Its concentration reflects the level of activity in a sample.
Sulfate reduction	<i>³⁵S sulfate reduction:</i> Radioactively labeled sulfate is incubated in field sample. Hydrogen sulfide formed is liberated by acid addition, trapped on a zinc acetate wick, and measured by scintillation counter.	A specialized lab technique useful in discovering nutrient sources for MIC and in quickly screening biocide activity in samples taken from the target system.
Enzyme activity	<i>Hydrogenase assay or sulfate reductase assay:</i> Measures enzyme activity in a field sample as a rate of reaction.	Commercial kits are available. Hydrogenase activity may be related to MIC, while sulfate reductase assesses the presence of SRB.

Identification of organisms can be accomplished by use of antibodies generated as an immune response to the injection of microbial cells into an animal, typically a rabbit. These antibodies can be harvested and will selectively bind to the target organism in a field sample. A second antibody tagged with a fluorescent dye is then used to light up the rabbit antibody bound to the target cells. In effect, the staining procedure can selectively light up target organisms in a mixed population or in difficult soil, coating or oily emulsion samples (Hunik et al., 1993).

Such techniques can provide insight into the location, growth rate, and activity of specific kinds of organisms in mixed biofilm populations. Antibodies that bind to specific cells can also be linked to enzymes that produce a color reaction in an enzyme-linked immunosorbent assay. The extent of color produced in solution can then be correlated with the number of target organisms present (Pope, 1992). While antibody based stains are excellent research tools, their high specificity means that they can only identify the target organisms. Other organisms potentially capable of causing problems are therefore missed.

Growth Assays The most common way to assess microbial populations in water samples is through growth tests using commercially available growth media for groups of organisms most commonly associated with industrial problems. These are packaged in a convenient form suitable for use in the field. Serial dilutions of suspended samples are grown on solid agar or liquid media. Based on the growth observed for each dilution estimates of the most probable number (MPN) of viable cells present in a sample can be obtained (Costerton and Colwell, 1977). The test can show some results in a few days, but the usual incubation period for the test is 14–28 days (Techniques for Monitoring Corrosion and Related Parameters in Field Applications, 1999).

However, despite the common use of these assays, only a small fraction of wild organisms actually grow in commonly available artificial media. Estimates for SRB in marine sediments, for example, indicate that only 1 in 1000 of the organisms present actually show up in standard growth tests (Jorgenson, 1978).

Activity Assays

WHOLE CELL Approaches based on the conversion of a radioisotopically labeled substrate can be used to assess the potential activity of microbial populations in field samples. This technique is specific to SRBs. It depends on bacterial growth for detection, but it generates results in ~2 days.

The sample is incubated with a known trace amount of radioactive-labeled sulfate. (SRBs reduce sulfate to sulfide.) After incubation, the reaction is terminated with acid to kill the cells and the radioactive sulfide is fixed in zinc acetate, which is sent to a laboratory for evaluation. This is a highly specialized technique, involving expensive laboratory equipment and the handling of radioactive substances (Techniques for Monitoring Corrosion and Related Parameters in Field Applications, 1999).

The radiorespirometric method that can use field samples directly without the need to separate organisms is very sensitive. Selection of the radioactively labeled substrate is key to interpretation of the results, but the method can provide insights into factors limiting growth by comparing activity in native samples with supplemented test samples under various conditions. Oil degrading organisms, for example, can be assessed through the mineralization of ^{14}C labeled hydrocarbon to carbon dioxide.

Radioactive methods are not routinely used by field personnel. However, they have been particularly useful in a number of applications including biocide screening programs, identification of nutrient sources, and assessment of key metabolic processes in various corrosion situations (Jack, 1999).

ENZYME-BASED ASSAYS An increasingly popular approach is the use of commercial kits to assay the presence of enzymes associated with microorganisms suspected to cause problems. For example, kits are available for the sulfate reductase enzyme common to SRB associated with corrosion problems (Odom et al., 1991). This technique takes advantage of the fact that SRBs reduce sulfate to sulfide through the presence of an enzyme, APS-reductase, common to all SRBs. Measurement of the amount of APS-reductase in a sample gives an estimate of total numbers of SRBs present. The test does not require bacterial growth and the entire test takes 15–20 min (Techniques for Monitoring Corrosion and Related Parameters in Field Applications, 1999).

Another example is the hydrogenase enzyme implicated in the acceleration of corrosion through rapid removal of cathodic hydrogen formed on the metal surface (Bryant et al., 1991). The test analyzes for the hydrogenase enzyme that is produced by bacteria able to use hydrogen as an energy source. The test is usually performed on sessile samples. The sample is exposed to an enzyme-extracting solution, and the degree of hydrogen oxidation in an oxygen-free atmosphere is detected by the addition of a dye (Techniques for Monitoring Corrosion and Related Parameters in Field Applications, 1999).

Performance of several of these kits has been assessed by field personnel in round robin tests. Correlation of activity assays and population estimates is variable. In general, these kits have a narrower range of application than growth-based assays making it important to select a kit with a range of response appropriate to the problem under consideration (Scott and Davies, 1992).

METABOLITES Adenosine triphosphate (ATP) is present in all living cells, but it disappears rapidly on death. The measure of ATP may thus provide a measure of living material. The ATP can be measured using an enzymic reaction, which generates flashes of light that are detected by a photomultiplier (Techniques for Monitoring Corrosion and Related Parameters in Field Applications, 1999). Commercial instruments are available that measure the release of light by the firefly luciferin–luciferase with ATP. The method is best suited to clean aerobic aqueous samples since suspended solids and chemical quenching can affect the results. Detection of metabolites, such as organic acids in deposits or gas compositions including methane or hydrogen sulfide by routine gas chromatography can also indicate biological involvement in industrial problems (Jack, 1999).

CELL COMPONENTS Biomass can be generally quantified by assays for protein, lipopolysaccharide, or other common cell constituents, but the information gained is of limited value. An alternate approach is to use cell components to define the composition of microbial populations with the hope that the insight gained may allow future damaging situations to be recognized and managed. Fatty acid analysis and nucleic acid sequencing provide the basis for the most promising methods in this category.

Fatty Acid Profiles Analyzing fatty acid methyl esters derived from cellular lipids can fingerprint organisms rapidly and, provided pertinent profiles are known, organisms in industrial and environmental samples can be identified with confidence. The immediate

impact of events, such as changes in operating conditions or the application of biocides, can be monitored by such analysis. Problem populations of certain organisms can also be identified in order to implement appropriate management responses in a timely fashion.

Nucleic Acid-Based Methods Specific DNA probes have been developed to detect segments of genetic material coding for known enzymes. A gene probe developed to detect the hydrogenase enzyme that occurs broadly in SRB from the genus *Desulfovibrio* has been tested on samples from an oilfield waterflood plagued with iron sulfide related corrosion problems. The enzyme was detected with this probe in 12 of 20 samples, suggesting that sulfate reducers that did not have this enzyme were also present in the operation (Voordouw et al., 1995). In principle, probes could be developed to detect potentially all sulfate-reducers. However, the operation of a battery of probes could be a daunting task where large numbers of field samples have to be analyzed.

To overcome this obstacle, the reverse sample genome probe (RSGP) was developed. With RSGP, the DNA from organisms previously isolated from field problems is spotted on a master filter following which the DNA isolated from field samples is labeled with either a radioactive or fluorescent indicator and exposed to the filter. Labeled DNA from the field sample sticks to the corresponding spot on the master filter when complementary strands of DNA are present. Organisms represented by the labeled spots are then known to be in the field sample (Voordouw et al., 1995).

Detailed Coupon Examinations A great deal of information can be learned by careful, in-depth examination of corrosion coupon surfaces using commonly available analytical techniques. A wide variety of samplers for introducing metallic surfaces of interest into a system are available. A popular sampling device is shown in Figure 33.65. Special handling of coupons after removal from the system being monitored is crucial to ensure that subsequent laboratory tests provide representative information. Biofilms in particular are highly sensitive to dehydration, exposure to air, temperature, mechanical damage, and other gross environmental changes that can occur during removal and transport of the coupon (Zintel et al., 2001).

Examination of coupons for microbial populations can be performed either directly or indirectly, using histological embedding techniques to preserve and remove the biofilm. Although fairly involved, the embedding technique offers several advantages over direct observation in that the biofilm and corrosion products are preserved for future analysis. Environmental scanning electron microscopy (ESEM) may also be utilized to examine biofilms on test coupons; however, exopolymers and corrosion products often obscure the cells, making quantification and identification difficult with this method.

33.3.5.5 Monitoring MIC Effects The presence of a biofilm on a metallic surface can greatly alter the local corrosion processes. In addition to the electrochemical changes that affect corrosion, biofilms can also modify other readily measured characteristics, such as pressure drop or heat-transfer resistance. Monitoring such microbiological influences can provide a useful indicator that a biofilm is present and that action should be taken to mitigate potential MIC.

Deposition Accumulation Monitors Methods for monitoring deposits can provide an indication of the accumulation of biofilm and other solids on surfaces or in orifices. For example, monitoring pressure drop across an orifice provides a simple method for

FIGURE 33.65 Biofilm sampling device with removable “buttons.”

continuous monitoring of deposit accumulation and biofilm accumulation. The main disadvantage of the pressure drop technique is that it is not specific to the biofilm build-up since it detects the total scaling and deposition effects in a line (Zintel et al., 2001).

These measurements can be made on actual operating units on-line, but they may also be done using model heat exchanger units or instrumented pipe loops run in parallel to system flow. Figure 33.17 shows such an instrumented pipe loop test unit with five parallel, instrumented pipe runs. Water flow from the target system is diverted through this unit, so that conditions are representative of the actual operating system (Jack, 2002).

Measurements of friction factors and heat exchange efficiencies can indicate fouling. While deposits of any sort can affect flow and heat transfer in an operating industrial system, biofilms are especially effective. A 165- μm thick biofilm shows 100 times the relative roughness of a calcite scale and a thermal conductivity close to that of water, that is, almost 100 times less than carbon steel (Jack, 1999). The assumption is generally made that a susceptible system showing extensive fouling is prone to MIC. Systems showing the effects of extensive fouling are operating inefficiently and may warrant remedial action, in any case.

Electrochemical Methods An electrochemical method for on-line monitoring of biofilm activity has been developed for continuous monitoring of biofilm formation without the need for excessive involvement of plant personnel (Figure 33.66a and b). A series of stainless steel or titanium disks are exposed to the plant environment. One set of disks is

FIGURE 33.66 (a) Schematic and (b) picture of the BioGEORGE MIC detection probe. (Courtesy of George Licina, Structural Integrity Associates, Inc.)

polarized (relative to the other set) for a short period of time each day. The electrodes are connected through a shunt the remainder of the time. Biofilm activity, which is also an electrochemical process, is monitored by tracking changes in the applied current when the external potential is on and the generated current when the potential is off (Zintel et al., 2001).

The onset of biofilm formation on the probe is indicated when either of these independent indicators deviates from the baseline level (Figure 33.67). Such a departure would then trigger the alarm located in a control box (Figure 33.68). The level of biofilm activity is also measured by the amount of variation from the baseline. The applied and generated

FIGURE 33.67 A plot of signals generated by a BioGEORGE MIC detection probe. (Courtesy of George Licina, Structural Integrity Associates, Inc.)

currents from a well-controlled system will be a flat line, devoid of any significant deviations.

Another experimental approach to detect MIC with an electrochemical signals is based on the use of small silver sulfide and silver chloride electrodes capable of detecting sulfides or chlorides by changes in the potential between the Ag/AgCl or

FIGURE 33.68 Control box of a BioGEORGE MIC detection probe. (Courtesy of George Licina, Structural Integrity Associates, Inc.)

Ag/Ag₂S electrode pairs (Zintel et al., 2001). The production of sulfides or concentration of chlorides by microbial action was shown to produce a nearly instantaneous change in the potential of the electrode pair, thus providing an indication of specific microbial activity.

33.3.6 Monitoring Pipeline CP Systems

Monitoring pipeline CP systems is a technically complex field. In many cases, condition monitoring requirements are specified by regulatory authorities. Since CP systems are expected to operate in demanding environmental conditions over long time periods, the reliability requirements of the associated hardware are high. Regular monitoring of the equipment is therefore an important aspect of any CP program.

An increasing trend toward selective remote rectifier monitoring, using modern communication systems and computer networks, is emerging to accomplish these tasks with reduced resources. Wireless cell phone and satellite communication systems are available for interrogating rectifiers in remote locations. The other aspect of monitoring a pipeline CP system is the monitoring of protection afforded to the pipeline. The following sections briefly describe some of the techniques used to carry out this work.

33.3.6.1 Close Interval Potential Surveys The principle of a close interval potentials surveys (CIPS) is to record the potential profile of a pipeline over its entire length by taking potential readings at ~ 1 m intervals. A reference electrode is connected to the pipeline at a test post and positioned in the ground over the pipeline at regular intervals for the measurement of the potential difference between the reference electrode and the pipeline (Figure 33.69).

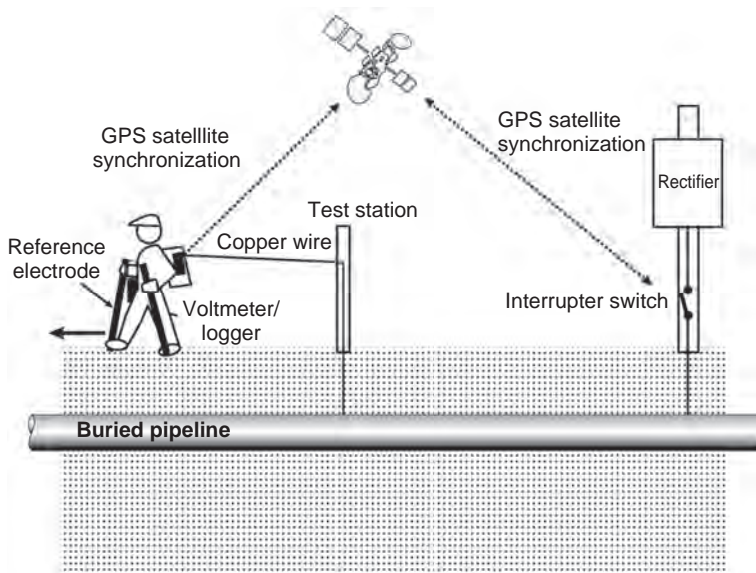

FIGURE 33.69 Schematic description of the CIPS methodology.

A three-person crew is typically required to perform these measurements. One person walking ahead locates the pipeline with a pipe locator to ensure that the potential measurements are performed directly above the pipeline. This person also carries a tape measure and inserts a distance marker (a small flag) at regular intervals over the pipeline. A second person carries a pair of electrodes connected to the test post by means of a trailing thin copper wire and the potential measuring instrumentation. The second person is also responsible for entering specific features as a function of the measuring distance. The third person collects the trailing wire, after individual survey sections have been completed.

The CIPS measurements are quite demanding on field crews and require extensive logistical support from both the pipeline operator and the CIPS contractor. Field crews are typically required to move over/around fences, roads, highways and other obstacles and difficult terrain. Breakage of the trailing copper wire is not uncommon and special strengthened wire has to be taped down onto road surfaces that are crossed.

An important consideration in the potential readings is the IR or ohmic drop error that is included in the potential measurements when a CP system is operational. A commonly used method to correct for the IR drop, often called making instant-off measurements, can be a very accurate way to make potential measurements. In reality, however, making measurements completely free of voltage drop error is not always possible because some currents cannot be easily interrupted.

Uninterruptible current sources may include sacrificial anodes directly bonded to the structure, foreign rectifiers, stray currents, telluric currents, and long-line cells (Ansuini and Dimond, 2005). Modern interrupters are based on solid-state switches and are programmable to perform switching only when the survey is performed during the day time. This feature minimizes the depolarization of the pipeline that may occur gradually due to the cumulative effects of the “off” periods.

When several rectifiers protect a structure, it is necessary that all rectifiers be interrupted at the exact same instant in order to obtain meaningful measurements. Pipeline operators usually specify that at least two rectifiers ahead of the survey team and two rectifiers behind the survey team have to be interrupted in a fully synchronized manner. The amount of time between current interruption and depolarization can vary from a fraction of a second to several seconds, depending on the details of the structure. In addition, capacitive spikes that occur shortly after current is interrupted may mask the instant-off potential. Measurements made with a recording voltmeter are preferred as they can be subsequently analyzed to determine the real instant-off potential (Ansuini and Dimond, 2005).

An example of graphical CIPS data is presented in Figure 33.70 (Bianchetti, 2001). In the simplest format, the “on” and “off” potentials are plotted as a function of distance. The usual sign convention is for potentials to be plotted as positive values. The difference between the “on” and “off” potential values should be noted. As is usually the case, the “off” potentials are less negative than the “on” values. When the relative position of these two lines is reversed, it indicates that some unusual conditions such as stray current interference may be at play.

The CIPS technique provides a complete pipe-to-soil potential profile and the interpretation of results, including the identification of defects, is relatively straightforward.

FIGURE 33.70 Over-the-line survey with cathodic protection.

33.3.6.2 Pearson Survey The Pearson Survey, named after its inventor, is used to locate coating defects in buried pipelines. Once these defects have been identified, the protection levels provided by the CP system can be investigated at these critical locations in more detail.

During a Pearson survey, an ac signal of ~ 1000 Hz is imposed onto the pipeline by means of a transmitter (Figure 33.71), which is connected to the pipeline and an earth spike as illustrated in Figure 33.72. Two survey operators make earth contact either

FIGURE 33.71 Instrumentation to carry out a Pearson survey. (Photo courtesy of Tinker & Rasor.)

FIGURE 33.72 Schematic description of the Pearson survey technique.

through aluminum poles or metal studded boots (Figure 33.73). A distance of several meters typically separates the operators. Essentially, the signal measured by the receiver provides a measure of the potential gradient over the distance between the two operators. Defects are located by a change in the potential gradient, which translates into a change in signal intensity.

As in the CIPS technique, the measurements are usually recorded by walking directly over the pipeline. As the front operator approaches a defect, increasing signal intensity is recorded. As the front person moves away from the defect, the signal intensity drops and later picks up again as the rear operator approaches the defect. The interpretation of signals may obviously be more difficult when several defects are located between the two operators.

In principle, a Pearson survey can be performed with an impressed CP system still energized. However, sacrificial anodes should be disconnected since the signal from these may otherwise mask actual coating defects. A three-person team is usually required to locate the pipeline, perform the survey measurements, place defect markers into the ground, and move the transmitters periodically.

FIGURE 33.73 Pipeline CP fault testing with Pearson-type detector. (Photo courtesy of Tinker & Rasor.)

By walking the entire length of the pipeline, an overall inspection of the right of way can be made together with the measurements. In principle, all significant defects and metallic conductors causing a potential gradient will be detected. There are no trailing wires and the impressed CP current does not have to be turned on and off.

The disadvantages associated with Pearson surveys are similar to those of CIPS, as the entire pipeline has to be walked and contact established with the ground. The technique is therefore impractical in many areas, such as roads, paved areas, or rivers.

33.3.6.3 Direct Current Voltage Gradient Surveys The direct current voltage gradient (DCVG) surveys are a more recent method to locate defects on coated buried pipelines and to assess their severity. The technique again relies on the fundamental effect of a potential gradient being established in the soil at coating defects under the application of CP current. In general, the greater the size of the defect, the greater the potential gradient.

The potential gradient is measured by an operator between two reference electrodes, for example, copper sulfate electrodes, separated by a distance of approximately one-half of a meter. A pulsed dc signal is imposed on the pipeline for DCVG measurements. The pulsed input signal minimizes interference from other current sources (e.g., CP systems, electrified rail transit lines, telluric effects). This signal can be obtained with an interrupter on an existing rectifier or through a secondary current pulse superimposed on the existing “steady” CP current.

The operator walking the pipeline observes voltage deflections on a precision voltmeter to identify defect locations. The presence of a defect is indicated by an increased deflection as the defect is approached, no deflection when the operator is immediately above the defect and a decreasing deflection as the operator walks away from the defect (Figure 33.74). The high precision in locating defects (~ 0.1 to 0.2 m) represents a major advantage in minimizing the work of subsequent digs if corrective action needs to be taken.

The DCVG technique is particularly suited to complex CP systems, for example, areas with a relatively high density of buried structures. These are generally the most difficult survey conditions. The DCVG equipment is relatively simple and involves no trailing wires.

33.3.6.4 Corrosion Coupons Cathodic protection (CP) coupons are now being used as an alternative method to make potential measurements that may be substantially free of voltage drop error. A CP coupon is a small piece of metal that is electrically connected to the structure at a test station. The potential of a coupon will closely approximate the potential of any exposed portion of the structure (holiday) located in the vicinity of the coupon. By disconnecting the coupon from the structure at the test station, an instant-off potential measurement can be made on the coupon without having to interrupt any other current sources. However, these measurements are still not completely free of voltage drop error. Any voltage drop occurring in the electrolyte in the distance between the reference electrode and the coupon surface will still be incorporated into measurements. Placing a reference electrode as close as possible to a coupon can minimize this error. However, the reference electrode must not be placed so close that it shields the coupon (Ansuini and Dimond, 2005).

Perhaps the most important consideration in the installation of corrosion coupons is that a coupon must be representative of the actual pipeline surface/defect. The exact

FIGURE 33.74 Schematic description of the DCVG methodology.

metallurgical detail and surface finish as found on the actual pipeline are therefore required on the coupon. The influence of corrosion product build-up may also be an important factor. The environmental conditions of the coupon have to be matched with those of the pipe being monitored, for example, temperature, soil conditions, soil compaction, and oxygen concentration.

Measurement of current flow to/from the coupon and its direction can also be determined, for example, by using a shunt resistor in the bond wire. Importantly, it is also possible to determine corrosion rates from the coupon. Electrical resistance sensors provide an option for *in situ* corrosion rate measurements, as an alternative to weight loss coupons.

33.3.7 Atmospheric Corrosion Monitoring

The economic losses caused by atmospheric corrosion are tremendous and account for the disappearance of a significant portion of metal produced. Atmospheric corrosion has been reported to account for more failures in terms of cost and tonnage than any other type of material degradation processes. Atmospheres have been classified into four basic types:

Industrial: An industrial atmosphere is characterized by its pollution level, two constituents of which are particularly corrosive (i.e., sulfur compounds and nitrogen oxides). When present, these contaminants may combine with dew or fog to produce a highly corrosive acid film on exposed surfaces.

Marine: Marine atmospheres are often laden with a sea salt mist or aerosol particles that can be carried by the wind to settle on exposed surfaces. The quantity of salt

contamination typically decreases with distance from the saline source, and is greatly affected by wind currents.

Rural: A rural environment does not usually contain strong chemical contaminants, but it does contain organic and inorganic dusts. Its principal corrosive constituent is moisture. In tropical environments, in addition to the high average temperature, the daily cycle includes a high relative humidity, intense sunlight, and long periods of condensation during the night.

Indoor: Indoor atmospheres can be generally considered to be quite mild. However, the presence of local contaminants can transform ambient air into a very corrosive environment if it is not properly ventilated or controlled through dehumidification, for example. Additionally, the consequences of indoor corrosion have been drastically amplified by the incredibly small volume of the material that needs to be damaged before causing a fault in modern computer and communication equipment. The microchip in an automobile, for example, is not directly subjected to the same environmental hazards as the car body. However, the tolerance for corrosion loss in electronic devices is many orders of magnitude less, that is, on the order of picograms (10^{-12} g). The minimum line width in the state-of-the-art printed circuit boards (PCBs) in 1997 was already $<100\text{ }\mu\text{m}$. On hybrid integrated circuits (HICs), line spacing may be $<5\text{ }\mu\text{m}$ (Frankenthal, 2000).

Various methods have been developed for measuring the factors that influence atmospheric corrosion. Temperature, RH, wind direction and velocity, solar radiation, and amount of rainfall are easily recorded. Not so easily determined are dwelling time of wetness (TOW), and the quantity of sulfur dioxide and chloride contamination. However, methods for these determinations have been developed and are in use at various test stations.

By monitoring these factors and relating them to corrosion rates, a better understanding of atmospheric corrosion can be obtained for planning maintenance procedures and inspection schedules, for the prediction or outdoor performance of materials and systems, and to circumvent the effects of corrosion products on the environment.

33.3.7.1 Relative Humidity and Time of Wetness Relative humidity is defined as the ratio of the quantity of water vapor present in the atmosphere to the saturation quantity at a given temperature, and it is expressed as percent (%). A fundamental requirement for atmospheric corrosion processes is the presence of a thin-film electrolyte that can form on metallic surfaces when exposed to a critical level of humidity (Figure 33.75). While this film is almost invisible, the corrosive contaminants it contains are known to reach relatively high concentrations, especially under conditions of alternate wetting and drying.

The critical humidity level is a variable that depends on the nature of the corroding material, the tendency of corrosion products and surface deposits to absorb moisture, and the presence of atmospheric pollutants (Roberge, 2000). It has been shown that, for example, this critical humidity level is 60% for iron if the environment is free of pollutants.

In the atmospheric classification scheme described in ISO 9223 (Corrosion of metals and alloys—Corrosivity of atmospheres—Classification, 1992). The TOW is an estimated parameter based on the length of time when the relative humidity is $>80\%$ at a temperature $>0^{\circ}\text{C}$. It can be expressed as the hours or days per year or the annual percentage of time. Experience from applying the ISO classification system has shown, however, that

FIGURE 33.75 Schematic description of the atmospheric corrosion of iron.

certain observations need further clarification. Substantial corrosion has also been measured on specimens exposed at temperatures well below 0°C , which is in direct contradiction to the ISO criterion (King et al., 2001). It has been proposed on the basis of these results, that the TOW in cold environments be estimated as the length of time that relative humidity exceeds 50% and the ambient temperature exceeds -10°C .

A method of measuring the TOW has been developed by Sereda and correlated with the corrosion rates encountered in the atmosphere (Sereda et al., 1982). The moisture sensing elements in this sensor are manufactured by plating and selective etching of thin films of appropriate anode (copper) and cathode (gold) materials in an interlaced pattern on a thin nonconductive substrate (Figure 33.76). When moisture condenses on the sensor it activates the sensor, producing a small voltage (0–100 mV) across a $10^7 \Omega$ resistor.

Thin sensing elements are preferred in order to preclude influencing the surface temperature to any extent. Although a sensor constructed using a 1.5-mm thick glass

FIGURE 33.76 Interlocking combs of gold and copper electrodes in a ‘Sereda’ humidity sensor. (Courtesy Kingston Technical Software.)

reinforced polyester base has been found to be satisfactory on plastic surfaces, this will not be the case with the same sensing element on a metal surface with a high-thermal conductivity (Standard Practice for Measurement of Time-of-Wetness on Surfaces Exposed to Wetting Conditions as in Atmospheric Corrosion Testing, 1999). For metal surfaces, the sensing element should be appreciably thinner. Commercial epoxy sensor backing products of thickness of 1.5 mm, or less, are suitable for this purpose.

33.3.7.2 Pollutants Sulfur dioxide (SO_2), which is the gaseous product of the combustion of fuels that contain sulfur such as coal, diesel fuel, gasoline, and natural gas, has been identified as one of the most important air pollutants that contribute to the corrosion of metals.

Less recognized as corrosion promoters, are the nitrogen oxides (NO_x), which are also products of combustion. A major source of NO_x in urban areas is the exhaust fumes from vehicles. Sulfur dioxide, NO_x , and airborne aerosol particles can react with moisture and ultraviolet (UV) light to form new chemicals that can be transported as aerosols. A good example of this is the summertime haze or smog over many large cities. Up to 50% of this haze is a combination of sulfuric and nitric acids.

Sulfur dioxide is usually measured in terms of its concentration in air in units of $\mu\text{g}/\text{m}^3$. Precise methods are available to monitor continuously the amount of sulfur dioxide in a given volume of air. However, this is only indirectly related to the effect of sulfur dioxide on corrosion since only the actual amount of hydrated sulfur dioxide or sulfur trioxide deposited on metal surfaces is important.

Since it is the SO_2 deposited on the metal surface that affects the corrosion, deposited SO_2 has been measured as its reaction product in terms of sulfate deposition rate on the surface in units of mg/m^2 day. The pollution levels can also be measured in terms of the concentration of the dissolved sulfate (SO_4^{2-}) in rain water.

33.3.7.3 Airborne Particles (Chlorides) The behavior of aerosol particles in outdoor atmospheres can be explained by invoking the laws that govern their formation, movement, and capture. These particles are present throughout the planetary boundary layer and their concentrations depend on a multitude of factors including location, time of day or year, atmospheric conditions, presence of local sources, altitude, and wind velocity. Size is normally used to classify aerosol because it is the most readily measured property and other properties can be inferred from size information (Hidy, 1984). The highest mass fraction of particles in an aerosol is characterized by particles having a diameter in the range of 8–80 μm (Feliu et al., 1999). Some studies have also indicated that there is a strong correlation between wind speed and the deposition and capture of aerosols. In such a study of saline winds in Spain, a very good correlation was found between chloride deposition rates and wind speeds above a threshold of 3 m/s or 11 km/h (Morcillo et al., 2000).

The lifetime of any particular particle depends on its size and location. Studies of the migration of aerosols inland of a sea coast have shown that typically the majority of the aerosol particles are deposited close to the shoreline (typically 400–600 m) and consist of large particles ($>10\text{-}\mu\text{m}$ diameter), which have a short residence time and are controlled primarily by gravitational forces (Feliu et al., 1999; Morcillo et al., 2000). The aerosols that form also have mass and are subject to the influence of gravity, wind resistance, drop-let dry-out, and possibilities of impingement on a solid surface, as they progress inland.

Airborne salinity refers to the content of gaseous and suspended salt in the atmosphere. It is measured by its concentration in air in units of $\mu\text{g m}^{-3}$. Since it is the salt that is deposited on the metal surface that affects the corrosion, it is also often measured in terms of deposition rate in units of $\text{mg/m}^2 \text{ day}$. The chloride levels can also be measured in terms of the concentration of the dissolved salt in rain water.

A number of methods have been employed for determining the contamination of the atmosphere by aerosol transported chlorides (e.g., sea salt and road deicing salts). The “wet candle method”, for example, is relatively simple, but has the disadvantage that it also collects particles of dry salt that might not be deposited otherwise (Standard Test Method for Determining Atmospheric Chloride Deposition Rate by Wet Candle Method, 2002). This technique uses a wet wick of a known diameter and surface area to measure aerosol deposition (Figure 33.77). The wick is maintained wet using a reservoir of water or 40% glycol–water solution. Particles of salt or spray are trapped by the wet wick and retained. At intervals, a quantitative determination of the chloride collected by the wick is made and a new wick is exposed.

In reality, the wet candle method gives an indication of the salinity of the atmosphere rather than the contamination of exposed metal surfaces. The technique is considered to measure the total amount of chloride arriving to a vertical surface and its results may not be truly significant for corrosivity estimates.

FIGURE 33.77 Schematic of a wet candle chloride apparatus.

FIGURE 33.78 A typical subfloor simulation box surmounted by a wet candle chloride measuring device that has been installed at several sites in Australia and New Zealand. (Courtesy of Branz, New Zealand.)

In order to evaluate the chloride deposition rates in a confined space, such as a ventilated subfloor where corrosion of fasteners can be quite severe, a special collecting box shown in Figure 33.78 was used in which the airborne chlorides were collected on horizontal and vertical filter papers positioned at different locations from the box openings (Figure 33.79).

For obvious reasons, the test chambers used in this study were thoroughly cleaned of chlorides before setting them outdoor. Rigid plastic material panels stuck at predetermined positions with self-adhesive pads were used to hold the filter papers with chloride-free plastic paper clips. The roof protected the surface from direct rain, but the filter papers were still exposed to deposition of the airborne chlorides and possibly some rain. The paper was removed every month for chemical analysis. A wet candle with its own roof cover was installed on each box (Figure 33.78) to provide a measure of the level of chlorides outside the boxes.

33.3.7.4 Atmospheric Corrosivity The simplest form of direct atmospheric corrosion measurement is by coupon exposures. Subsequent to their exposure, the coupons can be subjected to weight loss measurements, pit density and depth measurements, and to other types of examination. Flat panels exposed on exposure racks are a common coupon-type device for atmospheric corrosivity measurements. Various other specimen configurations have been used, including stressed U-bend or C-ring specimens for SCC studies. The main drawback associated with conventional coupon measurements is that extremely long exposure times are usually required to obtain meaningful data, even on a relative scale. It is not uncommon for such programs to run for 20 years or longer (Roberge, 2006).

FIGURE 33.79 Horizontal and vertical filter papers installed inside a subfloor simulation box. (Courtesy of Branz, New Zealand.)

Some variations of the basic coupon specimens can provide rapid material–corrosivity evaluations. The helical coil adopted in the ISO 9226 methodology is a high surface area–weight ratio coupon that gives a higher sensitivity than panel coupons of the same material (Corrosion of metals and alloys–Corrosivity of atmospheres–Determination of corrosion rate of standard specimens for the evaluation of corrosivity, 1992). The use of bimetallic specimens in which a helical wire is wrapped around a coarsely threaded bolt can provide additional sensitivity and forms the basis of the CLIMAT coupon that was developed to classify industrial and marine atmospheres (Doyle and Wright, 1982).

An ASTM standard describes the construction of CLIMAT coupons. According to this standard, CLIMAT coupons can be made from 1100 aluminum (UNS A91100) wire wrapped around threaded rods of nylon, 1010 mild steel (UNS G10100 or G10080), and CA110 copper (UNS C11000) (Standard Practice for Conducting Wire-on-Bolt Test for Atmospheric Galvanic Corrosion, 1999). The mass loss of aluminum wire after 90 days of exposure is considered to be an indication of atmospheric corrosivity. However, the relative corrosivity of atmospheres could be quite different for the various combinations of materials.

The aluminum wire on copper bolts has been found by many to be the most sensitive of the three proposed arrangements in the ASTM standard. This was corroborated in a recent paper that clearly demonstrated the superior sensitivity of the Al–Cu arrangement for all types of simulated environments, as is shown in Table 33.9 (Calderon and Arroyave, 2005). While this arrangement is the most sensitive, the use of triplicate coupons on a single holder additionally provides an indication of the reproducibility of the measurements.

TABLE 33.9 Mass Loss of Aluminum Wire Exposed in Different Environments

Environment	Helical Coil	Mass Loss (%)		
		Al–Nylon	Al–Cu	Al–Fe
Rural	0.02		0.88	0.19
Urban	0.03	0.060	0.77	0.25
Marine	0.03	0.066	5.48	3.9
Marine–urban	0.03		4.29	2.83

Such a CLIMAT coupon with three copper rods installed at the NASA Kennedy Space Center (KSC) beach corrosion test site (Figure 33.80) is shown immediately after it had been installed (Figure 33.81a), after 30 days (Figure 33.81b), and after 60 days (Figure 33.81c). The KSC has the highest corrosivity of any test site in the continental United States (Coburn, 1978). The mass loss recorded after a shorter exposure than usual can be very high. In the present example, it was already 16% of the original aluminum wire after only 60 days.

The CLIMAT coupons sensitivity to atmospheric corrosivity can be used to study fluctuations on a microenvironmental scale (Klassen et al., 2002). In the following example, a supporting panel (Figure 33.82) was placed ~2 m above the ground on a pedestrian bridge concrete support ~4 m from a moderately trafficked highway during the winter months when deicing salts are used. Six sets of CLIMAT units were deployed on the panel with each set in a different microenvironment produced by various baffle

FIGURE 33.80 Aerial view of the NASA Kennedy Space Center beach corrosion test site where atmospheric corrosivity is the highest corrosivity of any test site in the continental United States. (Courtesy of NASA.)

geometries. The overall atmospheric conditions, for example, temperature and relative humidity, were therefore the same for each set except for the differences in the rate of aerosol deposition.

The average mass loss experienced by the CLIMATs exposed in different baffling geometries is also shown in Figure 33.82. One obvious conclusion from these measurements is that shielding, whether from wind or direct precipitation, can dramatically reduce the corrosion rate of components exposed to the same time-of-wetness factor. In fact, there was a 24-fold difference between the average mass loss in the boxed-in and boldly exposed coupons.

34.1 INTRODUCTION

A surface of a material is its interface between the bulk and the external phase, which can be solid, liquid, or gas, in contact with the bulk material. Surface engineering of materials is important for improving the properties of the surfaces for applications in diverse fields,

including mechanical, chemical, petrochemical, biomedical, electronic, power, automotive, construction, aerospace, missile, and many others covering almost all the fields of human activity (Stanley, 2005). As the demand for these engineered materials with improved surface properties is increasing, controlling and characterizing the surfaces is becoming increasingly important to ensure the designed performance of the components (Rok, 2009; Callister, 2006; Polak and Pande, 1999; Totten and Liang, 2004). There are several reasons for evaluation of the materials available, and some of them are listed below:

- to ensure that the material conforms to the specifications of the application it is used in;
- to investigate the development of material properties with processing and fabrication methods used;
- to monitor the performance of the material in different kinds of working environments in the intended application; thus, predicting the extent of damage (such as wear and corrosion).

Various standards are available for the measurement of surface properties of materials. The availability of these standards of measurement removes the ambiguities on the reliability of the obtained data. These standards specify measurement details, such as design specifications, apparatus used and calibration procedures for the same, test procedures, and range of data obtained and its reliability. Few standards organizations with interest in surface engineering include ASTM (American Society for Testing and Materials), SAE (Society of Automotive Engineers), ASME International (American Society of Mechanical Engineers), and ISO (International Organization for Standardization). In this chapter, an overview of the surface properties of materials and also the standard methods available for their measurement and characterization is presented. Various surface properties including, mechanical, physicochemical, topographic, and structural properties are discussed in detail. The combination of these characteristic properties can give an idea about the surface state of any particular material.

34.2 SURFACE PROPERTIES

34.2.1 Surface Finish or Surface Texture

The surfaces of most of the materials are not very smooth and have regular and irregular features, which tend to form a pattern or texture on the surface. These surface features are often formed during initial processing or in-service degradation. Surface finish is related with the geometric irregularities of the surfaces of the solid materials, and is defined in terms of roughness, waviness, lay, and flaws (Reidenbach et al., 1994). These basic components of surface texture are shown in Figure 34.1. Surface roughness is a measure of finer irregularities in the surface finish. Numerically, it is the average deviation of the surface valleys and peaks, expressed in micrometers (Blau, 1992). Surface waviness refers to the repeating irregularities on which the surface roughness is superimposed. These features tend to affect the performance of the engineered component in different ways, and hence should be measured and controlled for improved performance of the component. For example, the surface features significantly influence friction, lubrication, and wear characteristics of materials.

FIGURE 34.1 Basic components of surface texture.

In order to analyze the surface topography of a specimen effectively, the profile generated by the measuring instrument has to be evaluated according to the internationally accepted surface parameters. Each of these parameters characterizes a specific aspect of the surface. These parameters are categorized as follows:

- *Amplitude Parameters:* They are a measure of the vertical characteristics of the deviations on the surface.
- *Spacing Parameters:* They are a measure of the irregularities along the surface irrespective of their amplitude.
- *Hybrid Parameters:* They give us details of the combination of amplitude and spacing of the irregularities.

These surface roughness parameters along with their description and the mathematical formulae used for their calculations are presented in Table 34.1 (Reidenbach et al., 1994; Blau, 1992; Creath and Wyant, 1990; Bhushan, 2001; Takadoun, 2008).

The surface topography is commonly measured using contact-type or stylus-type surface profilometers (Blau, 1992; Creath and Wyant, 1990). A stylus profilometer consists of a diamond tip that acts as a mechanical stylus having radius of curvature ranging between 1 and 2 μm . The surface under observation is moved under the stylus orthogonally in micron steps. The vertical movements of the stylus along the surface allows for the topographic defects to be studied using a sensor that generates electrical signals, which are digitized and processed by the computer, giving the topographic measurement of the surface. The primary surface profile is then subjected to various filtering techniques that separate the roughness, waviness lay, and form features of the surfaces. These profilometers can also cover an area by multiple scans. These profilometers are available in various forms ranging from bench-mounted instruments to portable devices of smaller sizes, which are very convenient for in situ measurements of large components.

Also, there are noncontacting three-dimensional profilometers using optical systems for detection of surface heights. The measurement of the state of a surface by optical

TABLE 34.1 Surface Roughness Parameters and the Corresponding Formulae Used for Calculation (Reidenbach et al., 1994; Blau, 1992; Creath and Wyant, 1990; Bhushan, 2001; Takadoun, 2008)

Parameter	Description	Formula
R_a	Arithmetic average of absolute values	$R_a = \frac{1}{n} \sum_{i=1}^n y_i $
R_q, R_{RMS}	Root mean squared	$R_q = \sqrt{\frac{1}{n} \sum_{i=1}^n y_i^2 }$
R_v	Maximum valley depth	$R_v = \min_i y_i$
R_p	Maximum peak height	$R_p = \max_i y_i$
R_t	Maximum height of the profile	$R_t = R_p - R_v$
R_{sk}	Skewness	$R_{sk} = \frac{1}{nR_q^3} \sum_{i=1}^n y_i^3 $
R_{ku}	Kurtosis	$R_{ku} = \frac{1}{nR_q^4} \sum_{i=1}^n y_i^4 $
R_{zDIN}, R_{tm}	Average distance between the highest peak and lowest valley in each sampling length, ASME Y14.36M—1996 Surface Texture Symbols	$R_{zDIN} = \frac{1}{s} \sum_{i=1}^s R_{ti},$ where s is the number of sampling lengths, and R_{ti} is R_t for the i th sampling length
R_{zJIS}	Japanese Industrial Standard for R_z , based on the five highest peaks and lowest valleys over the entire sampling length	$R_{zJIS} = \frac{1}{5} \sum_{i=1}^5 R_{pi} - R_{vi},$ where R_{pi} and R_{vi} are the i th highest peak and lowest valley, respectively

method utilizes a laser or white beam to scan the surface. It is generally conducted using a confocal microscope or an interferometric microscope. These techniques provide very high resolution and rapid data acquisition making them particularly useful in microtopography. These noncontact techniques have become more popular in surface topography, in spite of being expensive, due to the ease of analysis and accuracy in the results obtained along with their ability to scan the surfaces without damaging them.

Other advanced equipments that give significantly improved performance particularly at finer length scales are very high resolution local probe microscopes, which include scanning tunneling microscope (STM) and atomic force microscope (AFM) (Creath and Wyant, 1990). These instruments use very short-range interactions between a fine probe and the sample surface, and hence yield very high resolution as compared to the previously described techniques. The resolution of the final image obtained depends on the size of the probe and the variation of probe-surface interaction with the distance to the surface. While STM is not suitable for nonconducting materials, AFM can be used for any kinds of surfaces to achieve atomic scale resolutions. The resolution of each type of instrument and their applications are tabulated in Table 34.2 (Creath and Wyant, 1990; Bhushan, 2001; Takadoun, 2008).

TABLE 34.2 Resolution and Applicability of Various Surface Roughness Measurement Instruments (Creath and Wyant, 1990; Bhushan, 2001; Takadom, 2008)

Technique	Information Obtained	Vertical Resolution, nm	Lateral Resolution	Types of Specimen
Stylus profilometry	Profilometry, topography, morphology, scar depth, wear volume	0.5	100 nm	Any flat specimen
Scanning tunneling microscopy (STM)	Topographical imaging, profilometry, compositional mapping, morphology, film thickness, spectroscopy, structure, defects	0.03–0.05	Atomic	Conductors
Atomic force microscopy (AFM)	Topographical imaging, friction force mapping, profilometry, morphology, film thickness, scar depth, wear volume, spectroscopy, structure, defects	0.03–0.05	Atomic to 1 nm	Any kind of specimen

34.3 MICROSTRUCTURAL ANALYSIS

Microstructure refers to the microscopic description of individual constituents present in a material. It involves description of composition, phases, crystal structures, crystal orientations, grain sizes, phase/grain size distributions, defects (dislocations, pores, cracks, inclusions), and so on. The microstructure influences the macroscopic behavior in terms of its physical properties, mechanical properties, tribological characteristics, corrosion properties, and so on. One can predict the performance and properties of a material for a given application from the microstructure of the material. Major determinants of the properties of a material come from the corresponding constituent chemical elements present and the processing method. It is very important to determine the structural elements and processing/microstructural defects, which influence the properties of a material.

For performing microscopic analysis, samples are generally prepared using standard metallographic techniques. The technique involves a series of steps such as grinding, polishing, and etching to reveal the microstructure of the sample surface. The sample can be analyzed using optical or electron microscopy after metallographic preparation. It is usually done using a light microscope to observe the morphology of the phases resulting from phase transformations such as solidification and heat treatment. Structural features investigated through the light microscope include surface morphology, size of the precipitates, compositional inhomogeneities, microporosity, corrosion, thickness, structure of surface coatings, and microstructure of defects. Electron microscopy is conducted using scanning electron microscope (SEM) and the transmission electron microscope (TEM) (Bozzola and Russell, 1999). SEM is carried out on the specimen surfaces and the TEM on the electron transparent thin foils made out of bulk specimens. The electron microscope offers a better depth of field and higher resolution than a light microscope. We generally use scanning electron microscope and transmission electron microscope, where the SEM images the surface of the material, while the TEM reveals internal structure (Bozzola and Russell, 1999; Zinkle et al., 2009; Voort, 2004). The only disadvantage of the electron

microscopes is that they operate under vacuum and they cost significantly more than the light microscopes, but the quality of the results obtained using them are unparalleled. The details about each of the microscopic techniques are included in the following section.

34.3.1 Optical Microscopy

Optical microscopy refers to the microscopic inspection of the sample at lower magnification using an instrument known as an optical or light microscope. The specimen is polished carefully using the traditional polishing techniques and is placed perpendicular to the axis of the objective lens for inspection by optical microscopy. Light rays are focused on the sample that reflects some of the rays back to the lens. The image of the sample positioned can thus be observed. The image seen in the microscope not only depends on how the specimen is illuminated and positioned but also depends on the characteristics of the specimen. This image can be captured digitally to generate a micrograph. We can observe the microstructural features such as coating integrity, porosity, voids, oxide layer at different magnifications depending on the capability of the instrument.

34.3.2 Scanning Electron Microscopy

The electron microscopes use a high energy beam of electrons to form an image by illuminating the specimen under high vacuum. To control the electron beam, the electron microscope uses electrostatic and electromagnetic lenses, which aid in focusing the beam to form an image. A schematic view of different components of an SEM and their typical functions is shown in Figure 34.2. SEM is one of the most important characterization

FIGURE 34.2 Schematic representation of an SEM (Bozzola and Russell, 1999).

tools in metallurgy. It is useful in obtaining high resolution images, which are essential for microstructural study of any specimen. Scanning electron microscopy is different from optical microscopy in the way the image is obtained. It creates image by focusing high energy electrons and detecting signals from the interaction of the electrons with the specimen's surface. The signals can be secondary electrons, characteristic x-rays or backscattered electrons. Using an SEM has the advantages of producing images of high resolution and large depth of field. With an SEM, we can produce images of very high magnification up to $50,000\times$ very quickly and easily, which is not possible with a light microscope. SEM has got the added advantages of good compositional contrast and relative ease of affordability not only in terms of the cost but also in terms of reliability and the throughput. Another aspect to be remembered is that the sample has to be conductive in order to dissipate the charge during SEM. Therefore nonconductive surfaces have to be gold or carbon coated to make them conductive so that no charging occurs. Major limitation of SEM is the use of a very high vacuum, which restricts what we can look at. SEM is widely used by biologists, materials, and mineral scientists for microstructural analysis.

34.3.3 Transmission Electron Microscopy

In transmission electron microscopy (TEM), image is formed by a beam of electrons passing through an ultra-thin specimen. TEM allows analysis of the microstructure with atomic scale resolution. The TEM can be divided into three sections: illumination system, specimen stage, and imaging system. The illumination system consists of the electron gun with a set of two or more condenser lens. A schematic representation of different components of TEM and their functions is shown in Figure 34.3. The electron gun generates electrons by thermionic or field emission effects, which are focused on to the sample using the condenser lens. The condenser lens system should consist of at least two electron lenses. The first condenser lens, which is a strong magnetic lens, uses the electron source as object and produces a real image of different sizes depending upon the lens current thereby determining the spot size. The second condenser lens, which is a weak magnetic lens, offers low magnification or no magnification but controls the brightness or the intensity of the beam, directs the beam through a condenser aperture. It restricts the high angle electrons and dismisses any aberration. The condenser lens system also consists of a condenser aperture and condenser stigmator to correct for any astigmatism resulting from the two-condenser lens. The beam then strikes the sample and transmits through it, based on the thickness of the sample. TEM samples are generally made circular with a diameter of 3 mm, and it must be made sure that the specimens are thin enough to transmit the electrons through them to form the magnified image. The imaging system consists of an objective lens, objective aperture, selected area aperture, projector lens, TEM screen, and camera. Objective lens focuses the transmitted beam into an image, whereas the high angle beam is restricted by the objective aperture and selected area aperture. The function of the intermediate lens is to change the image magnification and form diffraction patterns on whole of the TEM viewing whereas the purpose of projector lens is to form an image or diffraction pattern across the TEM screen. The image then hits the phosphor image screen that converts the electron image into a visible form.

Using TEM, one can obtain very fine (as small as single atoms) internal microstructural details of the specimen. Magnifications of the order of $1,000,000\times$ can be obtained very easily using transmission electron microscopy. This technique is widely used to analyze finer details in a range of scientific fields including physical and

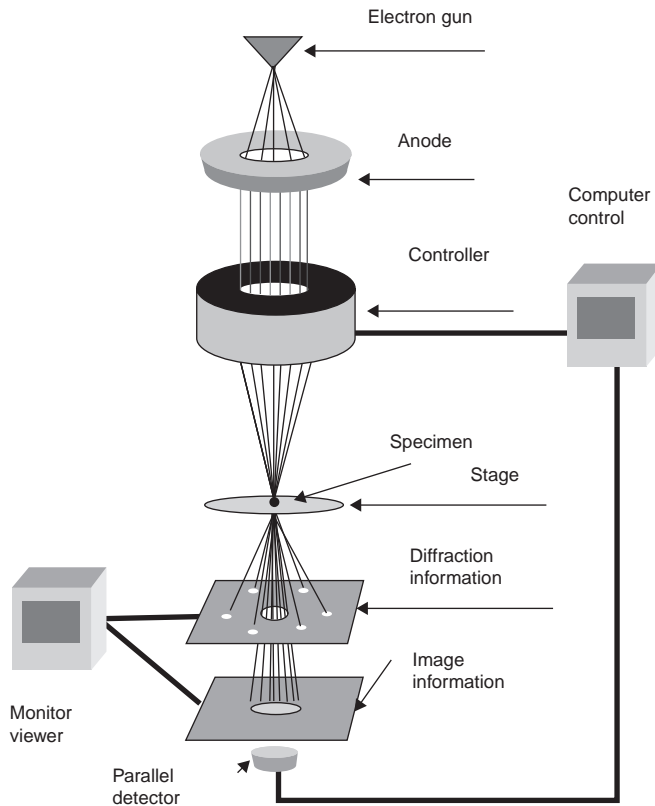

FIGURE 34.3 Schematic representation of a transmission electron microscope (Zinkle et al., 2009).

biological sciences. It finds applications in cancer research, virology, examination of biological specimens, materials science, and semiconductor research. In spite of the advantages, TEM has a number of drawbacks in many concerns. The sample preparation procedure involved is very tedious, extensive, and has to be done very carefully. The sample preparation procedure can also result in a change in the structure. Another limitation is that the field of view of the specimen being very small, it might not represent the properties of the whole surface. There is also a possibility of damage of the sample by the electron beam, especially in the case of biological materials. Regarding the economy point of view, TEM is expensive when compared to other microscopes.

34.4 COMPOSITIONAL ANALYSIS

The chemical composition of surfaces plays a significant role in determining the material properties. Using advanced tools, we can determine the chemical, elemental, and molecular composition of material giving us an idea of the composition of few outer layers of the surfaces under observation. Such an analysis is very important as the properties of surfaces on the outer layers control their electrical, chemical, or mechanical properties. The surface compositional analysis can be done by bombarding a material with ions,

electrons, x-rays, or photons (Voort, 2004). For this analysis, one can use numerous techniques such as x-ray photoelectron spectroscopy, auger electron spectroscopy, and many others for a wide range of materials including photovoltaics, microelectronics, polymers, biological specimens, and many others (Creath and Wyant, 1990).

34.4.1 Energy Dispersive x-ray Analysis

Energy dispersive x-ray spectroscopy technique is used in conjunction with scanning electron microscope to analyze the elemental composition of a specimen. This technique makes use of the x-rays, which are emitted from the sample in response to the bombardment of the electron beam, to characterize the chemical composition of the region of specimen under observation. The microscopic features or phases as small as 1 μm present in the sample can be analyzed using this technique. In this technique, a high energy electron beam is focused onto the region of the specimen to be studied. This beam of charged particles excites the atoms on the surface resulting in release of energy in the form of x-rays. X-ray detector of the EDS measures the number and energy of the x-rays emitted from the specimen. The energy of the x-ray is a characteristic of the element from which it is emitted and hence, helps us in identifying the element associated. The number of x-rays of each characteristic radiation and their relative counts are recorded in the form of a spectrum. This spectrum helps us in determination of the relative amounts of each element present both qualitatively and quantitatively within the analyzed region. This technique facilitates qualitative elemental analysis with sensitivity down to a few atomic percent. Major limitation of this method is that low atomic number elements are detected only by some systems equipped with special detectors.

34.4.2 X-ray Photoelectron Spectroscopy

X-ray photoelectron spectroscopy, also called electron spectroscopy for chemical analysis, is a qualitative spectroscopic technique that involves bombardment of the specimen surface with x-rays and the consequent measurement of photoemitted electrons. These photoemitted electrons have different kinetic energies characteristic of the emitting atoms and their bonding states. XPS measures elemental composition, empirical formula, chemical state, and electronic state of the elements existing in the material. It requires ultra high vacuum conditions for the analysis. It can be used to analyze the surface of few millimeter thicknesses to a depth of 1–10 nm. This technique can detect elements with atomic number greater than 2 (lithium and above). It is generally used to analyze inorganic compounds, metallic alloys, semiconductors, polymers, ceramics, elements, catalysts, paints, glasses, plant parts, medical implants, and many others. Hence, analysis of corrosion layers and oxide films can be done to determine the nature of chemical bonds of the main elements and impurities.

34.4.3 Auger Electron Spectroscopy

Auger electron spectroscopy is one of the widely used techniques for obtaining the chemical composition of solid surfaces. This is a surface specific technique and utilizes the emission of low energy electrons in the auger process to determine the composition of surface layers of a sample. Three steps involved in the characterization are atomic ionization, electron emission, and analysis of the emitted auger electrons. The surface is

bombarded with a focused beam of electrons generating auger electrons that are collected and measured. These auger electrons have discrete kinetic energies that are characteristic of the emitting atoms making this technique widely useful for finding elemental composition. The main advantages of this method include high sensitivity for chemical analysis (in the range of 5–20 Å), rapid data acquisition speed, ability to detect all the elements above helium, and its capability of high spatial resolution. Hence, it can be used to analyze adsorbed layers, thermal or anodic oxide films, thin deposits and segregated layers on surfaces within grain boundaries.

34.5 PHASE ANALYSIS

34.5.1 X-ray Diffraction

X-ray diffraction (XRD) is one of the widely used analytical techniques for identification of phases in a crystalline material and also amorphous phases. It can also be used to determine the size of the unit cell and fractional coordinates of atoms within the unit cell along with other structural information such as degree of crystallinity, preferred orientation, mechanical stresses, lattice strains, and stacking faults. It is possible to characterize the phases qualitatively as well as quantitatively using this technique (Cullity, 1978; Krawitz, 2001; Crankovic, 1986).

X-ray diffraction is a most common technique for the study of crystal structure and atomic spacing associated with the material. It is based on principle of constructive interference of monochromatic x-rays on a crystalline sample (Cullity, 1978). For analysis using this technique, x-rays are produced in a cathode ray tube. First, the filament is heated to produce electrons, which are accelerated onto a target by application of voltage and then bombarded. When these electrons have sufficient energy to displace electrons in the inner shells of the target material, characteristic x-rays are produced. Copper is most common target material used for single-crystal diffraction, with CuK_α radiation = 1.5418 Å. The x-rays, thus produced, are filtered to produce monochromatic radiation, collimated and then directed toward the sample. Testing is carried out by recording the intensity of the reflected x-rays on rotating both the sample and the detector. These incident x-rays interact with the sample surface and once they satisfy Bragg's law, constructive interference occurs resulting diffracted rays, and hence, a sharp peak that can be used for identification of the phase present. Bragg's law ($n\lambda = 2d \sin\theta$) gives the relationship between the peak position (2θ), interplanar spacing (d), and wavelength of the electromagnetic radiation (λ). The diffracted rays satisfying Bragg's law are recorded by a detector and are then converted into count rate, which is then output to a device. The diffractometer design is such that when the sample rotates in the path of the x-ray beam at an angle θ , the x-ray detector, which is mounted on an arm to collect diffracted x-rays, rotates an angle of 2θ . The sample and detector are rotated over a range of 2θ angles to obtain diffracted rays in all possible directions. Schematic of a typical diffractometer is shown in Figure 34.4. The diffraction peaks obtained are converted into d-spacings for identification of the mineral/phase. Each mineral has a set of unique d-spacings, and hence, phase identification and analysis of the sample can be done based on the characteristic radiation emitted.

X-ray diffraction is a most widely used nondestructive technique for identification of unknown crystalline materials (Krawitz, 2001). It finds applications for identification

FIGURE 34.4 Schematic diagram of x-ray diffractometer (Cullity, 1978).

of unknown phases in various research areas including geology, engineering, biology, environmental science, and biology. Other applications of this technique include identification of fine-grained materials such as clays, characterization of crystalline materials, unit cell dimension determination, and assessing the sample purity. In combination with specialized techniques, this technique can be used for determination of crystal structures by Rietveld refinement, thin film characterization, texture analysis, and determination of modal amounts of minerals. There is no complex sample preparation procedure involved, and the data obtained can be interpreted with relative ease. There are few limitations due to the manner in which the testing is carried out. If any particular phase is present in minor percentages (below 5%), it may not be detected during the analysis, and it is difficult to differentiate mixture of phases with low symmetry due to large number of diffraction peaks. Although it has few limitations, XRD is a very easy and straightforward method to identify unknown minerals.

34.6 MECHANICAL TESTING

34.6.1 Hardness Testing

The ASM Metals Handbook defines hardness as “*Resistance of metal to plastic deformation*,” usually by indentation (Crankovic, 1986). However, it may also refer to stiffness or resistance of any material to scratch, abrasion, or cutting. For a metal, it may be defined as the ability to resist permanent deformation on application of load. Hence, a metal having higher hardness has greater resistance to deformation.

Hardness measurement can be done on different scales including *macro*-, *micro*-, or *nano-scale* depending on the forces on indenters and depth of indentations. In a metals industry, three types of tests generally carried out for hardness measurement are Brinell hardness test, Rockwell hardness test, and Vickers hardness test (Chandler, 1999). These tests determine the depth to which the ball or cone indenter sinks into the metal at any

given load in a specific period of time, and hence, estimate the materials resistance to deformation. Some of the most common and widely used hardness testing methods in today's industries are explained in the following sections.

34.6.1.1 Rockwell Hardness Test One of the most widely accepted and used hardness test method for bulk materials is the Rockwell hardness test. This is due to its ease, minimum chances of personal error, speed, smaller indentation size, and ability to distinguish small differences in hardness values. It uses the depth of penetration of the indenter at constant load as a measure of hardness.

In this method, a minor load of 10 kg is applied initially in order to seat the specimen followed by the application of major load (60, 100, and 150 kg are used depending on the material). The depth of indentation is recorded automatically in terms of arbitrary hardness numbers. Rockwell hardness testers use various indenters for different scales, and the major loads are applied accordingly. This implies that the Rockwell hardness depends on the load applied and the indenter used, and hence, one must specify the hardness by prefixing the hardness number with a letter indicating the hardness scale employed for testing. Many scales are available in this method, which serves special purposes. An improvement on Rockwell hardness test is the Rockwell superficial hardness test where the preliminary minor load is 3 kgf, and the major loads are 15, 35, and 40 kgf. Different scales are also available in Rockwell superficial hardness test for different purposes.

34.6.1.2 Microhardness Test Microhardness usually refers to the hardness obtained when the load applied does not exceed 1 kgf. The indenter used for microhardness is either Vickers diamond pyramid or Knoop elongated diamond pyramid. The surface to be tested is generally polished using metallographic techniques for precise measurement. The test procedure is similar to the standard Vickers hardness test, and precision microscopes having a magnification of around $500\times$ are used to measure the indentation size. The indentation size can be measured to an accuracy of $\pm 0.5\text{ }\mu\text{m}$ using these microscopes. It should be noted that care should be taken while measuring the size of the indentation to ensure accurate results.

The Knoop hardness number, KHN is mathematically the ratio of the load applied, P (kgf), to the unrecovered projected area, A (mm^2)

$$\text{KHN} = \frac{F}{A} = \frac{P}{CL^2} \quad (34.1)$$

where F is the applied load (kgf), A the unrecovered projected area of the indentation (mm^2), L the measured length of long diagonal of indentation (mm), and $C = 0.07028$ the indenter constant that relates projected area of the indentation to the square of the length of the long diagonal. The Knoop indenter is a rectangular diamond pyramid that produces an indentation having its long and short diagonals in the ratio of 7:1. The depth of a Knoop indentation is about 1/30 of the length of long diagonal.

The Vickers hardness number VPN or HV is given by the applied load (kgf) divided by the surface area of the indentation (mm^2)

$$\text{HV} = \frac{2F \sin(136/2)}{d^2}; \quad \text{HV} = 1.854 \frac{F}{d^2} \quad (34.2)$$

where F is the applied load (kgf), d the arithmetic mean of the two diagonals, d_1 and d_2 in mm, and HV the Vickers hardness. The Vickers diamond pyramid indenter is a square pyramid with an angle of 136° between its faces. The depth of indentation is about 1/7 of the length of diagonal.

34.6.1.3 Nanoindentation Indentation tests are the most commonly applied methods of testing of mechanical properties of advanced materials with microstructural features at much finer (nano/micro) scale. In this context, the term nanoindentation implies the continuous recording of the penetration of the indenter (penetration depth) and the corresponding load, as well as other variables (such as time, frictional force), rather than single-valued measurements of contact area (as in microindentation testing).

Nanoindentation using continuous depth recording (CDR) instruments has both advantages and disadvantages (Fischer, 2004). The advantage of CDR includes a high level of precision, ease of digitization, automation, and data processing. It is ideal for the measurement of creep as well as of plastic and elastic work. Furthermore, each test normally gives a complete loading/unloading cycle, rather than a single reading. As a sole method of measuring indent size, its disadvantage is the need for simplifying assumptions in order to

- separate plastic from elastic effects;
- determine the true zero of the depth measurements;
- allow for the piling-up or sinking-in of material around the indent;
- allow for geometric imperfection of the indenter when deriving absolute hardness values.

In addition to the above applications, the extremely small force and displacement resolutions (as low as 1 nN and 0.2 nm), which can be obtained in this technique combined with large range of applied forces, make this method useful for characterization of all types of material systems. It offers precise control over the data acquisition and sensitivity, which can be used to study the mechanisms of mechanical behavior of materials at submicron length scales. Nanoindentation finds numerous applications in study of dislocation behavior in metals, thin film characterization, fracture behavior of ceramics, residual stress analysis, and time-dependent behavior of polymers and soft metals. It is also an important tool for characterizing tribological behavior of materials including scratch resistance and wear resistance of coatings and bulk materials at nano-scale.

Load Versus Displacement Curve A typical load versus displacement curve obtained from recorded nanoindentation data is shown in Figure 34.5. The loading curve presents a typical parabolic behavior, which is associated with elastic-plastic deformations during the loading. The maximum tip penetration h_{\max} , the contact depth h_c , the residual penetration after unloading h_p , and the measured stiffness S are indicated in Figure 34.5. The elastic recovery after the unloading corresponds to the difference ($h_{\max} - h_p$). The form of these curves, including small changes in the increasing depth rate or in the elastic recovery under unloading, can give information about the surface response to the applied load, and consequently about the mechanical properties at the surface. These curves can be used to extract mechanical properties of the material such as hardness, modulus of elasticity, strain rate sensitivity, and activation volume (Fischer, 2004; Bhushan, 2007; Bhushan, 2000; Li and Bhushan, 2002). Hardness and young's modulus are obtained from this curve using Oliver and Pharr method and the set of formulae for analysis of rigid materials are listed below (for Berkovich indenter) (Fischer, 2004).

FIGURE 34.5 Schematic illustration of indentation load–displacement data showing important measured parameters (Fischer, 2004).

Reduced modulus

$$\frac{1}{E^*} = \frac{1 - \nu^2}{E} + \frac{1 - \nu'^2}{E'} \quad (34.3)$$

where E^* is the reduced elastic modulus, E is the modulus of the indented specimen, E' is the modulus of the indenter, ν is the Poisson's ratio of the specimen, and ν' is the Poisson's ratio of the indenter.

Contact area (for Berkovich indenter)

$$A = 3\sqrt{3}h_p^2 \tan^2 65.3 = 24.5 h_p^2 \quad (34.4)$$

where A is the contact surface area and h_p is the contact depth.

Hardness

$$H = \frac{P}{24.5 h_p^2} \quad (34.5)$$

where H is the hardness of the specimen and P is the load.

Elastic modulus

$$E^* = \frac{dP}{dh} \frac{1}{2h_p} \frac{1}{\beta} \sqrt{\frac{\pi}{24.5}} \quad (34.6)$$

where dP/dh is the slope of load-displacement curve (called stiffness), and β is a geometrical constant ($\beta = 1.034$ for Berkovich indenter).

Depth and Load-Sensing Equipment The equipment (shown in Figure 34.6) consists of a system of a vertical axis supported by springs to a cell. The indenter is at the end of the axis. The system is composed of a force actuator and a sensor of depth that is generally a

FIGURE 34.6 Illustrative showing different components of a nanoindenter (Bhushan, 2000).

capacitance displacement gauge. The force actuator is capable of applying forces as low as $1\ \mu\text{N}$, and the displacement gauge sensor can give a depth better than $0.1\ \text{nm}$. The maximum load used in this kind of equipment is about $500\ \text{mN}$. On the other hand, if better displacement and load resolutions are necessary, the maximum load is generally lower and depth resolution is increased for shallow penetration. The schematic of sample surface during and after the indentation, showing the parameters definition used in the equation, is as shown in Figure 34.7.

Errors and Limitations The correct measurement of mechanical properties from load and depth-sensing indentation depends on the minimization of errors and comprehension of the methods limitations. However, even in case of a well-calibrated machine, good results are not obtained if the sample presents a high surface roughness. Another problem appears when the material presents pileup at indentation. The pileup at the sides of indentation increases the contact area when the Oliver and Pharr method is used. Then the calculated values of hardness and elastic modulus are lower than the actual values. The errors and limitations in the load and depth-sensing equipment can be divided into three major groups: calibration of equipment and determination of contact surface, calibration of area function for the indenter, and sample effects such as roughness and pileup. Proper understanding of the reasons as to why these errors occur, and the means to minimize or account for these errors is very important to obtain accurate results by nanoindentation.

FIGURE 34.7 Schematic illustration of the unloading process during nanoindentation (Li and Bhushan, 2002).

Applications Load and depth-sensing indentation are applied to practically every kind of solid material. Some of the major applications of the nanoindentation technique include (Kuhn and Medlin, 2000)

- (i) determination of the hardness and elastic modulus of deposited thin films and coatings, principally metallic thin films and diamond-like carbon films;
- (ii) determination of mechanical properties of irradiated materials including ionic irradiated surfaces and plasma-based ion implantation; and
- (iii) study of mechanical properties of brittle materials, such as hardness, elastic modulus, toughness, and adhesion properties.

There are certain new areas where the depth and load-sensing indentation is being applied such as determination of plasticity at low dimensions, mechanical properties of nanostructured materials, stress-strain simulation and residual stress determination, viscoelastic properties of polymers, and the creep and strain rate effect on the deformation of materials at low temperature. In these cases, nonberkovich indenters may also be used to characterize mechanical properties other than hardness and elastic modulus.

34.6.2 Fracture Toughness

Fracture toughness is defined as a property that describes the ability of a material containing crack to resist failure. It is one of the most important factors for design considerations of any material (Kuhn and Medlin, 2000). Fracture toughness is denoted as K_c and has the units of $\text{MPa}\sqrt{\text{m}}$ (SI units). It is given by

$$K_c = Y \times \sigma_c \times \sqrt{\pi a} \quad (34.7)$$

where Y is a dimensionless parameter which depends on both crack and specimen sizes and geometries, σ_c is the critical stress for crack propagation (in MPa), and a is the half-crack length (in m). Thus, fracture toughness gives us an idea about the amount of stress required to propagate a preexisting flaw, and in turn, its damage tolerance during service. This is a very important property as there is always a possibility of occurrence of flaws during processing, fabrication or service of a component in the form of cracks, voids, inclusions, and surface defects. These flaws will lead to local concentration of stresses at the tip following which crack growth occurs. The crack propagation can be either unstable or stable, which decides the type of fracture in the specimen. The unstable crack propagation is generally associated with brittle fracture occurring at a well-defined point and can be characterized by a single value of fracture parameter. The stable crack propagation occurs in case of ductile fracture where fracture is an ongoing process and cannot be described by a single point. In case of brittle fractures, this growth will be rapid if the crack tip stresses exceed a critical value leading to failure. The fracture toughness depends on a number of factors such as temperature, environment, loading rate, material composition, microstructure of the material, specimen sizes, and geometries. Although fracture toughness can be obtained from literature, it is preferred to determine the same experimentally for any particular material or joint being designed.

Various measures of toughness are available. Impact toughness, which is widely used method, correlates the energy absorbed during fracture process of with toughness. The

FIGURE 34.8 Figure showing three modes of fracture (Kuhn and Medlin, 2000).

major drawback with this approach is that there is a large degree of uncertainty associated with this kind of empirical correlations. So, it is preferable to determine this property in terms of stress intensity factor (K_C) with the help of different techniques and approaches available. Fracture mechanics approach is widely used for its characterization and is classified into linear-elastic and nonlinear-fracture toughness testing methods (Kuhn and Medlin, 2000; Pabst et al., 1982).

Linear-elastic fracture mechanics approach is commonly used for evaluating the ability of component containing flaw to resist fracture (for design considerations). This approach uses the flaw size, features, geometry of the component and material properties for assessing the same. In general, for brittle materials, the fracture can occur in one of the three modes shown in Figure 34.8, and a roman numeral subscript is used to indicate the mode of fracture. Depending on the mode of fracture, the stress intensity factor is calculated using the corresponding equations taking into consideration the loading, crack size and structural geometry. The thickness of the specimen plays an important role in determination of K_C as the stress states adjacent to flaw changes with the thickness until it exceeds the critical dimension. For thin specimens, the value of K_C is dependent on its thickness, whereas for thicker ones (where specimen thickness is greater than crack dimensions), K_C becomes independent of thickness. This value of K_C is a true material property called plane-strain fracture toughness.

34.6.2.1 Plane-Strain Fracture Toughness Common configurations for the determination of plane-strain fracture toughness are single edge notch bend (SENB or three point bend), and the compact tension (CT) tests. For accurate analysis, thickness of the specimen must exceed the critical thickness (B). It has been proven experimentally that plane-strain conditions prevail when

$$B \geq 2.5 \left(\frac{K_{IC}}{\sigma_y} \right)^2 \quad (34.8)$$

where B is the minimum thickness required to produce a condition where plastic strain energy at the crack tip is minimal, K_{IC} is the fracture toughness of the material, and σ_y is the yield stress of the material. These K_{IC} values can be used to determine the crack length at any given design stress applied to a component using equation:

$$a_c = \frac{1}{\pi(K_{IC}/\sigma_y)^2} \quad (34.9)$$

It can also be used to estimate the critical stress value when a crack of given dimensions is found in a component.

$$\sigma_c \leq \frac{K_{IC}}{Y\sqrt{\pi a}} \quad (34.10)$$

Even though this is a standard procedure adopted for K_{IC} testing of metals, it does not hold good for ceramics as the introduction of precrack in the specimen affects the fracture toughness value considerably leading to erroneous measurement of values. The width of the notch should not exceed $100\ \mu\text{m}$ in order to obtain reliable values of K_{IC} . Also, the notch root has to be sharpened to a radius of less than $10\ \mu\text{m}$ to ensure a reliable toughness measurement. Thus, the sample preparation should be done very carefully to get accurate values of fracture toughness. These limitations led the investigators to find a less labor-intensive technique for quantification of this property, leading to the development of indentation fracture toughness measurement technique.

34.6.2.2 Indentation Fracture Toughness Fracture toughness can also be determined using the Vickers indentation technique in a much simpler and relatively accurate manner. Due to their efficiency, indentation techniques became very popular for toughness measurement of brittle substances (especially ceramics) (Lawn and Marshall, 1979; Anstis et al., 1981;; Strecker et al., 2005). The sample is indented using a Vickers hardness tester at a higher loads leading to the initiation of cracks from the four corners of the impression. Figure 34.9 shows the shape of an impression that is generally obtained on a brittle material. The K_C ($\text{MPa}\sqrt{\text{m}}$) is given by

$$K_C = 0.016 \left(\frac{E}{H} \right)^{1/2} \frac{F}{c^{3/2}} \quad (34.11)$$

where F is the applied load, E is the elastic modulus, H is the Vickers hardness, and c is the length of radial crack emanating from indentation corner. Even though the technique is

FIGURE 34.9 Fracture toughness measurement by Vickers indentation (Strecker et al., 2005).

easier, considerable care should be taken while measuring the length of the cracks as both equipment error and parallax error can cause considerable uncertainty in the calculated value. These tests are also prone to errors due to inhomogeneities in the material. In order to account for these errors, tests must be carried out repeatedly over a range of loads.

34.6.3 Tribological Properties

Tribology is the science of interacting surfaces in relative motion with each other, which includes the study and application of principles of friction, wear, and lubrication. It is a multidisciplinary field of research aimed at reducing material wear and hence increasing the life time and reliability of mechanical systems and also controlling friction in the same. Wear being one of the main reasons for the failure of the many components, it is very important to have a good understanding of the mechanisms of wear. Wear is defined as a progressive damage or loss of material of a surface caused by relative motion with respect to another surface (Chattopadhyay, 2001). Wear is generally classified into various ways. Based on the appearance of wear scar, damage surface can be considered such as pitted, spalled, scratched, polished, crazed, fretted, and scuffed. The wear can be adhesive, abrasive, or oxidative wear based on physical mechanisms of damage. The wear can be classified based on the conditions surrounding the wear situation such as presence of lubrication, rolling, high temperature, and stress sliding. These classifications are very useful to engineers in predicting different wear situations in different ways. The first way of classification based on appearance helps engineers in recognizing the changes in wear situations at different locations. Hence, one can adopt the corresponding measures of controlling it and thus enhancing the life of the component. The second way of classification based on the physical mechanism is very useful to the engineers in identifying the right mechanism of wear and predicting the wear loss. This approach also helps engineers in identifying the design parameters to be controlled or modified in order to improve the components service life. The third classification is useful from component designer point of view. The description of the wear situations helps the engineers to identify specific set of design rules, equations, and recommendations to be used. While each classification can be correlated with the other, the inter-relationships are not simple, direct, and complete. Due to the complex nature of the wear behavior, it is difficult to establish complete relations between operating conditions, wear mechanisms, and appearance.

The main objective behind performing a wear test is to trace the data that can be applied for a particular application in order to increase its life and reduce cost and maintenance for reliable performance of the particular component. As mentioned before, the nature of wear being complex there is no single, unique parameter to characterize wear behavior of any particular material. This complex nature of wear results in a need to carry out a variety of wear tests each addressing a particular aspect of wear situations. Wear tests are available for assessing the material behavior to different environments and working conditions (Chattopadhyay, 2001; Bayer, 2004; Ludema, 1996; Stachowiak, 2005; Becker and Shipley, 2002; Rabinowicz, 1995). Several standards are available which describe the apparatus, parameters to be varied and sample preparation for each of the tests as detailed in the following section.

34.6.3.1 Dry Sand–Rubber Wheel Abrasion Test This test is developed to predict the wear behavior in situations where low-stress scratching abrasion is the primary mode of wear. In this mode of wear, loose abrasive grains are dragged across a surface under

loading conditions which do not induce fracture of abrasive particles. This test is used to investigate the influence of various parameters such as abrasive particle size, shape, and material parameters on the wear behavior of the component. In this test, a stream of free-falling abrasives between wear specimen and a rotating rubber-coated wheel is trapped. The weight or volume loss in a substance in a very controlled environment is then recorded. This type of testing can be used to assess the scratching abrasion resistance of the material. A standard version of this test was developed by ASTM (ASTM G65), which describes main considerations for the design of apparatus and method of testing in detail.

34.6.3.2 Wet Sand–Rubber Wheel Abrasion Test This test is very much similar to the dry sand–rubber wheel test and also gives us the resistance to low stress scratching abrasion. The basic test concept is same in both the tests, but in the wet test the abrasive is in the form of water slurry. The wear is determined by weight or volume loss similar to that in dry sand–rubber wheel test. Both the tests are used extensively to investigate the scratching abrasion and have been found to correlate well with practical applications. A standard version for materials comparison with dry sand test has been developed by ASTM (ASTM G105). This kind of testing offers an advantage that the procedure can be modified to utilize slurry, which is more representative of the application. Hence, chemical effects associated with the application can be investigated.

34.6.3.3 Erosion by Solid Particle Impingement Using Gas Jets This test method helps the user in investigating the erosion behavior of materials based on the factors affecting it during its service. Gas jets are used to predict the solid particle erosion. It involves the determination of material loss by erosion with jet nozzle type erosion equipment. The conditions and procedures to be followed for this test are outlined in ASTM G76. In actual service, erosion involves particle sizes, velocities, attack angles, environments, and many other factors, which will vary over a wide range. Hence, any single test in one set of conditions might not be sufficient to predict the service life and performance of the component. The investigators should determine carefully the correlation of the results of this test for field performance or consider results from other methods and integrate them to estimate the wear life.

34.6.3.4 Block-on-Ring Wear Test Using Wear Volume It is one of the most commonly used tests for the determination of sliding wear of materials using block-on-ring geometry under different conditions. In this method, a stationary block specimen is pressed with a constant force against a rotating ring specimen at 90° to the axis of rotation of the ring. The resulting friction between the sliding surfaces (i.e., the block and ring) leads to material loss from both the specimens, and this material loss is used for wear analysis. Although both block and ring exhibit wear in this test, it is primarily used to study the wear of block material, in terms of its weight loss and hence wear volume. ASTM G77 describes the procedure to be adopted for this type of test explaining all different conditions. This method can be used for a wide range of materials making it a very flexible test. The test can be carried out using different gaseous atmospheres, lubricants, liquids, or gaseous temperatures in order to get conditions similar to actual service conditions. Rotational speed and load can also be varied to make the service conditions more similar to any particular application. In spite of its flexibility, the method has few disadvantages. As the block experiences more rubbing than the ring, the test is limited in terms of its ability to investigate the relative amount of wear between pairs of materials. Extensive data should

be collected in order to ensure the repeatability of the test. The correlation between the testing conditions and the service conditions varies with change in the test parameters.

34.6.3.5 Pin-on-Disc Wear Test This is also a commonly used test to study and assess the wear behavior of materials. It is a general test that evaluates the sliding wear of pairs of materials. It utilizes a radius-tipped or flat-ended pin to press against a flat rotating disc (specimen to be tested). The relative motion between two bodies results in material loss and thus gives an idea of its sliding wear behavior. The parameters that can be varied in these tests include size and shape of the pin, load, sliding speed, and material pairs. Also, the test can be done in controlled atmosphere and with lubrication. ASTM G99 outlines the standard procedure for this test.

34.6.3.6 Rolling Wear Test This test is used to address the rolling wear. It consists of a pair of driven rollers pressed against one another. The test is carried out by visually monitoring the damage or other condition of the roller surfaces after certain specified time of test duration. The number of cycles for the selected level of damage, which can be judged by the appearance of cracks, surface texture change or spalls, is thus obtained. The longer the test and higher the number of cycles, the greater is its resistance to rolling wear making the tests relatively longer. The main factors for this test are the surface velocities of the rollers, alignment of rollers, and geometrical tolerance of the rollers. This method is mainly used for evaluation of material pairs for rolling applications such as gears, cams, roller bearings, and ball bearings. One main limitation of this test is that the stress levels must remain in the range of the application and also in the elastic range. If plastic deformation occurs, the test becomes invalid. Hence, few materials such as thermoplastics cannot be tested using this method.

34.7 CORROSION PROPERTIES

Corrosion is defined as chemical or electrochemical reaction between a material and its surroundings that leads to deterioration of both the material and its properties at the surface level (Bardal, 2004). Most of the materials undergo some kind of interaction at least to some extent with the environment. The mechanism by which materials deteriorate when attacked by the surrounding is different for different classes of materials (namely, metals, ceramics, and polymers). In metals, it proceeds through material loss by either dissolution or formation of a nonmetallic layer or film (oxidation). Ceramics are resistant to corrosion, but they are also affected at elevated temperatures or adverse environments. In case of polymers, it is more frequently termed as degradation. Polymer can degrade when it absorbs a liquid solvent and swells on exposure.

Corrosive environments include the atmosphere, soils, acids, aqueous solutions, bases, inorganic solvents, salts, liquid metals, and many others. The problem of metallic corrosion is very common and most significant among the three classes of materials in the environments mentioned earlier. Corrosion mechanisms are classified into eight forms namely uniform, galvanic, crevice, pitting, intergranular, selective leaching, erosion-corrosion, and stress corrosion. The problems posed by these forms of corrosion adversely affect the maintenance of critical components. Thus, corrosion is a very important consideration for selection of a material for any application and finds relevance in all fields. For any component to serve the intended purpose at an acceptable level of efficiency, it has to

be properly designed taking into consideration all the factors including properties, performance, life, production, and maintenance cost. The severity of environments encountered by each material is one of the deciding factors for the choice of the material. Corrosion prevention is achieved mainly by careful material selection, environmental alteration, design, application of coatings or films to improve corrosion resistance, and cathodic protection. Some of the methods of corrosion measurement are briefly discussed in the following sections (Bardal, 2004; Shreir, 1963; Bernard and Cramer, 2003; Kruger, 2001; Romaniv et al., 1989).

Corrosion Measurement: Corrosion tests are aimed at determining the corrosiveness of the environment and the rate at which material loss takes place, thus providing a basic structure for the practical control of corrosion. Corrosion measurement is the quantitative method of determination of effectiveness of corrosion control and evaluation of prevention techniques, thus, helping the investigators to optimize the control and prevention methods. Likewise, corrosion monitoring is the practice of measuring and monitoring the corrosivity of any process under practical conditions using probes, which are inserted and continuously exposed to the process stream. These probes may be mechanical, electrical, or electrochemical devices. Some of the techniques measure the corrosion rate or metal loss directly while others give us an indication that a corrosive environment may exist. Corrosion monitoring techniques are used in industries to measure metal loss/corrosion rate in process systems directly. Thus, corrosion measurement, inspection and maintenance, is carried out in industries successfully in order to ensure the effectiveness of any particular component in actual service conditions. The corrosion rate gives an idea of how long any process equipment can be efficiently operated and the corresponding measures should be taken to improve the life of the same.

A large number of corrosion testing procedures exist. The process of corrosion testing and evaluation is subdivided into five steps as given below

- planning corrosion tests and evaluating results;
- performing laboratory corrosion testing;
- performing simulated service corrosion testing;
- performing in-service techniques for damage detection and monitoring;
- evaluating forms of corrosion.

Initially, the surface to be tested has to be prepared in such a way that they duplicate the surface of the material as it would be used, followed by the cleaning to remove any dirt on its surface. The specimen is now ready for corrosion testing, and the appropriate testing procedure has to be decided. This is done depending on the conditions of use by taking into consideration all individual effects of several controlling factors varying one at a time so as to investigate the behavior of the material in the corrosive medium being investigated. Different types of corrosion testing methods available are discussed in the following section.

34.7.1 Electrochemical Methods of Corrosion

This method is mostly used for metallic materials where the corrosion process is normally electrochemical involving a chemical reaction and transfer of electrons from one chemical species to another. During metallic corrosion, oxidation and reduction reactions occur at the metal–electrolyte interface by an electrochemical mechanism.

FIGURE 34.10 Corrosion process showing anodic and cathodic current components (Kruger, 2001).

This kind of testing is carried out in an electrochemical cell consisting of a working electrode (the metal under test), counter electrode (platinum), reference electrode (saturated calomel electrode), test cell, potentiostat, voltmeters for monitoring current and potential, and a recording device to record the data obtained during the experiment. In a potentiostatic experiment, a potential is applied and maintained between the reference electrode and working electrode for a specified period of time and the data obtained (tafel plot) is analyzed using software. Metal atoms lose or give up electrons by oxidation reaction, which are transferred to another chemical species by reduction reaction (e.g., hydrogen and oxygen). The rate at which corrosion occurs is determined by the equilibrium between the opposing reactions. The data obtained in this process is recorded in the form of a graph in which the vertical axis is potential and the horizontal axis is the current as shown in Figure 34.10. The sharp point in the curve indicates the point where the current changes sign indicating that the reaction changes from anodic to cathodic at that point.

The equilibrium potential of the metal in the absence of electrical connections is called open circuit potential, E_{oc} , and is a very important parameter, which must be measured. The value of anodic or cathodic current at E_{oc} is called corrosion current, I_{corr} , which is used to calculate the corrosion rate of the metal that is being tested. But, I_{corr} cannot be measured directly and has to be estimated by the electrochemical techniques. A model is generally used for this purpose, and it assumes that the rates of anodic and cathodic processes are both controlled by the kinetics of the electron transfer reaction at the metal surface and is fit using the tafel equation. Tafel equations for both anodic and cathodic reactions are combined for carrying out analysis of a corrosion system as given below

$$I = I_a + I_c = I_a(e^{(2.3(E - E_{oc})/\beta)}) - e^{(-2.3(E - E_{oc})/\beta)} \quad (34.12)$$

where I is the measured cell current (amp), I_{corr} is the corrosion current (amp), E is the electrode potential (volt), E_{oc} is the corrosion potential (volt), β_a is the anodic beta tafel constant (volts/decade), and β_c is the cathodic beta tafel constant (volts/decade).

A log I versus E plot is called tafel plot using which we calculate I_{corr} which is used for corrosion rate calculation using the formula:

$$\text{CR} = \frac{I_{\text{corr}} \times K \times \text{EW}}{dA} \quad (34.13)$$

where CR is the corrosion rate whose units are given by the value of K , I_{corr} is the corrosion current (amp), K is a constant that defines the units for the corrosion rate, EW is the equivalent weight (grams/equivalent), d is the density (gm/cc), and A is the sample area (sq/cm)

But, there are some complications that might lead to nonlinearities in the tafel plot such as concentration polarization, oxide formation, and other effects that alter the surface or occurrence of potential drop. These must be taken care of in order to get accurate analysis of the electrochemical corrosive behavior of metals.

34.7.2 Immersion Testing

This is a laboratory corrosion test most frequently used to evaluate the corrosion behavior of metals in aqueous solutions corresponding to the actual service environment, and hence, the test is adaptable to control important factors that influence results. In this method, the specimen to be tested is totally immersed in a corrosive solution for a period of time, and then removed for examination. A number of factors, such as composition of the solution, temperature, aeration, volume, velocity, method of immersion, duration of test, and method of cleaning of specimens after test, must be considered in order to achieve specific results and ensure adequate reproducibility of the results. It is possible to carry out the test under conditions similar to those encountered in practical situations, but it is very difficult to obtain reliable analysis. Various devices are used to investigate the effect of three main factors namely aeration, temperature, and velocity. Statistical analysis of the data obtained by these apparatus has demonstrated satisfactory reproducibility of the results. In order to achieve better control over the aforementioned parameters, alternating immersion tests are employed where the specimen is immersed in a solution and withdrawn from it in a pre-determined cycle. These tests may simulate certain circumstances of practical corrosion better and are hence preferred. These tests can also be used to evaluate the resistance of the metal to pitting, crevice, galvanic corrosion, hydrogen embrittlement and stress corrosion cracking by employing specifically designed specimens or environments.

34.7.3 Accelerated Tests

In practical situations where materials encounter alternating wet and dry cycles, the life of the system is severely affected as these conditions impose severe corrosion problems on the material. This is mainly due to the formation of partially dry corrosion products that can enhance the accumulation of corrosive agents in terms of absorption of moisture. The intensity of the corrosion attack induced by alternate wetting cycles helps one in estimating the corrosion prevention measures to be undertaken to prevent the accelerated corrosion. Various tests namely electrolytic tests, salt spray tests, corrodokote test, sulphur dioxide tests, and humidity tests are used to demonstrate

the accelerating corrosion damage in a relatively short period. They aim at measuring the accelerating corrosion damage under different conditions including increasing aeration for immersion tests, temperature, acidity of the corrosive medium, relative humidity, and velocity, which would be important in actual service conditions. By examining the above conditions, it is evident that caution must be exercised to get meaningful results in accelerated testing. There are a numerous errors that might result due to multiple failure modes, misapplied models, uncertainty of the model, unquantifiable corrosion factors, unexpected change in the factors during testing, and so on. Hence, one must be extremely cautious while doing these kinds of tests in order to predict the lifetime of a material for any particular application. Accelerated testing is a powerful tool which can be used to examine potential environments for new materials, and thus selecting a material in relation to its corrosion resistance and also determining the best method of corrosion prevention.

34.7.4 Atmospheric Tests

It is very common that every component will be exposed to atmosphere during its service and might be attacked by the atmospheric agents, which has to be studied carefully for improving the performance of the same. The simplest form of atmospheric corrosion measurement is the coupon exposure method. Here, flat panels are mounted and exposed in exposure racks. These coupons are subjected to weight loss measurements, pit density, depth measurements, and other kinds of examination subsequent to their exposure. The main disadvantage with this kind of test is that the specimen has to be exposed for extremely long periods of time to undergo corrosion and obtain meaningful data.

34.8 STANDARDS FOR SURFACE ENGINEERING MEASUREMENT

It is very important to know the standard test methods for any property measurement or material characterization as certified by many researchers to get accurate results and also to avoid ambiguity in the obtained results (Powell, 1978). They give a fairly good idea to an inexperienced person in a specific field to quickly gain knowledge about the measurement technique and parameters involved. There are three ways to identify a standard of interest as follows:

- surface condition based;
- property based;
- standard based.

Listed below are some important standards for surface properties measurements.

ASME B46.1-2002	Surface texture (surface roughness, waviness and lay)
ASME SA-370	Methods and definitions for mechanical testing of steel products
ASTM A 833	Standard practice for indentation hardness of metallic materials

ASTM B 277	Standard test method for hardness testing of electrical contact materials
ASTM B 294	Standard test method for hardness testing of cemented carbides
ASTM B 578	Standard test method for microhardness of electroplated coatings
ASTM B 721	Standard test method for microhardness and case depth of powder metallurgy (P/M) parts
ASTM C 1326	Standard test method for Knoop indentation hardness of advanced ceramics
ASTM C 1327	Standard test method for Vickers indentation hardness of advanced ceramics
ASTM D 5183	EN-standard test method for determination of the coefficient of friction of lubricants using the four-ball wear test machine
ASTM E 3	Standard guide for preparation of metallographic specimens
ASTM E18	Standard test methods for Rockwell hardness and Rockwell superficial hardness of metallic materials
ASTM E 92	Standard test method for Vickers hardness of metallic materials
ASTM E 140	Standard hardness conversion tables for metals relationship among Brinell hardness, Vickers hardness, Rockwell hardness, Rockwell superficial hardness, Knoop hardness, and scleroscope hardness
ASTM E 384	Standard test method for microindentation hardness of materials
ASTM E399	Standard test method for linear-elastic plane-strain fracture toughness K_{IC} of metallic materials
ASTM E 673	Standard terminology relating to surface analysis
ASTM E 1127	Standard guide for depth profiling in auger electron spectroscopy
ASTM G 32	Standard test method for cavitation erosion using vibratory apparatus
ASTM G 65	Standard test method for measuring abrasion using the dry sand/rubber wheel apparatus
ASTM G 73	Standard test method for liquid impingement erosion using rotating apparatus
ASTM G 75	Standard test method for determination of slurry abrasivity (Miller number) and slurry abrasion response of materials (SAR number)
ASTM G 76	Standard test method for conducting erosion tests by solid particle impingement using gas jets
ASTM G 77	Standard test method for wear resistance by block-on-ring wear test

ASTM G99	Standard test method for wear testing with a pin-on-disk apparatus
ASTM G 105	Standard test method for conducting wet sand/rubber wheel abrasion tests
ASTM G 133	Standard test method for linearly reciprocating ball-on-flat sliding wear
ASTM G190	Standard guide for developing and selecting wear tests
ASTM G 171	Standard test method for scratch hardness of materials using a diamond stylus
ISO 3274	Geometrical product specifications (GPS)—surface texture: profile method—nominal characteristics of contact (stylus) Instruments
ISO 3878	Hard metals—Vickers hardness test
ISO 4287	Geometrical product specifications (GPS)—surface texture: profile method—terms, definitions and surface texture parameters
ISO 4288	Geometrical product specification (GPS)—surface texture: profile method—rules and procedures for the assessment of surface texture
ISO 4545	Metallic materials—hardness test—Knoop test part 1: test method
ISO 6507-1	Metallic materials—Vickers hardness test part 1: test method
ISO 9277	Corrosion tests in artificial atmospheres—salt spray tests
ISO 11562	Geometrical product specifications (GPS)—surface texture: profile method—metrological characteristics of phase correct filters
ISO 12085	Geometrical product specification (GPS)—surface texture: profile method—motif parameters
ISO 14577-1	Metallic materials—instrumented indentation test for hardness and materials parameters part 1: test method
SAE J 448a	Surface texture (SAE standard)
SAE J 449a	Surface texture control (SAE recommended practice)

35.1 INTRODUCTION

35.1.1 Thermal Conductivity Requirements of Modern Technology

In many fields of modern engineering, physical material properties are becoming more and more important. Modern technical products such as cars, computers, space craft, or modern production machines would not be possible without significant improvements on

the material's side. The physical properties of the materials must be known and the changes of these properties, in case of modifications in composition and structure, must be understood. The thermal conductivity is one of these properties, which was underestimated in the past. In recent decades, however, the thermal conductivity has become more important for a wide range of applications. For modern alloys, the thermal conductivity must be known and optimized if they are utilized in engines or are used as model materials in polymer production machines. In the case where incorrect alloys are utilized or if the selected material does not offer the required thermal conductivity range, the performance of the final parts and products can be significantly compromised. Furthermore, the thermal conductivity is a crucial parameter for the simulation of casting processes. If the thermal conductivity (together with other parameters) is known in the solid and liquid, scientists can simulate the solidification process inside a mold, optimize the mold and cooling accessories, and make sure that the final part is produced without pores in the shortest possible time. Optimization by simulation is not limited to casting processes. Using finite element software, computer-based optimization of parts produced during a sintering process such as powder metals or ceramics is possible. Tailor-made materials with optimized thermal conductivity for a specific application can also be realized. In many cases, characterization of the thermal conductivity of a ceramic part has a crucial impact on the downstream application even if one does not expect it. For example, if the thermal conductivity of a ceramic brake disk is too low, hot spots will be generated on the brake during operation, which can in the worst case cause cracks and mechanical damage of the entire system. Of course, there are other examples, demonstrating the importance of this thermophysical property. Nowadays, reduction of the heating/cooling consumption of buildings is one of the key issues to reduce consumption of primary energy resources. To achieve this, insulating materials have been optimized for decades. The new requirements in some areas, however, made it necessary to develop completely new kinds of insulations, offering minimal thickness and at the same time outstanding heat transfer properties. Vacuum insulation panels are one development resulting from this. Installing a vacuum insulation panel with a thickness of 2 cm on a house wall or in a refrigerator can offer the same insulation performance as a 10- or 20-cm thick conventional foam or fiber insulation.

35.1.2 Thermal Conductivity—Background and Basic Equations

Now the question might be, what is thermal conductivity? Generally, you find definitions in many textbooks or on the Internet (Incropera and DeWitt, 1996, http://en.wikipedia.org/wiki/Thermal_conductivity). The thermal conductivity is generally described as a material property defining the material's capability to transfer heat. In other words, it means that if a temperature difference over the thickness of the material exists, the thermal conductivity describes how much heat is transferred through it. To make things clearer, one can imagine a simple experiment. There is a room inside a building with one wall to the outside. It is winter and the outside temperature is 0°C. The temperature in the room is similar to the entire building at 20°C. To keep the temperature inside the room at 20°C, we need a heating system. Without heating, the temperature will not stay at this temperature but will go down. If the wall is made out of 20 cm of dense concrete, we need to heat a lot. If we build the wall out of a 20-cm thick fiber insulation, the heating will be more than 30 times less. This means, by changing the wall material, I can

significantly influence the heat transfer through it and therefore the consumption of heat to keep the temperature inside the room constant. I can extend this experiment. Increasing the size of the wall will have an impact. Having the room at the corner of the building with two outside walls of the same size will increase the heating consumption by a factor of 2. Increasing the thickness of the wall will also have an impact. Doubling the thickness will reduce the heat flow through it by 50%. Taking into account outside temperature changes will result in another effect. If the temperature goes down to -20°C , the heating consumption will increase by a factor of 2. The reason is that the temperature difference over the wall thickness will increase to 40 K.

Of course, this experiment is greatly simplified. However, it helps us generate a simple equation:

$$\dot{Q} = -\lambda \cdot A \cdot \frac{\Delta T}{\Delta x} \quad (35.1)$$

\dot{Q} is the heat flow through the wall. This is nothing more than the heat going through the wall per time. A is the area of the wall. ΔT is the temperature difference between the outside of the wall and the inside. Δx is the thickness of the wall. λ is a property that depends on the material. We call it thermal conductivity. The standard unit of the thermal conductivity is $\text{W}/(\text{m K})$.

In many cases, the heat flow through the wall per unit area \dot{q} is used in Equation (35.1):

$$\dot{q} = -\lambda \cdot \frac{\Delta T}{\Delta x} \quad (35.2)$$

This is the simplest form of Fourier's law, as it was developed by Jean Baptiste Joseph Fourier in 1822. It describes the heat transfer in one dimension under stationary conditions. This means that the heat flow goes in one direction only, and no temperature change occurs inside or outside of our wall. The general form allowing a heat flow in all directions is as follows:

$$\vec{\dot{q}} = -\lambda \cdot \text{grad } T \quad (35.3)$$

In many cases, this equation is used to describe the heat flow through a material under stationary or quasi-stationary conditions. This means that temperature changes only occur on a long-term scale. For building refrigerators, this is a proper approach. For other processes, it is at least somewhat critical. In many applications we face a problem of temperature changes on the surfaces of a material. Here, we need a more complex differential equation:

$$\frac{\partial T}{\partial t} = \frac{\lambda}{\rho \cdot c_p} \cdot \frac{\partial^2 T}{\partial x^2} \quad (35.4)$$

where T is defined as temperature changes, t the time. ρ and c_p are the density of material and specific heat, respectively. Again, this is the simplest form of transient heat transfer

equation without any heat sources, only considering one-dimensional heat flow. Generally, one has to consider all dimensions. A more general formula is as follows:

$$\frac{\partial T(\vec{x}, t)}{\partial t} = \frac{\lambda}{\rho \cdot c_p} \cdot \Delta T(\vec{x}, t) + \dot{q} \quad (35.5)$$

Here, \dot{q} is the heat generation inside the material, which is in most practical cases 0. Furthermore, the quotient of thermal conductivity and density and specific heat is often defined as the thermal diffusivity a :

$$a \equiv \frac{\lambda}{\rho \cdot c_p} \quad (35.6)$$

The thermal diffusivity is also a material property. It is a material property describing how fast a material reacts to temperature changes. The thermal conductivity and thermal diffusivity are closely related to each other for dense solids. Materials with a high thermal conductivity have a high thermal diffusivity and vice versa.

For the solution of a heat transfer problem, Equation (35.6) has to be solved. Solving this equation is not a straightforward process. There is no general solution available. One has to consider the geometry, the initial boundary conditions, as well as the initial conditions. For a wide range of different heat transfer problems, Carslaw and Jaeger (1959) provided solutions in their book. Even though it was published in 1959, it is still one of the leading books related to the mathematical treatment of heat transfer problems.

Even though Equation (35.6) can be even more complex, one should go into this transient heat transfer equation in more detail. It is a second order partial differential equation describing diffusion of any kind of process. It can be used to carry out a heat conduction analysis as long as the heat transfer is based on the diffusion process. In dense solid materials, this is generally the case. For porous materials, and for gases or liquids, however, the situation can be different. Here, one has to consider other possible means of heat transfer.

Anyhow, let us get back to the thermal conductivity itself. The thermal conductivity is a material property. It can depend on the chemical and structural composition of a material. The best conducting macroscopic materials we know nowadays are diamond (up to 2000 W/(m K)) and highly conducting metals (several 100 W/(m K)). Graphenes and carbon nanotubes also offer high thermal conductivities. However, these materials are only available in very small dimensions. The lowest thermal conducting materials are vacuum insulation panels (VIP). Such structures can offer thermal conductivities in the range of a few mW/(m K). Especially for insulation purposes, such materials are getting increasingly important. Based on VIPs, one can build a refrigerator with a wall thickness of 1 cm. However, the insulation of such a wall is as good as a 10 cm foam insulation generally used today. An overview of the thermal conductivity is given in Figure 35.1. Here, various materials are presented with their thermal conductivity at room temperature. It must be pointed out that some of the materials mentioned can have a large variability in the thermal conductivity. For many materials, it is difficult to estimate the thermal conductivity as impurities, additives or the internal structure can have a crucial impact on the thermal conductivity values.

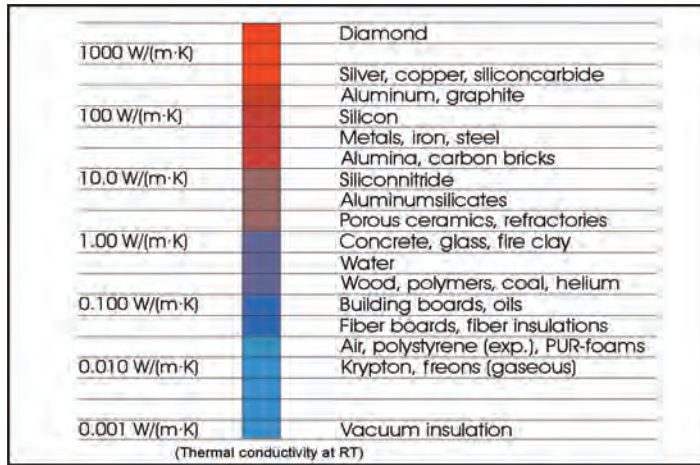

FIGURE 35.1 Overview of the thermal conductivity of different materials at room temperature.

For example, silicon carbide can offer a thermal conductivity of 400 W/(m K) if it is available as a pure single crystal. If it is a polycrystalline material with certain porosity and some additives inside, the thermal conductivity can be 20–50 times lower. To understand this, one has to analyze the heat transfer modes in more detail. If a heat transfer mode is very efficient in a material, it will directly lead to a high thermal conductivity.

35.1.3 Modes of Heat Transfer in Materials

Everything mentioned above is valid for the most important heat transfer mechanisms in solid materials. However, it is not valid for all kinds of heat transfer. In general, heat can be transferred via conduction, radiation, and convection. All these heat transfer modes must be considered to get a full picture of the amount of heat transferred through a material or structure.

35.1.4 Phonon Contribution to the Heat Transfer

Conduction is the most important heat transfer mechanism in solids. In solid materials there are two ways that heat can be transferred. The first one is phononic heat transfer. It is based on lattice vibrations and their movement through a solid structure. A mathematical description requires a thermodynamic approach. Such an explanation is given, for example, in (Reif, 1965; Salmang and Scholze, 1982):

$$\lambda_{\text{Ph}} = \frac{1}{3} \cdot c_V \cdot \bar{v} \cdot l_{\text{Ph}} \quad (35.7)$$

The phononic contribution to the thermal conductivity λ_{Ph} is dominated by the changes in specific heat at a constant volume c_V , the sound velocity \bar{v} , and the mean free path length of the phonons l_{Ph} . The temperature dependence of the heat transfer is easy to explain. At very low temperatures, the temperature dependence is dominated by the changes in specific heat c_V . Here the thermal conductivity is proportional to T^3 . The

sound velocity shows no temperature dependence, while the mean free path length is only limited by the crystal size (in a perfect crystal) or by the crystallite size in a polycrystalline material. At high temperatures, the specific heat is nearly constant. The mean free path length, however, gets shorter. With increasing temperatures, the probability of phonon–phonon scattering effects increase, resulting in a shorter mean free path length of the phonons. This means that the mean free path length l_{ph} of the phonons is proportional to $1/T$. As the sound velocity is still independent from temperature, the changes in the phononic thermal conductivity follow the changes in the mean free path length. This is the dominating factor for temperatures above room temperature. Therefore, most crystalline insulating materials show a decrease in thermal conductivity with increasing temperature proportional to $1/T$.

35.1.5 Electron Contribution to the Heat Transfer

A similar approach can be carried out to analyze the contribution of free electrons in electrically conducting solids. In metals, electrons can move more or less freely through the solid structure. Therefore, they can also carry heat through the structure. In good electrically conducting metals, this heat transfer mechanism is by far the dominant one. This strong correlation between electrical and thermal conductivity was the basis of an empirical law, the Wiedemann–Franz law. It states that the quotient of thermal conductivity and electrical conductivity is a constant multiplied by temperature:

$$\frac{\lambda}{\sigma} = L \cdot T \quad (35.8)$$

In this equation, σ is the electrical conductivity and L is the Lorenz number. The Lorenz number is equal to $2.44 \times 10^{-8} \text{ W}\Omega\text{K}^{-2}$ (http://en.wikipedia.org/wiki/Wiedemann%E2%80%93Franz_law). This number, however, is only valid for highly conducting metals. For low electrically conducting metals, the number requires some adjustments to offer reliable correlations. For practical estimations, it is still a good approach. For accurate data, however, a separate measurement of both parameters would be recommended.

There might be the question of the temperature dependence of the electrical contribution to the thermal conductivity. This is a bit more complex. Explanations are generally based on the analysis of the scattering effects inside the material. First of all, one has to consider the number of electrons inside a material which generally increases versus temperature. However, the electrons can be scattered on defects inside the crystal structure. As long as there are no changes in the impurity content or in the defect structure, this scattering mechanism has no temperature dependence. There is another scattering mechanism, which is related to electron–phonon scattering. This depends on the number of phonons and shows a temperature dependence equal to T^{-3} . As a result, the temperature dependence of the electronic contribution is as follows:

$$\lambda_{el} \propto \frac{T}{a + b \cdot T^3} \quad (35.9)$$

There is even a more mathematical approach to develop and explain the temperature dependence of the electronic contribution that is given elsewhere (Tritt, 2004). This is generally referred to as the Drude-model.

35.1.6 Radiative Heat Transfer

Of course, heat can be transported via radiation from one place to another. This heat transfer mechanism is the dominant factor for bringing solar energy to earth. Anyhow, one has to consider that radiation is generally described by the Planck's law or Stefan-Boltzmann's law. Radiation is different than the other mechanisms mentioned prior. It does not require any media. It also works in vacuum. Furthermore, it is not a diffusion process and therefore, it is not considered in the equations in Section 35.1.2. One should consider that radiation can also have an effect on the effective heat transfer in solids. In translucent materials such as glasses or in semitransparent or translucent materials such as ceramics or foam and fiber structures, radiation can be the dominant heat transfer mechanism at high temperatures. Descriptions of the heat transfer generated by radiation can be found in various books such as (Siegel and Howell, 2002) and are not explained here in detail. Especially in insulating materials, this factor has to be considered.

35.1.7 Convective Heat Transfer

Convection is a heat transfer which does not occur in solid materials. However, in liquids or gases, this mechanism can be dominant. We can visualize convection with a simple experiment. By putting a pot of water on a kitchen stove and simply watching what happens after switching on the stove. After a few minutes, one can see that the hot water from the bottom is moving upwards and the cooled water is going down. We generated convective heat transfer inside the pot. It simply refers to the transport of heat by material transport. The mathematical treatment of convective heat transfer can be quite complex. As it generally does not occur in engineering materials, we refer to the corresponding literature related to this topic such as (Bejan, 2004).

In solid materials, generally the phononic and the electronic contributions are the dominant heat transfer mechanisms. In insulating materials, the situation gets more complex. Such materials generally have a solid structure and a lot of pores inside. Here, we do not have only the solid contribution. The heat transfer by the gas inside the pores has a significant impact as well. Furthermore, the materials are often translucent. Therefore, the radiation has a contribution as well. Around room temperature, this is generally in the range of a several percent of the entire heat transfer. In addition, there can be a coupling contribution resulting from the fact that several heat transfer mechanisms act parallel to each other. Therefore, we generally work with the effective thermal conductivity which is the sum of all contributions:

$$\lambda_{\text{effective}} = \lambda_{\text{solid structure}} + \lambda_{\text{gas}} + \lambda_{\text{radiation}} + \lambda_{\text{coupling}} \quad (35.10)$$

35.2 STATIONARY METHODS FOR MEASUREMENT OF THE THERMAL CONDUCTIVITY

Over the last few decades, various methods have been developed for characterizing the thermal conductivity of materials. The first methods employed for the measurement of this material property were based on the Fourier's equation (35.1). Nowadays, such stationary methods are used to analyze building materials and insulations. Generally, there are two standardized methods available for characterizing the effective thermal conductivity or the thermal resistance of low-conducting materials.

35.2.1 Heat Flow Meter Method

The heat flow meter technique (Blumm, 2002) is a fast and reliable tool for measurements around room temperature. The heat flow meter method (ASTM C 518, ISO 8301, EN 13163, etc.) is the most commonly used method for quality control and R&D. Modern heat flow meters are designed to offer high accuracy, fast evaluation, and ease-of-use. A typical heat flow meter system is shown in Figure 35.2.

In a heat flow meter, the sample which is generally several 10's of centimeters' long and wide and several centimeters' thick is sandwiched between a hot and a cold plate. In most instruments used nowadays, the temperature of the plates is set via a peltier system. Such systems offer homogeneous plate temperatures and a low thermal mass of the plates. This is one of the requirements to improve the testing speed. In the surface of the plates, thermocouples are embedded to measure the temperatures and to determine and control the difference between the hot plate and the cold plate. Additionally, heat flux transducers are installed in the central area (metering section) to determine the heat flow from the hot plate to the cold plate. The LVDT system (linear variable displacement transducer) measures the distance between the plates and therefore the sample thickness. By knowing the sample thickness, the temperature difference between the plates and the heat flow, the thermal conductivity can be determined according to Equation (35.1). For this, another point needs to be ensured. The heat flow should be one-dimensional. Therefore, the sample is generally made larger and the metering section is surrounded by a heated area (guard section). The schematic design is illustrated in Figure 35.3. For the general application in research and quality control, instrument specifications and design details must be prepared in such a way that the requirements of the current standards such as ISO 8301 or DIN EN 12667 are fulfilled. For example, in all instruments, the plate temperatures are measured at three different positions and therefore, requirements for plate flatness and emissivity are met.

FIGURE 35.2 Netzsch model HFM 436/3 Lambda Heat Flow Meter system.

FIGURE 35.3 Schematic design of the NETZSCH Heat Flow Meter HFM 436/3 Lambda.

Depending on the instrument version, tests are possible around room temperature (at a fixed mean sample temperature between 10 and 30°C). With the extended temperature versions, temperature-dependent tests can be carried over a broader temperature range. Samples are generally 30 by 30 cm in square with a thickness of up to 10 cm. One drawback of heat flow meter systems is that they are not absolute measurement devices. Prior to a sample test, the system must be calibrated. The calibration is necessary to correlate the output of the heat flux transducers (generally a voltage) and the heat flow going through it. This is done by putting a sample with known thermal conductivity inside the machine, carrying out a test and determining a calibration factor:

$$N = \frac{\lambda_{\text{cal}}}{V_{\text{hft}}} \cdot A \cdot \frac{T_u - T_l}{d} \quad (35.11)$$

The calibration factor N is given by the known thermal conductivity of the calibration standard λ_{cal} , the output of the heat flux transducer V_{hft} , the metering area A , the temperature difference between the upper and lower plate and the thickness of the calibration standard. If this is done, the calibration factor can be used to for any subsequent sample test. Of course, it is recommended to check the calibration factor from time to time. The speed of a heat flow meter test is one of the main reasons for the success of this method. Exchanging samples can be done within seconds and the test itself lasts generally no more than 10–20 min. A quasi-equilibrium can, in many cases, be reached in a matter of minutes, as the heat flux stabilizes and the measured thermal conductivity settles into its steady-state value even before the sample reaches total steady-state conditions. The dual heat flux transducer configuration—one on each plate—together with the low thermal mass of the plates and the fast control algorithms is the key for the fast test speed. The measurement on 10 different EPS specimens depicted in Figure 35.4 requires approx. 15 min per sample. Two test cycles were carried out. One test series was carried out at a mean sample temperature of 24°C according to ISO 8301 and DIN EN 12667. A second test series was carried out at $10 \pm 0.3^\circ\text{C}$ according to DIN EN 13163, a standard established specifically for those kinds of insulating polystyrene foams. In all cases, the

FIGURE 35.4 Quality control runs by means of an HFM 436 at mean sample temperatures of 24 and 10°C. Ten different specimens were used for this test cycle. The average testing time/sample was 15 min.

thermal conductivity shows a scattering of less than 1%. Furthermore, the results deviated by less than 0.5% from the manufacturers' specification.

Sometimes, it is useful to have data available not only at one specified temperature but over a broader temperature range. Here, the heat flow meter test can also be used. However, going from temperature to temperature requires longer testing times. An example for temperature-dependent tests on two PUR foams is presented in Figure 35.5. This test was carried out at a mean sample temperature between 0 and 40°C. Here, the reliability of the method even on temperature-dependent test can easily be seen. Modern instruments can cover an even broader temperature range. However, it is generally limited to a range between −20 and 90°C.

35.2.2 Guarded Hot Plate Method

The limited temperature range, the need for a calibration standard, and the limitation regarding tests in controlled atmospheres are the main drawbacks of the heat flow meter method. The guarded hot plate overcomes these problems. No system calibration is required as long as the uncertainty of the components and measurement devices offers a high accuracy. However, guarded hot plate tests often require long measurement times (days). Furthermore, the sample change is more complex compared to heat flow meter systems.

Modern guarded hot plate systems such as the new NETZSCH model GHP 456 *Titan* overcome most of the existing problems. The system is vacuum-tight by design. Therefore, measurements are possible under well-defined atmospheres. Even gas pressure-dependent tests are possible. This allows, for example, determination of the influence of the gas inside the pores on the effective thermal conductivity. The system is designed to

FIGURE 35.5 Low-temperature test on two different PU foams from the same batch. The thermal conductivity of the material was measured between 0 and 40°C on two different samples. The differences were less than 1%.

measure square samples 300 by 300 mm in size and up to 100 mm thick. Depicted in Figure 35.6 is a schematic design of a typical guarded hot plate system.

The hot plate, 150 by 150 mm in size, is sandwiched between two samples of the same material. The hot plate is surrounded by a 75 mm wide guard ring which is controlled to the same temperature as the hot plate and therefore prevents radial heat transfer laterally from the hot plate. Two auxiliary heaters are placed above and below the specimens. The

FIGURE 35.6 Schematic design of a state-of-the-art guarded hot plate system.

auxiliary heaters are generally brought to a temperature of 10–20 K below the hot plate temperature. Heat sinks with integrated cooling tubes are positioned above and below the auxiliary heaters. Temperature measurement of the plates is made with 28 sheeted PT100 temperature sensors with a temperature resolution of 0.001 K. The entire plate stack is surrounded by a sectional furnace (artificial environment). The furnace is controlled in such a way that it simulates a comparable temperature profile that occurs in the plate stack. This avoids radial heat loss from the plate stack. Furthermore, all wires from the plates (power cables, temperature sensor wires) are connected to the furnace. Therefore, no significant temperature differences occur. This prevents any heat flow via the wiring and avoids possible wire heat losses. The system can be equipped either with aluminum alloy plates for the temperature range between -160 and 250°C (mean sample temperatures) or with special high-temperature alloy plates for the range between -160 and 700°C (mean sample temperature). The temperature difference can generally be selected between 5 and 40 K. The system is designed for square samples 300 by 300 mm in size. The thickness can be between 5 and 100 mm.

The working principle is quite simple. The guard ring and the artificial environment ensure a one-dimensional heat transfer from the hot plate to the auxiliary heaters. By measuring the sample thickness, the temperature difference between the plates and the power input into the electrically heated hot plate under stationary conditions, the thermal conductivity can be directly determined:

$$\dot{Q} = -\lambda \cdot 2 \cdot A \cdot \frac{\Delta T}{\Delta x} \Rightarrow \lambda_{\text{eff}} = -0.5 \cdot (I \cdot U) \cdot \frac{1}{A} \cdot \frac{\Delta x}{\Delta T} \quad (35.12)$$

It must be considered that there is a slight modification compared to Equation (35.1) due to the fact that the heat flow from the hot plate that goes up and down. Therefore, the hot plate area must be considered twice.

A more realistic view into the instrument is presented in Figure 35.7. Here, the hoisting device can be seen on both sides of the instrument. The hoist opens the vacuum chamber, sectional furnaces, and the plate stack. In less than a minute, the operator has access to the test section for changing samples.

A photo of a modern system including the vacuum-tight housing, and the power supplies is shown in Figure 35.8. The complexity of a guarded hot plate system is clearly seen.

Depicted in Figure 35.9 are the results for the thermal conductivity measured on the NIST-certified standard reference material SRM 1450c high-density glass fiber board (Gills, 1997). The material is certified between 280 and 340 K (7 – 67°C). The measurements with the guarded hot plate system were carried out between 25 and 60°C . It can clearly be seen that the measured results are easily within the stated uncertainty of the standard material (2.6% according to (Gills, 1997)).

Presented in Figure 35.10 is the result of a measurement on a rigid polyurethane (PU) foam material carried out with the guarded hot plate system (solid triangles). The tests were performed with a guarded hot plate system between 40 and -160°C in steps of 20 K in a nitrogen atmosphere. Also shown is the result of a heat flow meter test on the same material (red circle) at room temperature. It can clearly be seen that the measurement results of the two techniques employed agree quite well around room temperature. The thermal conductivity of the PU-foam decreases almost linearly with decreasing temperatures around room temperature. Between -40 and -120°C , two steps were detected in the measurement results caused by the condensation of cell gases on the walls of the

FIGURE 35.7 Detailed schematic of the hoisting device, plate stack and feed through of the GHP 456 Titan.

foam structure. This causes a significant increase in the solid contribution to the effective thermal conductivity of the foam material. Below -120°C , the linear decrease of the thermal conductivity continues.

Depicted in Figure 35.11 is a result of a mineral fiber insulation measured up to the maximum test temperature of the system. The test was carried out between room temperature and 700°C (mean sample temperature). The radiative impact on the temperature dependence of the thermal conductivity can clearly be seen here. Up to 200°C , the increase is nearly linear. At higher temperatures, the radiative contribution to the thermal conductivity leads to a higher increase rate.

There are various other methods based on the above-mentioned techniques, allowing for measurement of the thermal conductivity. Generally, the stationary methods are limited in the thermal conductivity range they can cover. Heat flow meters and guarded hot plate systems can measure large samples up to a few $\text{W}/(\text{m K})$. With some modifications, those methods can be modified for tests on smaller samples and slightly higher thermal conductivities. However, for metals, ceramics, and other more conducting materials, other methods are generally employed.

35.3 TRANSIENT METHODS FOR THE MEASUREMENT OF THE THERMAL CONDUCTIVITY

For samples above $10 \text{ W}/(\text{m K})$, transient methods are generally used to determine the thermal conductivity. These methods are based on a completely different working principle. Here, the sample is not sandwiched between the hot and cold plates. The sample is brought to a certain temperature. After the sample reaches thermal equilibrium, a certain heating power is brought inside the sample or on its surface. From the temperature response, the thermal diffusivity or thermal conductivity is determined. This means that

FIGURE 35.8 NETZSCH GHP 456 Titan.

FIGURE 35.9 Thermal conductivity of NIST 1450c (test result and standard values from the certificate).

FIGURE 35.10 Thermal conductivity of a rigid polyurethane foam material.

for the analysis of the results, solutions of the transient heat transfer equation (35.4 and 35.5) must be found. A traditional way of measuring the thermal conductivity is the so called hot wire technique (Davis, 1984).

35.3.1 Hot Wire Method

In a hot wire system, a linear heat source (hot wire) is embedded in the sample. Generally, two sample bodies are prepared and a metallic wire is sandwiched between the two bodies. During the test, a constant heating power is generated inside the sample by the hot wire. The resulting temperature rise at the hot wire, or at a well-defined distance to it, is measured versus time. The experiment is illustrated in Figure 35.12:

FIGURE 35.11 Thermal conductivity of a mineral fiber insulation up to 700°C.

FIGURE 35.12 Heating of a sample by the hot wire embedded in the center.

Assuming the hot wire is infinitely thin and generates a homogenous heating of the sample, the mathematical treatment of the resulting data is related to a solution of the transient heat transfer equation. The solution depends on the point at which the temperature rise is measured. In a cross wire arrangement, a thermocouple is placed at the hot wire and the temperature rise is measured there. A second possibility is to place a temperature sensor parallel to the hot wire at a well-defined distance. Another possibility is to use the hot wire itself as a temperature sensor if the resistance change versus temperature is known (T(R)-technique). All three methods have advantages and drawbacks. An overview is presented in Figure 35.13.

Nowadays, the T(R)-technique is most commonly used. This technique can be adapted to different shapes of the heat source. Even sensor disks or plates with the hot wire directly embedded can be used.

The hot wire technique is often used to characterize larger sample sizes. Refractory bricks are often measured using this method. The main drawbacks of the method are that

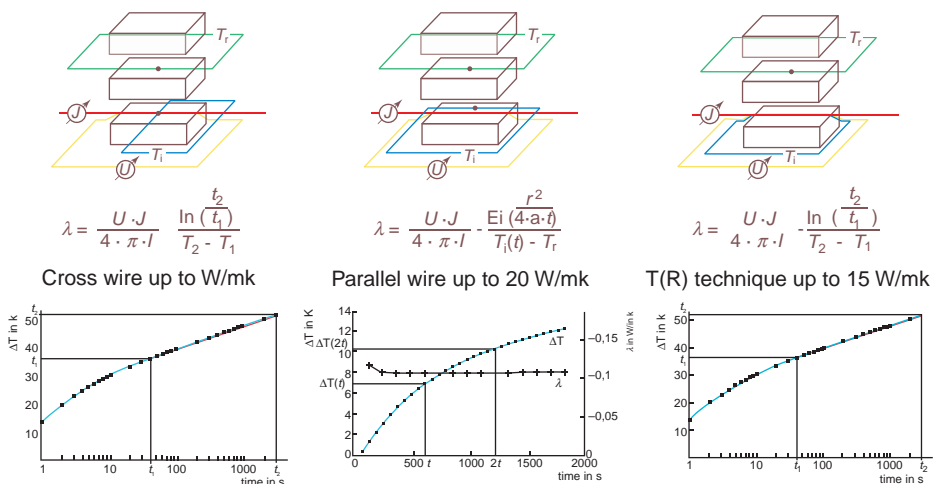

FIGURE 35.13 Different measurement methods used in a hot wire system.

tests on small samples are difficult and the preparation of the sample takes some effort and has a direct impact on the measurement accuracy. Where the sample preparation is perfect, errors of more than 15% are possible. Furthermore, tests on electrically conducting materials or materials reacting with the hot wire are difficult and often reduce the possible accuracy. Here, the hot wire must be insulated or protected to offer reasonable test results. Therefore, more and more people select other methods offering faster results and which do not require as much effort in sample preparation. One method used more and more often is the flash or laser flash method.

35.3.2 The Flash Method

For measurement of the thermal conductivity of highly conductive materials and small sample dimensions, respectively, the laser flash method is commonly used (Parker et al., 1961). This method is an absolute technique for determination of the thermal diffusivity. However, the specific heat can also be determined by laser flash. Generally, the measured raw data signals between a calibration standard and the sample are compared and the specific heat can be measured. Together with the density, which in many cases only has a weak temperature dependence, the thermal conductivity can be determined. Of course, many researchers use other techniques such as differential scanning calorimetry (DSC) (Blumm and Kaisersberger, 2001) and dilatometry (Blumm, 1999) to determine the specific heat and density change. By using those other methods, additional information such as the temperatures and enthalpy changes resulting from phase transitions and the thermal expansion or the coefficient of thermal expansion can be gained. The flash method has established itself to be the most widely used method for measurement of medium and highly conducting materials. Short measurement times, easy sample preparation, high accuracy and the simple possibility of doing temperature dependent tests are only some of the advantages of this contact-less, non-destructive measurement method. In a flash test, a plan-parallel sample is heated in a furnace to the required measuring temperature. The front face of the sample is then heated by a short light pulse (typical light pulse length < 1 ms). The light pulse is often generated by a laser system or a high power Xenon flash lamp. The heat injected on the front surface by the absorbed light spreads in the sample and leads to a temperature rise on the rear face of the sample. This temperature increase is measured with an infrared detector versus time. The schematic design of the vacuum-tight laser flash system according to Bräuer et al. (1992), used for the measurements, is shown in Figure 35.14. The head of an Nd:YAG-Laser is located in the lower part. With this laser, laser pulses with lengths between 0.3 and 1.2 ms and energies of up to 25 J can be generated. Additionally located in the lower part of the system is a sensor with which the pulse shape of the laser is detected. This allows for a correction of any pulse length influences. The sample is located on a sample carrier in the center of the tube furnace. The sample temperature is measured with thermocouples, being in contact with the sample or placed close to it. The temperature rise on the rear face of the sample is generally recorded with infrared detectors (e.g. InSb or MCT) looking directly at the rear face of the sample from above. Flash systems generally allow accuracies in the range of 3–5%.

A photo of a modern laser flash system is depicted in Figure 35.15. Here, the setup with electronics and power supply (left side) and the base unit furnace and detector housing (right side) can be seen in detail.

The typical detector signals in a flash test look pretty straightforward. At the time zero, the light pulse hits the sample surface. The resulting temperature increase on the surface

FIGURE 35.14 Schematic design of the NETZSCH LFA 427.

propagates through the sample. Thus, the temperature on the back surface starts to increase as well. It reaches a maximum before the temperature of the sample slowly goes back to ambient temperature. Three typical detector curves are depicted in Figure 35.16.

One might question how a thermophysical property can be achieved from these detector curves? There are two properties which can be determined here. The specific heat is related to the height of the measured signal. Considering the same sample dimensions and the same energy input by the light source, the specific heat is higher if the detector signal is lower and vice versa. The thermal diffusivity can be determined by analyzing the temperature change versus time. Again, a solution of the transient heat transfer equation under certain initial and boundary conditions is required. Such a solution is presented here.

FIGURE 35.15 Photo of the NETZSCH model LFA 427 laser flash system.

In the following theoretical description, a cylindrical sample body with thickness d was assumed. The origin of the coordinate system is placed in the front and center of the sample face. The x direction should run parallel to the sample surface. The basis of our analysis is the transient heat transfer equation in one dimension as mentioned before (4). It must be pointed out the T is the temperature change and not the absolute temperature for the following analysis:

$$\frac{\partial T(x, t)}{\partial t} - a \cdot \frac{\partial^2 T(x, t)}{\partial x^2} = 0 \quad (35.13)$$

Neglecting the heat loss on the surfaces of the sample body (adiabatic approach), the boundary conditions for the sample front and rear faces can be specified as follows:

$$\frac{\partial T(0, t)}{\partial x} = 0; \quad \frac{\partial T(d, t)}{\partial x} = 0 \quad (35.14)$$

FIGURE 35.16 Typical detector curves in a flash experiment. The three curves show the results of different materials with a different thermal diffusivity/conductivity.

For initial conditions, a delta-shaped light heat pulse is used. This can be described as follows, whereby Q_0 is the energy per area brought in by the laser:

$$T(0,0) = \frac{Q_0}{\rho \cdot c_p \cdot g} \quad (35.15)$$

Here g is a thickness of a very thin layer on the front surface of the sample. The above-mentioned differential equation can be solved under the mentioned initial and boundary conditions as follows (Parker et al., 1961):

$$T(d,t) = T_\infty \left[1 + 2 \sum_{n=1}^{\infty} (-1)^n \cdot \exp\left(-\frac{n^2 \pi^2 a t}{d^2}\right) \right] \quad (35.16)$$

This solution is relatively simple, but yields limited accuracy in practice. On the one hand, a merely one-dimensional heat flow is assumed. Heat losses, which are inevitable at high temperatures and materials with a low thermal diffusivity, are not considered. Finally, a delta-shaped heat pulse can technically not be realized. Corrections are therefore essential to offer a high level of accuracy under all possible measurement conditions.

35.3.2.1 Evaluation Considering Pulse Length Influences and Heat Losses For measurements at very high temperatures or with low conducting materials, a mathematical treatment considering heat losses from the surfaces is required. An example of such a measured curve (detector signal) for a low conducting sample material at 100°C is shown in Figure 35.17. In the adiabatic case, a decrease in the measuring signal should not occur at any point of time. The measuring signal should increase as a function of time until an asymptotical critical value is reached. In the presented, real measured curve, however a

FIGURE 35.17 Laser flash measuring curves (detector signal) for a silicon carbide green body at 100°C.

clear increase for times of more than 3000 ms can be seen. The evaluation according to the adiabatic model yields values which are 13.7% too high.

A model, first introduced in 1963 by Cape and Lehman, overcomes issues like this. An evaluation considering the real geometry (cylindrical samples), that is, the transient heat transfer equation in cylinder coordinates, is recommended there:

$$\frac{\partial T(x, r, t)}{\partial t} - a \cdot \nabla^2 T(x, r, t) = \frac{1}{\rho \cdot c_p \cdot d} \cdot q(x, r, t) \quad (35.17)$$

The right part of the equation describes an original term for the heat development corresponding to the light pulse in a flash test. For the consideration of heat losses from the surfaces, radiation losses were assumed. Apart from losses from the sample's front and rear faces, radiation from the side faces of the sample cylinder may also occur. The description of the boundary conditions requires three equations (35.18) in this case:

$$\begin{aligned} \frac{\partial T(0, r, t)}{\partial x} &= \frac{1}{\lambda} \cdot 4\sigma\epsilon_x T_0^3 \cdot T(0, r, t) \\ \frac{\partial T(d, r, t)}{\partial x} &= \frac{1}{\lambda} \cdot 4\sigma\epsilon_x T_0^3 \cdot T(d, r, t) \\ \frac{\partial T(x, R_s, t)}{\partial r} &= \frac{1}{\lambda} \cdot 4\sigma\epsilon_r T_0^3 \cdot T(x, R_s, t) \end{aligned} \quad (35.18)$$

ϵ_i are the emissivities of the different surfaces, T_0 is the sample temperature prior to the light pulse injection, σ is the Boltzmann constant, and R_s is the radius of the sample body.

The same initial conditions for a delta-shaped heat pulse are used as described before:

$$T(0, 0) = \frac{Q_0}{\rho \cdot c_p \cdot g} \quad (35.19)$$

The above-mentioned differential equation can be solved under the given initial and boundary conditions according to Cape and Lehmann (1963) as follows:

$$T(r, t) = T_{\infty} \cdot \sum_{m=0}^{\infty} C_m X_m \sum_{i=0}^{\infty} D_i(r, Y_r) \cdot \exp[\omega_{im}(t - \tau)/t_c] \quad (35.20)$$

Taking the real pulse shape of the laser into consideration, this can be integrated into the following equation:

$$T(r, t) = T_{\infty} \cdot \sum_{m=0}^{\infty} C_m X_m \sum_{i=0}^{\infty} D_i(r, Y_r) \int_0^t d\tau \cdot W(\tau) \cdot \exp[\omega_{im}(t - \tau)/t_c] \quad (35.21)$$

Thereby X_m are the positive roots of the transcendent Equation (35.22).

$$(X_m^2 - Y_x^2) \cdot \tan(X_m) - 2 \cdot X_m Y_x = 0 \quad (35.22)$$

Y_x is the facial biot number which defines the contribution of the axial (facial) heat loss by means of the following equation:

$$Y_x = 4 \cdot \sigma \cdot \varepsilon_r \cdot T_0^3 \cdot \lambda^{-1} \cdot d \quad (35.23)$$

If X_m and Y_x known, $C_m X_m$ from Equation (35.21) can be calculated as follows:

$$C_m X_m = (-1)^m \cdot \frac{2a}{d} \cdot \frac{X_m^2}{X_m^2 + 2Y_x + Y_x^2} \quad (35.24)$$

The coefficient $D_i(r, Y_r)$ determines the contribution of the radial heat loss. They are described by the following equation:

$$D_i(r, Y_r) = \frac{2 \cdot Y_r}{Y_r^2 + z_i^2(Y_r)} \cdot \frac{J_0\left(z_i \cdot \frac{r}{r_0}\right)}{J_0(z_i)} \quad (35.25)$$

J_0 are the integer Bessel functions. Y_r describes the contribution of the real heat losses and is defined by the following equation:

$$Y_r = 4 \cdot \sigma \cdot \varepsilon_r \cdot T_0^3 \cdot \lambda^{-1} \cdot R_s \quad (35.26)$$

z_i are the positive roots of the following transcendent equation:

$$Y_r \cdot J_0(z_i) = z_i \cdot J_1(z_i) \quad (35.27)$$

The term ω_{im} in the exponential function is calculated with Equation (35.28), in which only known sizes occur:

FIGURE 35.18 Detector signal during a measurement of Pyroceram 9606 at 900°C as well as the fit by means of the model curve.

$$\omega_{im} = -\left(\frac{d}{\pi}\right)^2 \cdot \left(\frac{X_m^2}{d^2} + \frac{z_i^2}{r_0^2}\right) \quad (35.28)$$

The characteristic time t_c is defined as follows:

$$t_c = \left(\frac{d}{\pi}\right)^2 \cdot \frac{1}{a} \quad (35.29)$$

$W(\tau)$ depicts the standardized, light pulse shape.

The mathematics sound complex. However, modern flash devices are computer controlled and the analysis is fully automated. Using the above mentioned mathematical equations embedded in a non-linear regression routine, the thermal diffusivity is determined within seconds and all possible influencing parameters are considered. An example for such a fitting process is presented in Figure 35.18.

35.4 TEST RESULTS ON VARIOUS ENGINEERING MATERIALS

35.4.1 Results on Various Kinds of Materials

An example of a thermal conductivity result of a modern insulation material (Styrodur C) is shown in Figure 35.19. As can be seen, the thermal conductivity increases linearly from 0.019 W/(m K) at -100°C to 0.033 W/(m K) at room temperature. Explanation of the temperature dependence of the thermal conductivity is difficult. All heat transfer mechanisms have a certain temperature dependence. The composite of all results include the typical linear dependence around room temperature. The results from the two tests are nearly the same and within a typical uncertainty of a well-designed, guarded hot plate system.

FIGURE 35.19 Thermal Conductivity of an XPS foam insulation (Styrodur C) between -100 and 25°C (two different tests).

Presented in Figure 35.20 are the results measuring purified water. The tests were carried out between 25 and 50°C using an LFA system equipped with aluminum container systems for liquids. Literature values (Incropera and DeWitt, 1996) for the density and specific heat were employed for the analysis. Additionally, literature values (different sources) for the thermal conductivity of water are shown in the plot. It can clearly be seen that the results for the thermal conductivity are in the typical range for water. Both, the

FIGURE 35.20 Thermal diffusivity and thermal conductivity of water measured in a sample holder for liquids and pastes.

thermal diffusivity and thermal conductivity increase slightly with temperature. The difference between the individual results and literature values for the thermal conductivity are generally less than $\pm 2\%$.

Presented in Figure 35.21 are the thermophysical properties (thermal diffusivity, specific heat, and thermal conductivity) of a polycarbonate material between room temperature and 300°C . The sample is an amorphous solid at room temperature. Therefore, the material was first heated above the glass transition (up to 200°C). At this temperature, the material is soft/liquid. At 200°C , the lid was pressed on the crucible to bring the sample to the required shape. After that, the sample container was cooled down to room temperature and the actual test was started. This procedure ensured a plane parallel disk between the aluminium walls of the container and good thermal contact between the container and the sample. As can be seen in Figure 35.1, the thermal diffusivity shows a nearly linear decrease between room temperature and 130°C . Between 130 and 150°C , a step to lower values was obtained. This effect is caused by the glass transition in the material. Above the glass transition, only a slight temperature was detected in the thermal diffusivity. The specific heat (measured by differential scanning calorimetry) shows a nearly linear increase versus temperature. During the glass transition, the typical step to high values was obtained. The resulting thermal conductivity shows a continuous increase versus temperature. No significant influence of the glass transition was obtained.

Presented in Figure 35.22 are the measurement results of an NR/BR rubber mixture between -125 and 75°C . The specific heat used for calculating the thermal conductivity was measured by an additional DSC test. It can clearly be seen that the thermal diffusivity decreases over the entire temperature range. Between -75 and -50°C , a step is visible in the thermal diffusivity. The specific heat increases over the entire temperature range. In addition, a step is visible in the same temperature range as the step in the thermal diffusivity results. Both steps can be explained by a glass transition in the rubber material. The thermal conductivity does not show any effects of the glass transition; a nearly linear increase was obtained over the entire temperature range.

FIGURE 35.21 Thermal diffusivity, specific heat, and thermal conductivity of polycarbonate (PC).

FIGURE 35.22 Specific heat, thermal diffusivity and thermal conductivity of an NR/BR rubber mixture between -125 and 75°C .

Presented in Figure 35.23 are the specific heat, thermal diffusivity and thermal conductivity of a polycrystalline graphite material. Such materials are quite interesting for several reasons: The density only shows a weak dependence versus temperature. Also the heat transfer is mainly based on the contribution of the lattice structure. The specific heat, however, shows a large increase versus temperature below room temperature. This can be

FIGURE 35.23 Specific heat, thermal diffusivity and thermal conductivity of a polycrystalline graphite material between -125 and 450°C .

explained by the Debye theory (Kittel, 2005), which describes the temperature dependence of the specific heat. At low temperatures, the specific heat should increase proportionally to T^3 (temperature in Kelvin). At high temperatures, the specific heat should converge to a constant value. The temperature range in which the material starts to differ from the T^3 depends on the Debye-temperature, which is a material-specific property. This temperature is comparably high for carbon materials (above 2000 K). Therefore, one can expect that the specific heat below and around room temperature still closely resembles the T^3 behaviour. The thermal diffusivity depends mainly on the mean free path length of the phonons. This mean free path length decreases versus temperature. Therefore, the thermal diffusivity should be proportional to T^{-1} (Kittel, 2005).

Determining the thermal conductivity according to Equation 35.6 should therefore show an increase versus temperature proportional to T^2 at low temperatures and a decrease proportional to T^{-1} at high temperatures. Considering such a temperature dependence, a maximum should occur in the thermal conductivity in the range between. For most ceramic materials, this maximum is generally in the low-temperature range. Due to the high Debye temperature of graphite, however, its maximum should be around or slightly above room temperature. As can be seen from Figure 35.23, the test results follow the expected theoretical behavior almost exactly. Only at temperatures below -50°C is the thermal diffusivity slightly below the expected temperature dependence. However, one should keep in mind that the mean free path length of the phonons cannot increase infinitely when the temperature is decreasing. The mean free path length cannot be longer than the size of a crystallite inside the sample. This, of course, results in the fact that the thermal diffusivity cannot increase infinitely but should converge to a constant value which is dependent on the structure of the material itself. This explains the low-temperature behavior of the thermal diffusivity. The thermal conductivity shows the expected maximum which was measured around 100°C .

Depicted in Figure 35.24 are the thermophysical properties of an SiC (silicon carbide) ceramic between room temperature and 1000°C . The thermal diffusivity and specific heat were determined with a laser flash system. Using the measured data, the thermal conductivity was calculated by multiplying the thermal diffusivity, specific heat and room-temperature bulk density. The thermal diffusivity values decrease over the entire temperature range. The specific heat increases, as can be expected from the Debye theory. The thermal conductivity also decreases over the entire temperature range. However, it is at a very high level (nearly $150\text{ W}/(\text{m K})$) at room temperature, which is typical for polycrystalline SiC ceramics.

Presented in Figure 35.25 are the test results (thermal diffusivity, specific heat, and thermal conductivity) measured on a magnesia–carbon refractory material with a carbon content of approx. 20%. The specific heat increases versus temperature as expected from the Debye theory. Furthermore, the results are between the typical values for pure magnesia and pure carbon (Incropera and DeWitt, 1996). The thermal diffusivity decreases versus temperature over the entire temperature range. Between 300 and 500°C , a step was detected in the results which can be explained by the decomposition of the organic binder. The decomposition of the binder yields a slightly higher porosity and carbon black between the grains of the refractory. This results in an increased thermal resistance between the grains, causing a decrease in the thermal diffusivity of the entire material. The thermal conductivity shows a slight increase up to 100°C , which can be explained by the strong increase in specific heat in this temperature range. This increase compensates for the decrease in thermal diffusivity. At higher temperatures, the changes in thermal

FIGURE 35.24 Specific heat, thermal diffusivity and thermal conductivity of a silicon carbide (SiC) ceramic between room temperature and 1000°C.

conductivity are mainly controlled by changes in thermal diffusivity. The slight drop in thermal conductivity above 800°C is most likely due to contact/surface reactions between the carbon and the oxide material inside the refractory. The value changes from ~25 W/(m K) at room temperature to ~16 W/(m K) at 1000°C, typical for magnesia refractories with a significant carbon content.

FIGURE 35.25 Thermophysical properties of a magnesia carbon refractory material (20 wt.% carbon content).

35.4.2 Full Thermophysical Properties Characterization of a Polymer and a Ceramic

35.4.2.1 Test Results on PTFE The thermophysical properties of polytetrafluoroethylene (PTFE) were determined between -130 and 150°C . For this, various test techniques were employed. For the thermal expansion measurements on the PTFE, a pushrod dilatometer was employed. The specific heat of PTFE was measured using a differential scanning calorimeter. The thermal diffusivity was measured using laser flash. Using the measurement results, the thermal conductivity was calculated according to Equation 35.1.

$$\lambda(T) = \rho(T) \cdot c_p(T) \cdot a(T) \quad (35.30)$$

Presented in Figure 35.26 are the measured linear thermal expansion and the expansivity of PTFE. The expansivity or physical coefficient of thermal expansion is defined as the rate-of-expansion divided by the original sample length:

$$\text{Expansivity} = \frac{1}{L_0} \cdot \frac{dL}{dT} \quad (35.31)$$

Starting at -130°C , the sample length increases over the entire temperature range with a slight increase in the rate-of-expansion versus temperature. Beginning at 19.2°C , two overlapped steps were detected in the thermal expansion curve. The two expansion steps are due to the solid–solid transitions (Villani, 1990). From the well-ordered to the partially ordered phase, an expansion step of approximately 0.4% was measured. For the transition from the partially ordered to the fully disordered phase above 35°C , a smaller step of approximately 0.1% was measured. Maxima in the expansivity were detected at 23.6 and 32.3°C . Those temperatures represent the points of the strongest expansion of the material during the phase transition. Above the phase transition range, the thermal expansion continuously increases with an increasing rate-of-expansion.

FIGURE 35.26 Thermal expansion and expansivity of the PTFE material.

FIGURE 35.27 Volumetric expansion and density change of the PTFE material.

Presented in Figure 35.27 are the volume and density change of the PTFE material. The volume at room temperature was set to 100%. The volume increases over the entire temperature range. The steps in the measured thermal expansion of course show up in a similar way in the volume change. The density decreases from $2.254 \text{ g} \cdot \text{cm}^{-3}$ at -130°C to $2.041 \text{ g} \cdot \text{cm}^{-3}$ at 150°C . As expected, the upward steps in the volume cause a step downward in the density curve.

Depicted in Figure 35.28 is the apparent specific heat (specific heat and overlapped transition enthalpies) of the PTFE material. At low temperatures, the specific heat increases versus temperature as can be expected from the Debye-theory (Kittel, 2005). At 19.0°C (onset temperature), an endothermal peak overlaps the specific heat. The peak shows two separate maxima at 23.5 and 31.6°C , indicating that two overlapped transitions occur in this temperature range. The two transitions are due to structural changes in the material (well-ordered to partially ordered hexagonal structure and partially ordered to disordered structure). The structural changes are related with an entire enthalpy change of 7.76 J/g . Above the solid–solid phase change region, no significant phase transition was obtained in the measured specific heat until the melting range of the material was reached (240 – 360°C , peak temperature at 337.2°C). The heat of fusion was measured to be 40.56 J/g .

Presented in Figure 35.29 is the thermal diffusivity of the PTFE material versus temperature. As can be seen from the results, the thermal diffusivity decreases continuously with temperature outside the phase change region. This can be explained by solid-state physics (Kittel, 2005). PTFE is a partially crystalline material. The heat transfer inside the material is dominated by phonon conduction (by the lattice structure). For such materials, the temperature dependence of the thermal diffusivity is mainly related to changes in the mean free path length of the phonons. Due to more phonon–phonon interactions at

FIGURE 35.28 Apparent specific heat of the PTFE material.

higher temperatures, the mean free path length gets shorter with increasing temperature and is proportional to $1/T$. Therefore, the thermal diffusivity shows a $1/T$ dependence as well. Around room temperature, significantly lower values were measured. This effect is most likely due to the structural changes in the material mentioned earlier. During the phase change, the material structure becomes more disordered, causing stronger scattering of the phonons and therefore a shorter mean free path length. This results in a reduced thermal diffusivity. In any case, it must be mentioned that measurement of the thermo-physical properties in a phase change region is critical, as the phase transition enthalpy can have an impact on the measurement and on the resulting data. In the fully disordered

FIGURE 35.29 Thermal diffusivity of the PTFE material.

structure, the values are lower than in the ordered structure. The temperature dependence of the thermal diffusivity above 25°C is small. Only a very weak step was measured around 125°C. This is the typical temperature range of the glass transition of the amorphous content inside PTFE.

Depicted in Figure 35.30 are the thermal diffusivity, specific heat and density change of the PTFE material versus temperature. The enthalpy changes caused by phase transitions are removed from the specific heat results by a linear interpolation of the values measured before and after the phase transitions. It can clearly be seen that all measured thermophysical properties show a slight step or slope change in the temperature around room temperature. The strongest impacts of the structural changes on the measured result were detected in density and thermal diffusivity, which show significantly different behavior before, during and after the phase change.

Figure 35.31 shows the thermal conductivity of the PTFE material calculated from the measured results by multiplying the thermal diffusivity, specific heat and density. In the low-temperature range, the thermal conductivity is nearly constant. The values are around 0.32 W/(m·K). At room temperature, significantly lower values (around 0.26 W/(m·K)) were found compared to the results prior to and after the phase change. Obviously, the structural changes in the material reduce the thermal conductivity by more than 10%. Above 35°C, the thermal conductivity shows a slight increase versus temperature. Constant or slightly increasing thermal conductivities are typical for such partially crystalline polymer materials. No further transitions were measured in the temperature range above 100°C. Typical literature values for the thermal conductivity of pure PTFE materials are around 0.25 W/(m·K) (data sheet Polytetrafluoroethylene, Goodfellow, <http://www.goodfellow.com/csp/active/static/G/Polytetrafluorethylen>, 2007). The results measured in this work are slightly higher (approximately 6%) at room temperature and significantly higher at low or high temperatures. However, most of the literature data refer to tests carried out at room temperature and therefore in the phase change region.

35.4.2.2 Thermophysical Properties of Zirconia Before, During, and After Sintering In the production of high-tech ceramics, a powder is generally mixed with additives and a binder, pressed to a green body, and then sintered at elevated temperatures. For optimization of the production process and an optimum temperature profile during sintering, the thermophysical properties of the material must be known prior to, during and after the sintering process.

Laser flash, differential scanning calorimetry, and pushrod dilatometry were applied to an yttria stabilized zirconia ceramic prior to, during, and after the sintering process. Using the test results, the thermophysical properties required for simulation of the temperature profiles occurring in real ceramic green bodies during the production/sintering process were determined.

Presented in Figure 35.32 are the specific heat, density change, and thermal diffusivity of the zirconia green ceramic. The density change was determined from the measured length change with the dilatometer and a room-temperature bulk density of 3.089 g/cm^3 . For the density change, the mass change during the binder burnout was also taken into consideration. The influence of the binder burnout results in a slight density decrease between 300 and 500°C . During sintering, the density increases to approx. 5.8 g/cm^3 at 1600°C . The specific heat was measured on an already debinded material. Therefore, no influence of the binder burnout overlaps the measurement result. The specific heat increases over the entire temperature range. At high temperatures, nearly no temperature dependence was obtained which is in agreement with the well-known Debye theory. The thermal diffusivity was first measured on the green body with binder. The green body with binder component shows a thermal diffusivity of approx. $0.24 \text{ mm}^2/\text{s}$ at room temperature. The values slightly increase with increasing temperature. Above 300 K, a decrease in the measured data of approx. 50% can be seen. This step is caused by the binder burnout. The binder reduces the thermal contact resistances between the particles. Due to the decomposition of the binder, this contact medium is eliminated and the influence of the thermal contact resistance increases. The measurement on the debinded material between room

FIGURE 35.32 Density change, specific heat and thermal diffusivity of a zirconia green body between room temperature and 1600°C.

temperature and 500°C clearly shows the influences of the binder on the transport properties of the material. The test results over the entire temperature range below the binder burnout are significantly lower than for the sample with binder. Between 500 and 800°C, a continuous increase in the thermal diffusivity was evident; above 800°C, a further increase was determined. A possible reason for this rise could be the beginning of the formation of sintering necks between the powder particles. In the range of the main shrinkage (volume sintering), an increase in the temperature dependence of the thermal diffusivity can be seen.

Presented in Figure 35.33 are the measured thermophysical properties of the sintered zirconia material. As can be expected, the density shows a nearly linear decrease versus temperature. The specific heat was not influenced at all by the sintering process. The same values were obtained. The thermal diffusivity shows a decrease versus temperature. The temperature dependence is more or less proportional to $1/T$. This can be expected for ceramic materials since the thermal diffusivity only depends on the mean free path length of the phonons. Due to increased scattering phenomenon, this path length is getting smaller for higher temperatures.

Figure 35.34 depicts the thermal conductivity of zirconia for the green and sintered zirconia material. The thermal conductivity results were computed from the measured data by multiplying the density, specific heat and thermal diffusivity. It can clearly be seen that the green body with binder has a higher thermal conductivity than the green body without binder. This is mainly due to the influence of the binder on the thermal diffusivity. Comparing the data for the sintered material with that for the debinded green body, a difference of a factor of 20 was determined in the range around room temperature. During sintering, the thermal conductivity shows a large increase caused by the increase in thermal diffusivity and density.

The temperature dependence of the thermal conductivity of the sintered zirconia shows a slight decrease versus temperature. Comparing the data with literature (Schlichting

FIGURE 35.33 Density change, specific heat and thermal diffusivity of sintered zirconia between room temperature and 1500°C.

FIGURE 35.34 Thermal conductivity of a zirconia green body (with and without binder) and the sintered ceramic between room temperature and 1600°C.

et al., 2001), a good agreement was found. This source indicates room temperature values of approx. 3.2 W/(m K) for zirconia stabilized with 5.2% yttrium oxide. Up to 1273 K , these values decrease to approx. 2.5 W/(m K) .

With the help of the measured data, simulation of the temperature profile in a zirconia part was made by means of Finite-Element-Calculations (ANSYSTM). For the calculations, the measurement data of the debinded zirconia green body during heating was used. For the part geometry, an infinitely expanded cylinder with an initial diameter of 30 mm was employed. The temperature program for the outer edge layer consisted of a constant heating rate of 5 K/min . The heat energy was correspondingly adjusted so that this heating remained constant over the entire simulation range between room temperature and 1600°C .

Shown in Figure 35.35 are the results for a surface temperature of 103°C . Under the assumed conditions, a temperature difference of approx. 50 K occurs between the surface and center. Such a large temperature gradient combined with the high coefficient of thermal expansion can cause cracks and structural damage and larger sintering parts. Therefore, a lower heating rate should be considered for the real production of such a ceramic material.

Simulation of the temperature distribution at a surface temperature of 1602°C is depicted in Figure 35.36. The difference between the central and surface temperature is only approx. 4 K . This can be explained by the considerably higher thermal conductivity of this almost entirely sintered ceramic. Further, it must be mentioned that the diameter of the cylinder was reduced to 24 mm ; this was taken into account in this calculation.

FIGURE 35.35 Calculation of the temperature distribution in a debinded zirconia green body (cylinder with a diameter of 30 mm) at a surface temperature of 103°C .

FIGURE 35.36 Calculation of the temperature distribution in a zirconia cylinder (with a diameter of 24 mm) at a surface temperature of 1602°C.

Figure 35.37 shows the results for the temperature distribution at different surface temperatures between 100 and 1600°C over the radius. The change of diameter during sintering of the component from initially 30 to approx. 24 mm can clearly be seen. The temperature differences continuously decrease with increasing temperature.

36.1 THERMAL BOUNDARY RESISTANCE MAY LIMIT ACCURACY IN CONTACT-BASED THERMAL CONDUCTIVITY (κ) MEASUREMENTS

The issue of heat transport in materials has a long and venerable history ranging from the early investigations of Fourier. The efforts have been mostly focused on the

estimation of the thermal conductivity (κ) based on the widely accepted relationships below, which relate the heat flux (Q) to the temperature difference (ΔT), with the thermal conductance (K) as the constant of proportionality, and the heat flux through an equivalent cross-sectional area (A) to the temperature gradient ($\nabla \cdot T$) across a specified length (L).

$$Q = K\Delta T \quad (36.1a)$$

$$Q = -\kappa A \nabla \cdot T \quad (36.1b)$$

From geometrical considerations ($K = \kappa[A/L]$). The conventional method of the κ determination then use steady-state or transient/time-dependent measurements, incorporating the analysis of the heat conduction equation at any position, r , and time, t , i.e.,

$$\frac{\partial T(r, t)}{\partial t} = \nabla \cdot [\kappa(r, t) \cdot \nabla \cdot T(r, t)] \quad (36.2)$$

Equation (36.2) is solved with respect to specified boundary conditions (Carslaw and Jaeger, 1986; Ozisik, 1968), and the isotropic value of the κ ($\equiv \kappa(r, t)$) are the values that are widely reported.

However, a major issue in such methods is the use of physical contacts, which serve for heat transfer from the heater (which generates the Q) into the material that needs to be characterized. Now, it is well known that the thermal boundary resistance (R_{TBR}) (Swartz and Pohl, 1989) due to contact-material interfaces could limit the thermal conductivity/conductance (Chen, 1998). An additional thermal resistance ($= 1/K$)/unit area, R_{TBR} would then contribute to obtain an apparent value of the thermal conductivity (i.e., κ_{app}), which is really the value being measured/reported and not the true/intrinsic value (i.e., $\kappa_{\text{int}} \equiv \kappa$), that is, through

$$R_{\text{app}} \left(= \frac{L}{\kappa_{\text{app}}} \right) = R_{\text{TBR}} + R_{\text{int}} \left(= \frac{L}{\kappa_{\text{int}}} \right)$$

From a physical point of view, the heat transport across the interface of the contact and the material could be significantly affected by the thermal boundary resistance (TBR), which mainly arises due to the reflection, transmission, or absorption of heat-carrying phonons (collective lattice vibrations) (Kittel, 1996) at the interface. In addition, the surface/interface beneath the thermal energy sensors (e.g., thermocouples and thermometers) would also modulate heat flow and lead to errors/spurious readings, and so on. Consequently, much effort has been expended to provide an explanation and to account quantitatively for the influences of the TBR on thermal conductivity measurements. At the very outset, since interface conditions are mostly unpredictable (unless extreme care is taken to test with materials under specialized conditions, vacuum, cryogenic temperatures, etc. the used phenomenological models are at best approximate and serve only as a guide or provide limits for the effects of the TBR.

Such models were first quantitatively discussed in detail for solid-liquid Helium interfaces, which were posited to have an associated Kapitza resistance (Pollack, 1969).

The corresponding Kapitza resistance/TBR between materials was then found to depend on the ratio of the materials' Debye temperatures (Stoner and Maris, 1993). It was proposed that a ratio close to one could result in a closer match of the phonon wavelengths and enhanced phonon transmission, compared to when the ratio was much different than unity, cf., 0.05 for a lead–diamond interface. In this context, two basic models, that is, (1) the acoustic mismatch model (AMM) and (2) the diffuse mismatch model (DMM) have been used (Swartz and Pohl, 1989) to understand the κ in the context of conduction across an interface/boundary. In the AMM, the constituents on either side of the interface are treated as bulk solids, in a continuum approximation, with an associated acoustic impedance, $Z (= \rho v)$, where ρ is the bulk material density and v the associated acoustic velocity. The heat flux across the interface is then determined (Little, 1959) by the product of the incident number of phonons and the transmission probability, which in turn is inversely proportional to the relative contrast in the Z values of the materials constituting the interfaces, for example, the maximum transfer of heat occurs when the two materials have identical Z values. Due to the materials being modeled as continua, the detailed nature of the interface is ignored in the AMM approximation, that is, the phonon wavelength (λ_{ph}) > interface roughness. However, at increasing phonon energy/decreasing λ_{ph} , the phonon mean free path (l) could be comparable to the scale of surface roughness and imperfections, and the AMM would be inappropriate (Swartz and Pohl, 1989; Little, 1959).

Alternately, the diffuse mismatch model (DMM) implicitly considers the detailed nature of the interface through considering individual phonon traversal. The phonons impinging on the interface lose memory of their original state (direction, polarization, etc.) subsequent to scattering. The transmission of any phonon is now determined by whether there is a corresponding phonon, on the other side, of same energy to which scattering can occur, that is, by the phonon distribution or the density of states (DOS), $g(\omega)$. Although both the AMM and the DMM have been applied to simulate experimental situations, their simplified formulation considering primarily elastic scattering, generally precludes universal agreement (Swartz and Pohl, 1989) with practical situations. For example, in the case of SiO_2 and SiN_x films deposited on Si substrates, the DMM was shown to yield good agreement at low temperatures (<20 K) while it differed from experimental observations by an order of magnitude at room temperature (Lee and Cahill, 1997). Typically the DMM, which considers a greater number of phonons elastically scattering would be thought to predict a higher thermal conductance/conductivity compared to the AMM (Lee and Cahill, 1997). Indeed, the highest K , corresponding to the phonon radiation limit, is manifested through the DMM (Swartz and Pohl, 1989). However, inelastic scattering processes, for example, due to point defects (Koh et al., 2009), interfacial roughness, tunneling, excitation of surface phonons, phonon down-conversion (Kelly, 1985), and influence of electrical carriers, or strain at the interface are not considered in either model and make detailed prediction difficult.

To understand the interface scattering in more detail, molecular dynamics (MD) simulations, which serve to check the diffusive approximations inherent in the Boltzmann transport formalism underlying the Fourier relationships have been attempted (Chen et al., 2004). In MD, mutual atom–atom interactions, for example, modeled through Lennard–Jones (Kittel, 1996; Chen et al., 2004) or other inter-atomic potentials (Volz and Chen, 1999) are considered, and the heat flux computed from the product of the atomic forces and velocities.

36.2 OPTICAL MEASUREMENTS OF κ MAY AVOID CONTACT-RELATED ISSUES

Considering the unpredictable influences of the contacts, it was recognized that non-contact methodologies for measurement of κ , for example, using optical beams to provide both heating and subsequently probe temperature gradients/distributions, could provide an alternative. In this regard, a “flash method” was proposed in 1961 (Parker et al., 1961) whereby a discharge from a flash lamp (of 400 J in energy) was incident on the front surface of a sample (1–3 mm in thickness) and analysis of the time (t) variation of temperature (T) at the back surface of the sample correlated to the thermal diffusivity ($\alpha = \kappa/C\rho$), where C is the specific heat and ρ the material density—Figure 36.1. It was noted that the C can be determined through the maximum temperature rise at the back surface. Generally, such transient-based techniques have an advantage over steady-state methods in that the T - t curves can be generated, which implicitly contain the diffusivity parameter, and a single experiment can be used to deduce the values of κ , C , and α . The flash method, now using laser pulses, has since been subject to extensive development, for example, by NETZSCH[®] Instruments (N. T. Analysis, <http://www.netzsch-thermal-analysis.com/>), in the commercial sector. It is then indeed remarkable that the determination of α could be reduced to $(= 0.1388 \times l^2/t_{1/2})$ where the l is the sample thickness and $t_{1/2}$ the “time at 50% of the temperature increase measured at the rear of the test sample in seconds”—taken from the laser flash apparatus (LFA) 427 brochure at NETZSCH.

FIGURE 36.1 Schematic of laser flash apparatus (LFA) used to measure the thermal conductivity (adapted from the LFA 427 brochure at NETZSCH).

However, issues with nonuniform heating over a finite heating spot area, the accuracy of the temperature monitoring system, and the proper fitting of the T - t curves (considering possible heat losses) all have to be considered (Baba and Ono, 2001) and calibrated to yield a precise value of the thermal diffusivity. Correspondingly, monitoring the heat pulse propagation (originating, say, from an electrical current pulse) at locations on the sample away from the contacts could also be used to determine κ and C through computation of the statistical moments of the T - t curve ($\int_0^\infty \Delta T(x, t) t^n dt$ for $-\infty < n < \infty$) (Arriagada et al., 2009).

36.2.1 Probing κ in Lower Dimensional Structures (Thin Films and Nanostructures)

While measurements on bulk materials (defined by a thickness adequate to permit the diffusion of the heat from the pulse and establish a T - t profile where the temperature at the surface, T_s decays to at least a value of $(1/e) T_s$, (where e is the base of the natural logarithm) at the back surface of the sample) are enabled adequately through the laser flash-based methods, new challenges arise in the measurement of thin films. An estimate of the thickness at which the flash methods, as described previously, may not be adequate can be deduced through the diffusion length $L \sim \sqrt{\alpha t}$ [The $(1/e) T_s$ and the $L \sim \sqrt{\alpha t}$ are rules of thumb given that a common time-dependent solution for $T(r, t)$ from Equation (36.2) varies as $\exp(-cL^2/\alpha t)$, where c is a numerical constant). As an average value of α for solids is of the order of $1 \text{ cm}^2/\text{s}$ and that the time resolution can be 0.1 ns (with state-of-the-art, fast sampling oscilloscopes at 10 GS/s), the minimum thickness is of the order of 100 nm . As thin films of around this thickness are used extensively, for example, in the semiconductor industry (Ohring, 2002; Sze and Ng, 2006), and as the thin films are deposited on substrates, an alternate technique is required to measure the intrinsic κ of the film, free of the influence of the substrate.

Higher time resolution measurements would then be required and are provided through transient thermorefectance (TR)-based techniques (Paddock and Eesley, 1986). A “pump-probe” methodology is invoked, where initially a pump mode-locked Ti-sapphire laser (Saleh and Teich, 2007) with pulse width $< 1 \text{ ps}$ and pulse intensity $1\text{--}10 \text{ nJ/pulse}$ corresponding to mW powers (Capinski et al., 1999; Schmidt et al., 2008) is incident onto and heats the thin film sample. The heating modifies the refractive index, and hence changes the reflectivity of the film which to a first approximation is proportional to the temperature change, ΔT (also see Section 36.2.2). The reflectivity is subsequently probed, after a calibrated time delay, through a weaker intensity (of the order of 0.01 nJ/pulse) probe laser. The probe laser beam can either be distinct or can be referenced to the pump laser (through an attenuator) and needs to be focused onto the heated spot, quite accurately (Capinski and Maris, 1996). The spatial resolution of the incident laser spot is diffraction limited and is typically $5\text{--}10 \mu\text{m}$ and the laser beam penetration is of the order of the electromagnetic skin depth (Fox, 2001), which is $\sim 20 \text{ nm}$ (at a laser wavelength $\sim 633 \text{ nm}$ and material resistivity of $\sim 0.1 \Omega \text{ cm}$). Such a large aspect ratio, between the spot size and the skin depth, essentially ensures one-dimensional heat flow from the surface downward and could be thought to measure cross-plane thermal conductivity. The reader can consult additional references on the discussion of optical methods such as Raman spectroscopy (Christofferson et al., 2008) and charge-coupled device (CCD)-based image acquisition methods (Christofferson et al., 2008), which have also been used to map temperature distributions.

36.2.2 Probing the Anisotropy in the κ

Generally, while material thermal conductivity (κ) is traditionally defined from the ratio of the heat flux to the temperature gradient as a second-rank tensor, it is typically regarded as a scalar and an isotropic materials property. Anisotropy in the thermal conductivity is not generally considered even in thin films or even in one-dimensional nanostructures, such as nanowires (Boukai et al., 2008) or nanotubes (Bandaru, 2007) where anisotropy could be thought to be obviously present, for example, intuitively the κ values along and perpendicular to a strictly two-dimensional film or a one-dimensional wire would not be expected to be the same (a structure is effectively n -dimensional if the length in the $(3-n)^{\text{th}}$ dimension/s is less than the λ_{ph} —in the case of thermal conductivity). Limits to κ should then be considered, for example, in terms of the mean free path, l and particular phonon wavelength, λ_{ph} , especially when the relevant length scales in the film approach the carrier mean free path (Chen, 1998; Sondheimer, 1952; Baillis and Randrianalisoa, 2009; Narumanchi et al., 2004).

Although substantial progress has been made in the past few years in understanding heat conduction in lower dimensional structures (Cahill et al., 2003; Chen and Shakouri, 2002) many issues are still unresolved. There is still difficulty in accurate measurement (Cahill et al., 2002), and precise understanding of the phonon interactions with interfaces/boundaries has not yet been obtained. In case of thin films, a few attempts have been made to correlate possible anisotropies to film and measurement geometry (Borca-Tasciuc et al., 2001), where for example, a variation dependent on the direction heat flow, cross-plane (κ_{cp}) or in-plane (κ_{ip}), was noted. The discussion has then largely been framed on the basis of the classical (Kittel, 1996) interpretation of the κ , as the product of the specific heat capacity (C), the phonon group velocity (v), and the mean free path (l) that is, $\kappa \sim Cvl$. Although the assumptions of classical mechanics are inadequate to explain electron motion, due to the spin degree of freedom, classical modeling is typically considered adequate for phonons.

It then naturally follows that a reduction of any of the constituent terms would reduce the κ . As such, a reduction cannot be surmised from an elementary formulation of the Fourier heat conduction problem, and various phonon transport models have then been considered (Narumanchi et al., 2005)—ranging from the “gray” approximation where all the phonons (both acoustic and optical) are taken as equally contributing to the heat transport to “semi-gray” models (Chen and Shakouri, 2002; Chen, 2000) where mostly longitudinal acoustic (LA) phonons contribute while optical phonons are relatively stationary due to their small dispersion and group velocity. A relative partitioning of the C values between the acoustic and optical phonons also results. A further improvement on the previous considerations arises through consideration of the phonon dispersion in the first Brillouin Zone (BZ), typically considered isotropic (Dolling and Cowley, 1966), through polynomial fits to the experimental spectra (Baillis and Randrianalisoa, 2009). The resulting $\omega - k$ fits can then be utilized to determine the frequency dependent v , while the C can be estimated through taking the temperature derivative of the total energy obtained by integrating the fits over the BZ (Kittel, 1996). However, the remaining factor in the thermal conductivity expression, l is not amenable to analytical calculation/fitting as it depends on the influencing (Peierls, 1955) intimate details of the underlying material, such as anharmonic interactions, defects and impurities, and surface corrugation, which are rarely the same in any two particular material structures. The sensitivity of the l to such details is quite difficult to determine theoretically and, due to its importance for

the κ , needs to be experimentally probed. For example, when one considers the l as a vector, with decomposition into three orthogonal components in a rectangular coordinate system, l_x , l_y , and l_z , there would be three corresponding values of the κ , κ_x , κ_y , and κ_z . Limits to l could be also considered, for example, in terms of the mean free path and particular phonon wavelength, especially when the relevant length scales approach the carrier mean free path (Chen, 1998; Sondheimer, 1952; Baillis and Randrianalisoa, 2009; Narumanchi et al., 2004). Presently, there are very few reports on the experimental determination of the thermal conductivity tensor (Quelin et al., 1993), and typically the isotropic value is suggested (Che et al., 2000). It is then of interest to explore experimental methods for the determination of the κ tensor, which could then yield insight into the relevance of the isotropy assumption. It could be reasonably expected that the effects of anisotropy would be increasingly manifest in lower symmetry crystal structures as well as lower dimensional materials, such as two-dimensional thin films or one-dimensionally oriented nanowires.

We then consider exploring anisotropy in the thermal conduction through exploring a prototypical system incorporating thin films of silicon arranged on an insulating substrate. In addition to its immense technological usage, silicon can be configured in silicon-on-insulator (SOI) structures, where Si thin films can be prepared with varying thickness (from an atomic layer upward) on an underlying oxide of low thermal conductivity (~ 1.4 W/mK). The advantage of the SOI manifold is that the Si thin films can be considered to be approximately thermally independent of the underlying structure. Such a configuration permits the characterization of thin films, say < 100 nm in thickness, that would be too difficult to handle in practice. However, it should be noted that while the Si films are typically close to single-crystalline, processing could introduce random defects/impurities. In addition to enabling easier experimentation (the alternate would be to suspend the Si through complicated etching procedures), the SOI structure is commercially used in electronic devices, where it has been indicated that up to a 25% increase in speed concomitant with a 50% reduction in the consumed power is achievable (Sze, 2003). However, enhanced electronic switching performance is coupled with enhanced heat production (Pop, 2010), the dissipation of which is a major issue with SOI-based structures.

It is then of much scientific and technological interest to investigate thermal conduction issues through Si thin films in SOI structures. This involves first, the determination of both the κ_{cp} and κ_{ip} (assuming that the in-plane conduction is isotropic). At present, the majority of the experiments involve periodic surface heating—at an angular frequency— ω , though an electrical resistor, for example, as in the 3ω method (Cahill, 1990) where a metal line serves as both the heater and the thermometer, or through the use of a pump laser, for example, as in time domain thermoreflectance (TDTR) (Paddock and Eesley, 1986; Capinski et al., 1999) or frequency domain thermoreflectance (FDTR) (Schmidt et al., 2009). The thermal conductivity is deduced through an analysis of the measured signal, for example, the third harmonic of the voltage in the 3ω method or through the change in reflectance of the surface from a probe laser in TDTR, the physical basis of which is the spread of the thermal wave in the underlying films/layers. Although heat from a point source would diffuse radially, the use of metal lines of finite width or pump laser spot diameters of much greater than the thermal penetration depth (TPD) $\sim \sqrt{\kappa/\omega C}$, results in quasi-one-dimensional heat transfer and the probing of the κ_{cp} . A few corrections in the measurement of the κ_{cp} , to account for the degree of orthogonal heat flow have been described (Borca-Tasciuc et al., 2001) to understand the relative influences of the TPD, heater width, underlying layer thickness, and thermal conductivity

anisotropy, and other geometry dependent correction factors in the 3ω method. Alternatively, in TDTR/FDTR methods, the effects of heat accumulation (e.g., when the material does not reach its unperturbed state between two successive laser heating pulses) on radial heat transfer have been probed (Schmidt et al., 2008) and used to extract the in-plane and cross-plane thermal conductivity values of highly oriented pyrolytic graphite (HOPG). Generally, a greater sensitivity to lateral heat spreading would be achieved with an underlayer of low κ due to the slower diffusion of heat from the heating spot.

Although the above state-of-the-art methodologies may yield some measure of the anisotropy of the thermal conductivity, they nevertheless provide an indirect measure. It would be desirable to develop a simpler method for measuring the anisotropy in any material. One possible methodology, in the spirit of the above discussion, involves correlating the changes in the optical reflectance to the temperature (Rosencwaig et al., 1985), which would be most suitable for a noncontact method and which mitigates issues such as boundary resistances and heater capacitances (Borca-Tasciuc et al., 2001). The concomitant difficulties are the sensitivity of the measured signal-to-surface conditions and wavelength (Tessier et al., 2003). As mentioned earlier, the SOI structure would be an ideal platform to consider thermal conductivity anisotropy through TR measurements, the principles of which will now be discussed in detail.

36.3 THERMOREFLECTANCE (TR)

36.3.1 Principles

TR involves experimental methods which allow for noninteractive interrogation of the relative or absolute temperature of a surface or interface of a metallic or semiconducting material, enabled through the temperature dependence of the material's electronic energy levels and macroscopically manifested through the dielectric constant (ϵ) and change in the measured reflectance.

A little more specifically, the response incorporates the effects of temperature increase/heating through a shift of the electron/hole Fermi energy in metals or semiconductors, which in turn modulates the light absorption characteristics and reflectivity (Fox, 2001). Hence, the heating of an electrically conducting material can be measured optically and the extent of heating would be a function of the inherent thermal conductivity. The thermal modulation of reflected light from semiconductors was initially used to study band structure (Berglund, 1966), and such a method was concomitantly exploited for the study of heat transport. One advantage was that it allowed for temperature mapping of arbitrary sample surface geometries. This feature has great utility in understanding thermal transport in microelectronics and MEMS where "hot spots" can easily develop. In addition, as this optical method is noninteracting, it may allow for the thermal measurement of sensitive nanoscale devices such as nanowires or suspended structures.

The TR signal, with respect to the total reflected amplitude, is typically two to five orders of magnitude smaller and requires highly sensitive detection techniques. The response is also dependent on the wavelength of light used (Tessier et al., 2001, 2003), surface condition, and the existence of transparent overlayers (Ju and Goodson, 1998; Maize et al., 2008; Tessier et al., 2006). Using modified microscopes or other custom-built CCD-based setups, temperature resolutions of 10 mK and diffraction-limited spatial resolutions are fundamentally possible and have nearly been achieved (Mayer et al., 2006).

TR relies on the dependence of the reflectivity of a material, which for example, can be described through the change in refractive index or, equivalently, the change in dielectric constant due to temperature. The reflectivity of the surface of a material with respect to a normal, incident electromagnetic wave is defined as

$$R = \left(\frac{\tilde{n} - 1}{\tilde{n} + 1} \right)^2 \quad (36.3)$$

where \tilde{n} is the wavelength-dependent complex refractive index, $\tilde{n} = n + ik$, with the real part, n proportional to the bending of the light, while k represents the light attenuation. Differentiating and normalizing the R gives the contribution due to the change in both Δn and attenuation constant, Δk :

$$\frac{\Delta R}{R} = \frac{4(n^2 - k^2 - 1)\Delta n + 8nk\Delta k}{[(n + 1)^2 + k^2][(n - 1)^2 + k^2]} \quad (36.4)$$

The above can be expressed equivalently through the variation of the complex dielectric constant, $\tilde{\epsilon}(=\tilde{n}^2) = \epsilon_1 + i\epsilon_2$, as:

$$\frac{\Delta R}{R} = \frac{2A}{A^2 + B^2} \Delta \epsilon_1 + \frac{2B}{A^2 + B^2} \Delta \epsilon_2 \quad (36.5)$$

where $A = n(n^2 - 3k^2 - 1)$ and $B = k(3n^2 - k^2 - 1)$.

In a semiconductor, a temperature change could be considered to be manifested through the modulation/change of the fundamental energy band gap, E_g , whereby $\Delta \tilde{\epsilon} = (\partial \tilde{\epsilon} / \partial E_g) (\partial E_g / \partial T) \Delta T$. Such a relation considers that the material characteristics (e.g., thermal expansion and density) are relatively unchanged implying a low ΔT and from the above, the relative change in reflectance, $\Delta R/R$, is linearly proportional to the temperature, that is,

$$\frac{\Delta R}{R} = \frac{1}{R} \frac{dR}{dT} \Delta T = C_{TR} \Delta T$$

where C_{TR} is defined as the TR coefficient. The C_{TR} then incorporates various materials parameters and is quite sensitive, for example, to the surface (which changes the R) making published values (typically in the range 10^{-4} to 10^{-5} K^{-1} for metals and 10^{-3} for semiconductors) more useful as a guideline, rather than a reference. Consequently, the determination of C_{TR} needs calibration for an individual sample surface.

36.3.2 Thermoreflectance to Measure the κ of Thin Films

We now illustrate, through a specific case study, the practical usage of TR to measure thermal conductivity of thin films. Such a study is also aimed at a preliminary understanding of the issues of κ anisotropy that were discussed earlier, through the consideration of lateral/in-plane conductivity.

Previous measurements of the lateral thermal conductivity of Si thin films in SOI structures mainly used electrical resistance thermometry in the steady state (Asheghi et al.,

1997, 1998), where temperature variation at two distinct points (via *in situ* fabricated highly doped areas in the Si films) was measured using an electrical resistance change. Subsequently, the κ was fit using two-dimensional heat conduction models. In another effort (Liu and Asheghi, 2006), measurements on suspended Si thin film membranes, fabricated through wet etching techniques, were performed. However, this methodology requires comparison of a metal heater deposited on a suspended bridge, with and without the Si device layer present, and thermal contact issues related to the sensors could still be significant in the characterization of κ_{ip} . A scanning TR technique was also suggested (Ju and Goodson, 1998) to monitor the transient temperature distribution along the drift region of a SOI power transistor. However, the discrepancy in the trend of values in the earlier data (Asheghi et al., 1997, 1998; Ju and Goodson, 1999) with reduced values in later measurements and theoretical predictions (Liu and Asheghi, 2006) was noted.

We now consider the utility of the TR technique to monitor the κ_{ip} of Si thin films (in the submicron range) in SOI-based structures—Figure 36.2a. The experimental method

FIGURE 36.2 (a) Schematic of the SOI samples, which provides a test bed for the study of the thermal conductivity of thin Si films. The optical parameters governing the beam–material interactions, n : refractive index, and t : the material thickness, are indicated. (b) A diagram of the experimental principles in the measurement of the temperature profile of a heated SOI sample by rastering a laser beam (e.g., He–Ne laser), as a function of distance from the heater, on the sample surface.

was aimed to avoid thermal contact-related issues through the use of the TR-based temperature sensing. Although the details will be exemplified later the surface temperature gradient in the thin film induced through on-chip heating was monitored—Figure 36.2b. Based on the sensitivity of the TR to sample conditions, it was generally observed that the TR in the visible wavelength range on SOI structures must be carefully calibrated and understood considering the optical transparency and interference effects due to reflections from multiple interfaces, that is, air–Si, Si–SiO₂ (the buried oxide layer, BOX), and SiO₂–Si substrate, all of which are involved in the correlation of the measured TR intensity to the actual sample temperature. The optical response of the sample structure, as manifested through an optical characteristic matrix (OCM) (Born and Wolf, 1964), was then modeled and calculated to predict the device layer thickness at which the TR response is optimal, considering the probe wavelengths (Tessier et al., 2001, 2003) and overlayer thicknesses (Tessier et al., 2001, 2003, 2006; Maize et al., 2008; Ju and Goodson, 1998). A finite-element physics solver was used to calculate the temperature profile in the SOI structure, with the κ_{ip} of the device layer used as the only free parameter to fit the calculated surface temperature to the measured data. Finally, the determined κ_{ip} are compared to theoretical predictions (Chen, 1998; Sondheimer, 1952; Holland, 1963), and the potential application of the method to other film-on-substrate systems are discussed.

36.4 CHARACTERISTICS OF THERMOREFLECTANCE FROM Si THIN FILMS—MODELING AND CALIBRATION

The general principle of the thin film thermal conductivity measurement is that when the surface is heated in a localized region, the temperature distribution in the sample away from the heated region would be a sensitive function of the material properties, such as the κ_{ip} . In addition to surface roughness and contamination effects, any overlayer could also modify the spectral response of the TR, due to internal reflections and interference effects, as mentioned previously. Consequently, it is often preferred, in practice, to predict the C_{TR} using analytical methods, through knowledge of the temperature variation of the refractive index and thermal coefficient of expansion. For example, in the pertinent case of a Si substrate with a silicon dioxide overlayer, the C_{TR} has been derived as a function of thickness of the overlayer (Ju and Goodson, 1998). The reasonable agreement of the calculated values with experimentally measured results suggested that the former can be sufficient for estimation of the overlayer and spectral dependence of the C_{TR} .

The TR contribution of the top Si film/device layer was deconvoluted from the underlying layers/substrate through calculating the sensitivity of the TR intensity to the thickness and temperature of the device layer. The purpose was to show that the TR signal intensity could be maximized through deliberate selection of the device layer thickness through evaluating the reflection matrix of the SOI structure. An interrogation wavelength (λ) corresponding to visible light, that is, at $\lambda = 633$ nm, and geometry, as specified in Figure 36.2 was chosen. The top layer is a single crystalline Si device layer (typically with thickness < 250 nm), with an underlying 1- μ m SiO₂ (BOX) layer, supported by a 675- μ m thick single crystal substrate. From an optical standpoint, the electromagnetic skin depth (Born and Wolf, 1964), d_{Si} , of Si, at $\lambda = 633$ nm, is ~ 2.3 μ m which suggested that incident radiation would penetrate through the Si device layer. The BOX layer was

optically transparent and was modeled with only a real component to the refractive index, while the substrate is much thicker than d_{Si} and is optically opaque.

If the incident radiation modeled as an electromagnetic plane wave and represented through

$$Q_0 = \begin{bmatrix} E_0 \\ H_0 \end{bmatrix}$$

with E_0 and H_0 as the free-space amplitudes of the electric and magnetic fields, is incident upon a slab of material with refractive index \tilde{n}_s , the resultant amplitude at depth z within the slab is given by

$$Q = \begin{bmatrix} E(z) \\ H(z) \end{bmatrix}$$

where $Q_0 = M_s Q$. M_s is the optical characteristic matrix (OCM) of the layered slab, comparing the amplitude of the propagated wave to that of the initial state, and is

$$M_s(z) = \begin{bmatrix} m_s^{11}(z) & m_s^{12}(z) \\ m_s^{21}(z) & m_s^{22}(z) \end{bmatrix} = \begin{bmatrix} \cos\left(\frac{2\pi\tilde{n}_s z}{\lambda}\right) & -\frac{i}{\tilde{n}_s} \sin\left(\frac{2\pi\tilde{n}_s z}{\lambda}\right) \\ -i\tilde{n}_s \sin\left(\frac{2\pi\tilde{n}_s z}{\lambda}\right) & \cos\left(\frac{2\pi\tilde{n}_s z}{\lambda}\right) \end{bmatrix} \quad (36.6)$$

The electric and magnetic fields are taken to be of the form, $E_x = E(z)e^{i(kz - \omega t)}$ and $H_y = H(z)e^{i(kz - \omega t)}$, respectively. For SOI structures, the M_{SOI} is equal to the product of the individual OCMs of each optically active layer, that is, the top Si device layer (dev) and the SiO_2 buried oxide (BOX).

$$M_{\text{SOI}}(z) = M_{\text{dev}}(z)M_{\text{BOX}}(z) \quad (36.7)$$

It can then be shown (Born and Wolf, 1964) that the total reflectance of the SOI structure, R_{SOI} , is

$$R_{\text{SOI}} = \left| \frac{(m_{\text{SOI}}^{11} + m_{\text{SOI}}^{12}\tilde{n}_{\text{air}})\tilde{n}_{\text{sub}} - (m_{\text{SOI}}^{21} + m_{\text{SOI}}^{22}\tilde{n}_{\text{sub}})}{(m_{\text{SOI}}^{11} + m_{\text{SOI}}^{12}\tilde{n}_{\text{air}})\tilde{n}_{\text{sub}} + (m_{\text{SOI}}^{21} + m_{\text{SOI}}^{22}\tilde{n}_{\text{sub}})} \right|^2 \quad (36.8)$$

The above equations can be generally used to find the reflectance of any layered structure of arbitrary dimensions, allowing for advanced measurements such as selective probing of nonsurface layers.

A plot of R_{SOI} as a function of the device layer thickness (t_{dev}) at $\lambda = 633 \text{ nm}$ is shown in Figure 36.3a, along with obtained experimental results, and indicated the accuracy of the modeling and experimental calibration. The peaks and troughs in the R_{SOI} are due to interference effects of the incident radiation from boundaries of the device layer. The shape of the variation, that is, broad peaks and narrow troughs, were due to a large refractive index contrast ($\tilde{n}_{\text{dev}} - \tilde{n}_{\text{BOX}} \sim 2.5$) between the Si device layer and the underlying oxide, and the periodicity was determined by one quarter of the optical path length ($t_{\text{dev}}\tilde{n}_{\text{dev}}$), where interference interactions will be most influential. It can then be inferred from the $R_{\text{SOI}} - t_{\text{dev}}$ variation, that the C_{TR} (or dR/dT) could be increased at an optimal

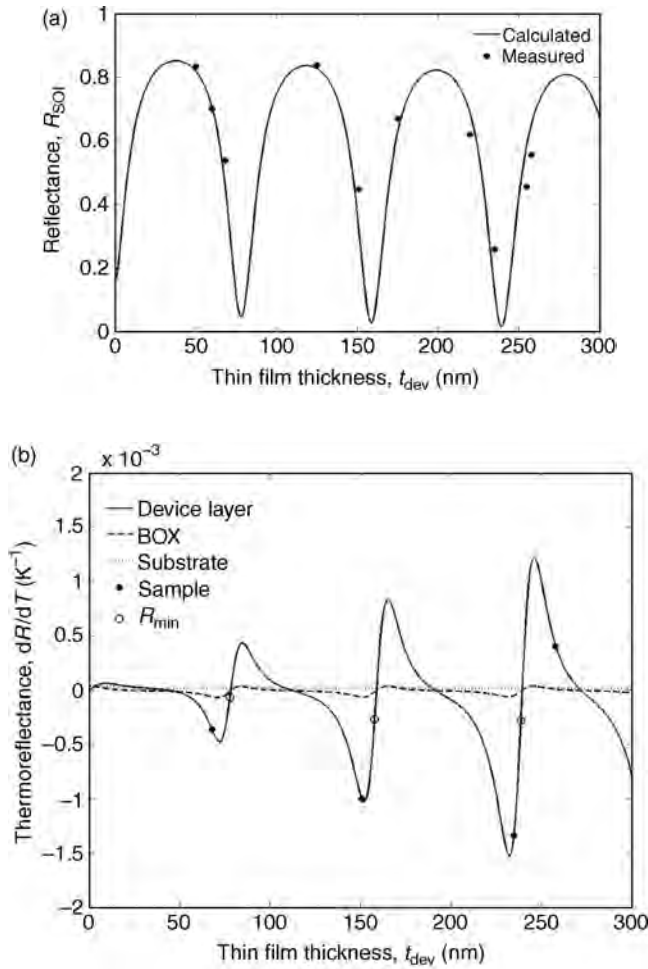

FIGURE 36.3 (a) The calculated and measured optical reflectance (R_{SOI}) of the SOI samples, with varying Si thin film/device layer thickness (t_{dev}). (b) The variation of the temperature derivative of the reflectance (dR/dT) with t_{dev} for the individual layers of the sample, including the top device layer, underlying BOX and the substrate. The values corresponding to the t_{dev} of the measured samples (Sample) and the minima (R_{min})—from Figure 36.3a, are indicated.

t_{dev} . Generally, when any layer of thickness, t , has a temperature variation ΔT , the change of the refractive index and thickness would be $\Delta \tilde{n} = d\tilde{n}/dT \Delta T$ and $\Delta t = \xi \Delta T$, respectively, where ξ is the linear thermal coefficient of expansion. For a given SOI sample with a specified device layer thickness, t_{dev} , and an initial temperature, T^0 , with reflectance $R(T^0, t_{dev})$, the change in the net reflectance, ΔR , can be written as:

$$\Delta R = \frac{dR}{dT} \Delta T = R(T^0 + \Delta T, t_{dev} + \Delta t) - R(T^0, t_{dev}) \quad (36.9)$$

For a unit rise in ΔT ($= 1$ K), and using Equations (36.7) and (36.8), a plot of ΔR versus the t_{dev} was formulated—as in Figure 36.3b, to show the individual dR_i/dT ($i = dev, BOX,$

or substrate) due to the uniform temperature rise for the i th layer. From an experimental point of view, the observed dR/dT of the SOI structure is modeled as arising from a linear superposition of the individual layers, as follows

$$\frac{dR_{\text{SOI}}}{dT} = \frac{dR_{\text{dev}}}{dT} + \frac{dR_{\text{BOX}}}{dT} + \frac{dR_{\text{han}}}{dT} \quad (36.10)$$

Such a model is necessary as the individual contributions of the layers of the SOI are not measurable and was justified on the basis of observations, through computational simulations using MATLAB[®], that the difference of dR_{SOI}/dT between (i) that found by considering and summing the individual contributions from each layer (each with a $\Delta T = 1$ K) and (ii) assuming that SOI structure as a whole has $\Delta T = 1$ K, is less than 1%.

The following were then observed from the plot: (1) there is a pronounced modulation of the dR_i/dT which could be either positive/negative, and which is proportional to the slope of R_{SOI} , (2) the dR_{dev}/dT is dominant over that of the other layers by almost two orders of magnitude ($10^{-3} \text{ K}^{-1} \text{ vis-à-vis } 10^{-5} \text{ K}^{-1}$) resulting from both the position of the device layer, and the much larger $d\bar{n}/dT$, and would be the chief contributor to the TR intensity, and that (3) there is a pronounced modulation of the dR_{dev}/dT increasing in amplitude with t_{dev} and exhibiting a maxima whenever there is a minimum in the R (cf., Figure 36.3a), and has the (4) experimental implication that there are select values of t_{dev} where the dR_{dev}/dT is maximum/minimum with a corresponding effect on the observed TR intensity. Consequently, the Si thin film thickness (t_{dev}) must be chosen carefully for maximal signal-to-noise ratio in the TR measurements, enabling more accurate determination of the thermal conductivity. Si thin films with $t_{\text{dev}} = 68, 151, 235$, and 258 nm were then chosen, corresponding to thicknesses near the maxima of the absolute dR_{dev}/dT shown in Figure 36.3b.

36.5 EXPERIMENTAL PROCEDURES

Si thin films of optimal t_{dev} thickness, following the discussion in Section 36.4, could be fabricated on SOI substrates through reactive ion etching (RIE) of the Si film. A measure of the electrical dopant density should be taken to look at possible effects on the variation of κ (in the work reported here, the density of $\sim 10^{15}/\text{cm}^3$ (Taur and Ning, 1998) was not expected to affect the thermal conductivity significantly (Asheghi et al., 2002)). Measurement and calibration of the film thickness was done through spectral reflectance, and error in the measurement was estimated to be less than 5 nm. The surface roughness introduced during the RIE was of the order of a few nanometers. A metal line was then deposited on the Si film surface to serve as an electrical resistance-based heater, for example, see Figure 36.2b. The heater line was constituted of a multilayer of Cr (10 nm)/Au (200 nm) deposited through electron beam evaporation and was typically 10-mm long and 8- μm wide, ensuring a sufficiently high aspect ratio to probe lateral conductivity. To characterize the possible current leakage from the heater into the substrate, 30 nm of SiO_2 was deposited underneath the heater line. However, measurements did not indicate any leakage effects precluding the need for such an oxide. Subsequent to the fabrication of the optimal t_{dev} films, the samples were mounted and wire-bonded to ceramic chip-carriers. Thermal epoxy was used to bond the substrate bottom to the sample holder. The overall sample configuration is schematically shown

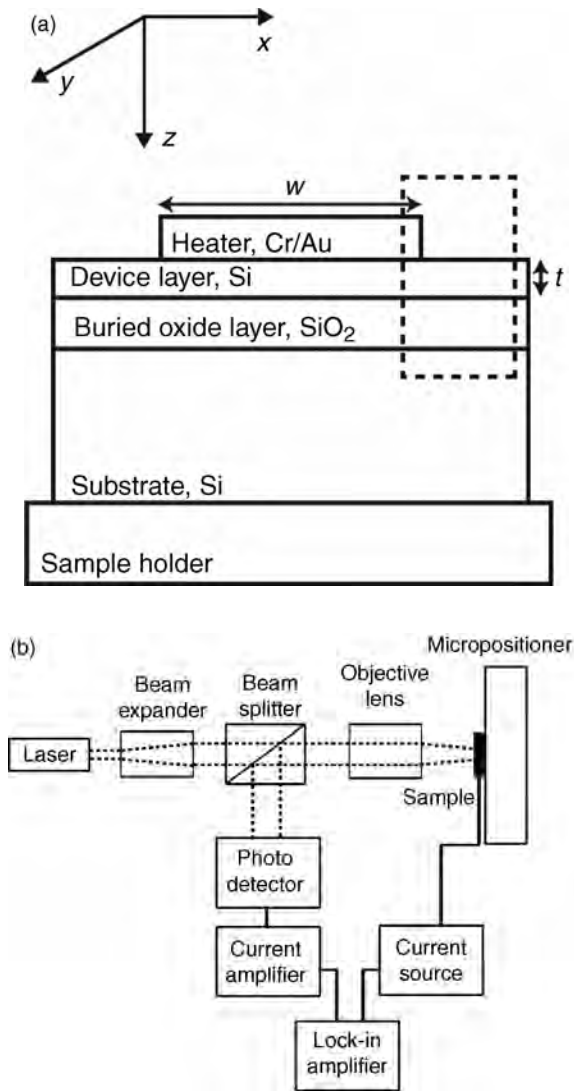

FIGURE 36.4 (a) Schematic of the cross-section of the measured samples (mounted on a chip carrier) with the heater. The lateral heat flow, in the x -direction, in the region delineated by the dotted box, is sensitive to the in-plane thermal conductivity (κ_{ip}) and the corresponding temperature variation along the surface can be estimated. (b) Schematic of the arrangement of apparatus used for the scanning TR thermometry.

in Figure 36.4a, and the setup for the measurement of the TR intensity is indicated in Figure 36.4b. It was assumed that the micropositioner (with $<0.5\text{ }\mu\text{m}$ resolution), to which the sample holder was mounted, was an adequate thermal sink and fixed the sample holder bottom to ambient temperature.

A sinusoidal current $I(f)$, at a given frequency f , was passed through the deposited metal line and induced Joule heating (with a harmonic component of $2f$, as derived from

the I^2 component of the heating). AC-based modulation techniques enable accurate lock-in-based detection of the effects of the induced heating with high signal-to-noise ratio. The thermal losses due to convection or radiation can be ignored through the use of time constants (and f values) not overlapping with the characteristic time scales associated with such loss mechanisms. Using lumped thermal analysis (Mills, 1999), it was estimated that, for the device layer thicknesses considered in our experiments, such time scales were of the order of magnitude of 0.01–0.1 s. Consequently, at a heating current frequency, f_h , of ~ 2.5 kHz, one can safely consider only the conductive heat transfer. Also, the estimated change in the surface temperature due to convective/radiative heat loss was estimated to be less than 1%, through elementary calculations using Newton's law of cooling and the Stefan–Boltzmann Law.

At the chosen f , the thermal wave propagates into the Si substrate, through the top device layer and the BOX. However, due to the orders of magnitude lower κ and much larger thickness of the oxide compared to that of the device layer, it can be assumed that there is a much larger temperature drop across the oxide. Hence, the top device layer is essentially isothermal through the thickness at any given distance from the heater. However, there seems to be significant lateral heat conduction in the BOX near the heater, which modifies the temperature profile of the device layer, and precludes the use of analytic expressions as in earlier studies (Asheghi et al., 1998). Consequently, finite element modeling was necessary to understand such variations, as will be discussed later.

A normally incident, linearly polarized He–Ne laser was then focused onto a heated sample through an objective lens. The spot size could be determined through a knife-edge technique, where the beam was scanned over the metal heater edge onto the Si film surface. Assuming a Gaussian beam profile, with intensity variation given through $I(x) = I_0 \exp(-x^2/2r^2)$, the spot radius, r , was found to be as small as $\sim 2 \mu\text{m}$. The sample was translated, with $0.2 \mu\text{m}$ resolution, rastering the focused laser spot across the surface—see Figure 36.2b. The reflected intensity was diverted through a nonpolarized beam splitter onto a diode detector connected to a lock-in amplifier synchronized to $2f$. Both the amplitude (proportional to the temperature fluctuations of the surface) and the phase (related to the sign of the C_{TR}) of the signal were recorded as a function of distance from the heater. The obtained values in the TR measurement were limited by the dark current noise of the detector, which was of the order of 4 nA.

36.6 RESULTS AND DISCUSSION

36.6.1 Determination of the Specific Heat, C , and the Phonon Group Velocity, v_g

A suitable assumed value of the density (ρ) and the specific heat (C) constituting the thermal diffusivity, $\alpha (= \kappa/\rho C)$ of the device layer was necessary before solving/modeling the transient heat conduction equation. Although the density may be assumed to be that of the bulk (CRC Handbook of Chemistry and Physics, 2004), $\rho_{\text{Si}} = 2329 \text{ kg/m}^3$, the bulk value of $C \sim 1.67 \times 10^6 \text{ J/m}^3\text{K}$ associated with the “gray” approximation of phonons (Chen, 2005), in which all phonons are treated identically, may not fully characterize their frequency dispersion. A more appropriate value of C which accounts for the phonon dispersion was derived (Chen, 1998; Sondheimer, 1952; Holland, 1963). To illustrate, it was assumed that only the acoustic phonons contribute to heat conduction, while the optical phonons do not, due to their small

group velocity, and that the specific heat capacity associated with heat conduction would be that appropriate for the former group.

The full phonon dispersion in Si, consisting of one longitudinal and two degenerate transverse modes (i.e., LA, TA and LO, TO modes) was considered. Using polynomial fitting functions to analytically describe the experimentally measured acoustic phonon dispersion (Brockhouse, 1959), a $\bar{C}_{\text{avg}} \sim 0.95 \times 10^6 \text{ J/m}^3\text{K}$, was calculated under the Debye model formulation (Kittel, 1996). An average phonon group velocity, \bar{v}_g , was also estimated by including the dispersion and normalizing as follows

$$\bar{v}_g = \frac{C_{\text{LA}} v_{g,\text{LA}} + 2C_{\text{TA}} v_{g,\text{TA}}}{\bar{C}_{\text{avg}}} \quad (36.11)$$

The resulting analysis yields $\bar{v}_g = 2274 \text{ m/s}$, which is notably smaller than the value typically considered for bulk, that is, $\sim 6000 \text{ m/s}$. Taking a κ value for Si ($\sim 140 \text{ W/mK}$), \bar{v}_g , and \bar{C}_{avg} , we obtain an average value of the mean free path, $\bar{l}_{\text{avg}} \sim 200 \text{ nm}$, implying more phonon-boundary interaction in thin films than traditional thermal analysis suggests. Thus, a reduction of κ_{ip} at film thickness near or less than \bar{l}_{avg} would be expected. Such a framework to understand the reduction of the in-plane thermal conductivity, κ_{ip} , in Si thin films (Narumanchi et al., 2004; Liu and Asheghi, 2006; Mazumder and Majumdar, 2001) and the device layer in SOI substrates (Asheghi et al., 1998; Ju and Goodson, 1999) has been previously established and agrees well with the above calculations.

36.6.2 Finite Element Modeling

As noted earlier, the SOI geometry along with the large aspect ratio of the heater (~ 40) *vis-à-vis* the device layer thickness (typically, $t_{\text{dev}} < 250 \text{ nm}$) implies a decaying temperature profile from the heater edge—in the x -direction, following Figures 36.2b and 36.4a. Consequently, a two-dimensional analysis of the heat conduction along the cross-section of the sample, perpendicular to the heater axis (i.e., the x - z plane), was pertinent. The Fourier heat conduction equation, for arbitrary geometries, can be solved through a finite element model (FEM) constructed in computational/CAD environments, for example, COMSOL Multiphysics[®] software, to determine the time-varying temperature along the surface of the device layer in the proximity of the heater and for analyzing the sensitivity of the device layer κ_{ip} . By choosing appropriate free parameters, the calculated temperature profiles could be fit to the measured TR data to elucidate the thermal properties of the device layer.

In accordance with experimental conditions, the following assumptions were used in the model: (1) the heat sink fixes the bottom substrate surface to room temperature, (2) sample surfaces exposed to air were taken to be insulating, that is, $(dT/dx)_{\text{surface}} = (dT/dz)_{\text{surface}} = 0$, (3) the power per unit area dissipated by the heater at the heater/device layer interface is equal to Joule heat generated by the heating current, and (4) the BOX and Si substrate have bulk thermal properties. The sensitivity of the model solution was examined with respect to the cross-plane thermal conductance, heating power, and frequency. It was found that the surface temperature was unperturbed by variation of the device layer κ_{cp} considered in this work, as well as from the introduction of TBRs at the device layer/BOX and BOX/substrate interfaces, with commonly accepted values (Cahill et al., 2003). The thermal epoxy between the substrate bottom and the

sample holder could introduce a resistance in series with the sink, and was estimated to be $\sim 10^{-3} \text{ m}^2\text{K/W}$. However, introduction of the boundary resistance in the model had no effect on the transient component of the surface temperature as the chosen f limits the thermal penetration depth to $\sim 75 \text{ }\mu\text{m}$ in Si, precluding the interaction of the thermal wave with the bottom of the substrate. In addition, variation of the heating power and frequency within the limits of specified machine error, $\sim 0.1\%$, did not yield a change in the surface temperature greater than the obtained precision. An example of the calculated temperature profile along the sample cross section near the peak of the heating cycle is shown in Figure 36.5a.

36.6.3 Experimental Measurements of the Lateral Temperature Variation

A typical TR scan, across the surface of the device layer ($t_{\text{dev}} = 258 \text{ nm}$) indicating the experimental data superposed on calculated temperature profiles with varying κ_{ip} is shown in Figure 36.5b. Each datum represents the maximum amplitude variation of the TR intensity as it varies in time at frequency $2f$, and whose x -coordinate coincides with the center of the probe beam. The error bars due to variation of the TR intensity are also labeled, but are too small to be visible. The magnitude of the TR intensity was scaled such that the values in the limit of $x \rightarrow \infty$, for example, when $x \sim 40 \text{ }\mu\text{m}$ in Figure 36.5b, match the calculated temperature. Although the total TR intensity was an average of the temperature profile convoluted with the spatially distributed intensity of the beam, the resulting measurement was still an accurate indication of the actual temperature at the center of the beam spot (Aubain and Bandaru, 2010). The solid curves represent equivalent, time-variant temperature amplitudes as a function of distance from the heater edge at various modeled κ_{ip} . The goodness-of-fit between the measured results and simulated curves was determined in the range of spatial values where modeled temperature profiles diverged by more than 10%, that is, at $4 \text{ }\mu\text{m} < x < 30 \text{ }\mu\text{m}$. The largest correlation coefficient between the scaled TR measurements and calculated temperature values was $R^2 = 0.9999$, corresponding to the fit with $\kappa_{\text{ip}} \sim 100 \text{ W/mK}$. It was noted that the values of κ_{ip} , matching 60 and 148 W/mK, have R^2 values of 0.9955 and 0.9978, respectively. While correlation remains high for the given calculated temperature profiles, their relative values could be used to indicate the most appropriate κ_{ip} so as to closely match experimental data.

Figure 36.5c shows the measured TR signal phase of the heat wave peak as a function of the distance from the heater, where decreasing phase indicates greater lag with respect to the heating frequency reference. The phase was a direct indication of the difference in sign of dR_{dev}/dT between samples of different thickness (cf., Figure 36.3). More specifically, comparing the signs of the dR_{dev}/dT for $t_{\text{dev}} = 258 \text{ nm}$ to other device thicknesses, that is, $t_{\text{dev}} = 68, 151, \text{ and } 235 \text{ nm}$, the former has a positive value while the latter have negative values. Consequently, the lock-in measurement of two TR signals with identical phase but opposite sign would be manifested in a π phase shift, as indicated in Figure 36.5c. It was also noted that the TR signal phase did not indicate a π phase shift as the beam was rastered from the Au heater line to the device layer, implying that dR_{dev}/dT and dR_{Au}/dT are of the same sign. As it was previously established that dR_{Au}/dT is negative at $\lambda = 633 \text{ nm}$ (Tessier et al., 2001; Raad et al., 2008; Christofferson et al., 2001), the dR_{dev}/dT of these SOI samples at these thickness must be negative as well, further supporting the OCM predictions plotted in Figure 36.3.

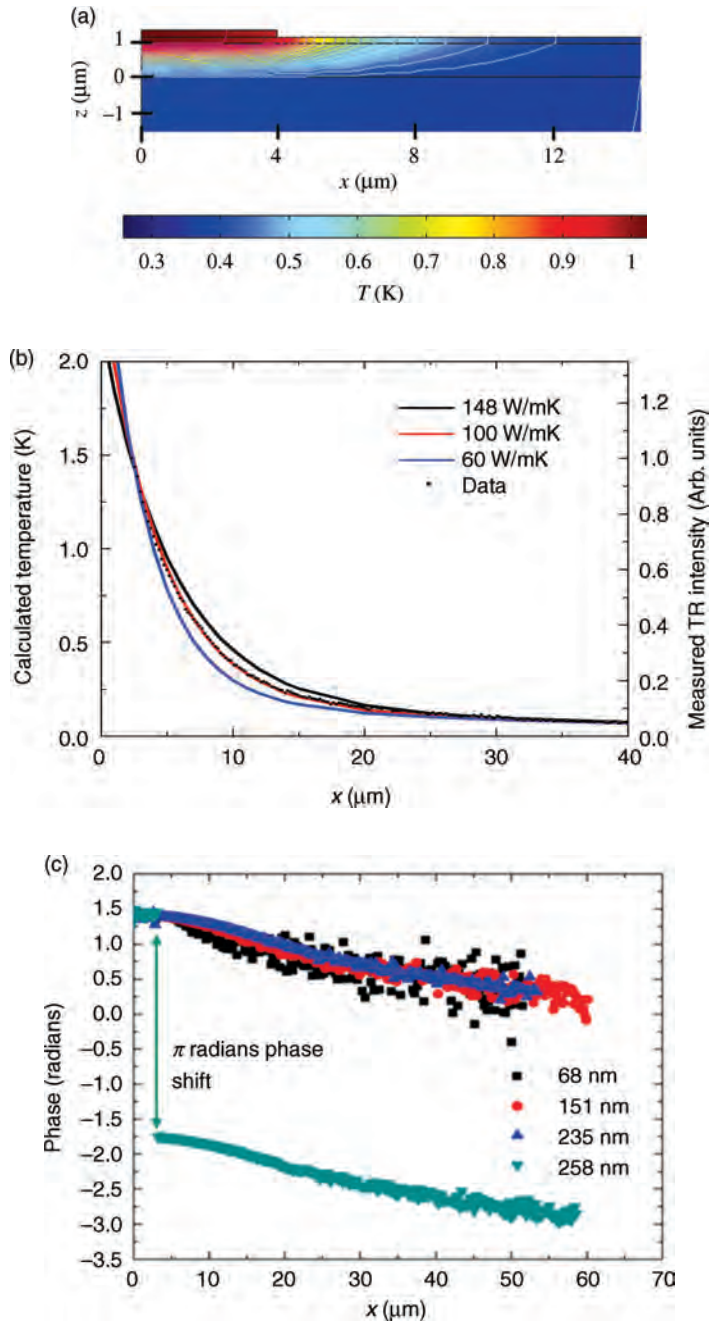

FIGURE 36.5 (a) Modeled variation, through FEM, of the temperature along the sample cross-section, indicated at the peak of a given heating cycle. (b) A typical TR scan across the surface of the device layer ($t_{\text{dev}} \sim 250$ nm) indicating the experimental data superposed on modeled temperature profiles with varying κ_{ip} . The error bars are too small to be visible. (c) The measured TR signal phase of the heat wave peak as a function of the distance from the heater is a direct indication of the difference in sign of TR intensity between samples of different thickness, cf., Figure 36.3b.

FIGURE 36.6 A comparison of the thermal conductivity values (obtained from the TR intensity fits in the present work) with those obtained previous literature (Aubain et al. 2010; Liu et al. 2005, 2006; Ju et al. 1999; Asheghi et al. 1998).

36.6.4 Estimation of the In-plane Thermal Conductivity of Si Thin Films

The principles outlined above were used to determine the values of the κ_{ip} and compare with the results obtained by other previous measurements (Ju and Goodson, 1999; Aubain and Bandaru, 2010), which have been plotted in Figure 36.6. Generally, a decreasing κ_{ip} is observed with respect to t_{dev} . The high accuracy and precision of the data obtained in this work—as in Figure 36.5b, stems from the accuracy in modeling as well as improved spatial resolution. Most notably, there seems to very good agreement between our measured κ_{ip} and those obtained through measurements with suspended Si structures fabricated from SOI substrates (Liu and Asheghi, 2006). Generally, suspended beam geometry greatly simplifies thermal analysis due to the restriction on heat conduction paths. However, fabrication of such geometries is elaborate and nontrivial involving controlled wet etching and is often not easily implemented for many thin films of interest, for example, those lacking a sacrificial intermediate layer. The comparison of the κ_{ip} previously measured through electrically resistive elements of suspended (Liu and Asheghi, 2006) and supported (Asheghi et al., 1997, 1998; Ju and Goodson, 1999) Si films show that measurements of supported samples seem to be less sensitive to the film properties (Ju and Goodson, 1999) or have high variability (Asheghi et al., 1998).

36.7 SUMMARY AND OUTLOOK

The modulation of reflected light as a function of the surface temperature of the material forms the basis of TR, and has been discussed in this work as a means to understand the

thermal conductivity (κ) of lower dimensional structures such as submicron thickness thin films. The TR response (both the magnitude and the sign) was found to be sensitive to the thickness of the thin film layer and modeled using an optical characteristic matrix formulation to choose appropriate thin film thicknesses. High aspect ratio, on-chip heating elements produced temperature profiles that were measured as a function of distance with respect to the heater edge, and the profiles were fit to a robust finite element model with the in-plane thermal conductivity (κ_{ip}) as the only free parameter. Comparison of the obtained thermal conductivity values with previous measurements confirms the validity of the technique and suggests that complete isolation of the thin film, as in earlier methodologies, from the substrate may not be required.

The advantage of the use of such optical methods to determine the κ is the possible elimination of electrical resistance-based sensing/thermometry, which suffers from thermal boundary resistance-related issues, which vary from device to device due to contact-material interfaces. The proposed TR-based methodology then provides a quick, noncontact-based optical metrology to determine the temperature profiles and thermal energy distributions.

In probing the frontiers of scientific and technological research, it is of interest to explore experimental techniques for the determination of the κ tensor, which could then yield insight, for example, into the relevance of the isotropy assumption prevalent in the literature. It would be reasonable to expect that anisotropy influences would be manifest in lower symmetry crystal structures as well as lower dimensional materials, such as two-dimensional thin films or one-dimensionally oriented nanowires and the methods described here may be useful in such investigations.

ACKNOWLEDGMENTS

We gratefully acknowledge support from the National Science Foundation (Grant ECS 0643761). The assistance of B. Fruhberger and R. Anderson at the Nano3 facility at UC, San Diego and discussions with A. Arriagada, M. Gollner, and R. Mifflin are appreciated.

37.1 INTRODUCTION

37.1.1 Metals and Alloys

Metals are a unique class of elements that provide special properties not available in naturally occurring materials such as wood, cement, and ceramics or in human-produced non-metallic polymeric materials. (Note: Some metals occur in elemental form in nature but most do not.) Since metals are frequently combined (alloyed) with other metallic and with some nonmetallic elements to produce alloys (metal combinations with certain desired properties), we refer all metallic materials in this chapter as “alloys” with the understanding that often pure or nearly pure metal elements may be used in design.

37.1.2 Purpose

The purpose of this chapter is to create a sufficient understanding of alloys so that selection of them for specific designs will be appropriate. The primary intent will be to cover alloy selection for structural purposes, that is, where the alloy must support its weight and, probably, the additional loads of a design. The chapter will provide sufficient information for the selector to work with designers to create successful components as well as to evaluate the capability of alloy providers and manufacturers to meet the required end uses of the design. To this end, mechanical, physical, and environmental property behavior that can influence alloy selection will be described.

There is no cook book for alloy selection. Proprietary alloys and/or proprietary/restricted processing can create conditions and properties not listed in a handbook or catalog of available alloys. Critical applications may require a selector to work with one or more manufacturers to develop an understanding of what is available and to determine what one can expect from a chosen alloy. At times, it may be necessary to develop a new or adapt different manufacturing processes for the utilization of alloys for specific applications.

37.2 COMMON ALLOY SYSTEMS

While there are many metallic elements, which are used to produce alloys, the more industrially important alloys in structural design are iron and its alloys (called ferrous alloys) or other (nonferrous) alloys based on copper, aluminum, magnesium, nickel, cobalt, titanium, and a handful of other metallic elements. Some special elements (e.g., zirconium and beryllium) also may find structural use in applications such as nuclear reactors or other devices. Precious metals (e.g., gold, platinum, and silver) are used for applications from jewelry to jet engines! Zinc-based alloys are important in die casting of small articles. [Note: The words *article* or *component* may be used interchangeably to indicate a designed item which, in service, will likely be part of a collection of items (e.g., a gas turbine). A gas turbine high-pressure turbine blade would be an article or a component.]

37.3 WHAT ARE ALLOYS AND WHAT AFFECTS THEIR USE?

Alloys, for purposes of this chapter, are solid entities of a given chemical composition, crystal structure, and metallurgical structure at the temperature of use. The range of temperature use can be from near absolute zero to many thousands of degrees. Alloys are made from metallic elements (and some nonmetallic ones added in minor amounts), which are recovered from various ores. In the process of recovery from ores and transfer to desired products, alloys most often are subject to melting (liquification), casting, and/or mechanical deformation processes. This chapter is not concerned with extraction from ores or the subsequent purification of alloy elements before the creation of specific alloys for structural use.

Alloys normally exist as a crystalline arrangement of individual atoms (see Figure 37.1). Aggregates of multiples of the basic crystalline individual units (e.g., face-centered cubic and body-centered cubic) are termed *grains*. These grains have the same arrangement/orientation of unit cells of the given alloy across their dimension. The mechanical properties of alloys are normally affected by chemistry and intrinsic unit-cell capability, grain size, grain shape and grain orientation, temperature, and certain other factors. Typically, properties of interest are tensile properties (Figure 37.2), fatigue properties (Figure 37.3), and high-temperature time-dependent properties such as creep rupture (Figure 37.4). Modulus of elasticity is another mechanical property used in design and additional properties such as toughness or crack propagation characteristics can be incorporated into structural design, though such properties are not always available.

The methods of preparing alloys can significantly affect their resultant properties. The preparation of an alloy normally will result from melting appropriate elements/alloys followed by pouring (casting) the molten alloy into a mold to produce an electrode for further primary melting or an ingot for remelting or for deformation processing. Generic mold shapes may be used to produce ingots if the cast alloy is to be remelted and cast into a specific mold shape (e.g., a blade for use in a gas turbine engine). Specific mold shapes may be used if articles are to be created directly by casting. The electrode, ingot, or component produced will show a “cast” structure, which will be influenced by the casting process and subsequent treatments applied to create the desired alloy properties.

Often, an alloy may be processed by one or more deformation processes, that is, a billet cut from an ingot may be formed to shape or mostly to shape by hot rolling, forging, and so on, to produce a “wrought” structure. There are a variety of possible cast structures

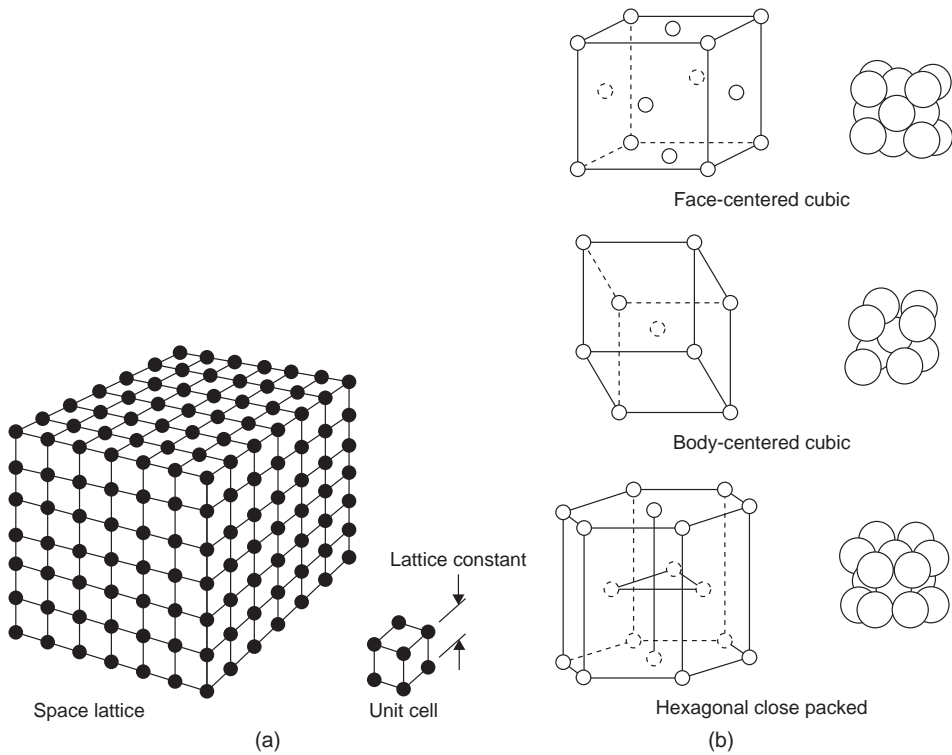

FIGURE 37.1 (a) Simple cubic lattice. Atoms are represented by solid spheres and, in this lattice, atoms are located at the corners of cubes which repeat indefinitely in three-dimensional space. (b) Common lattice structures for most metals/alloys.

FIGURE 37.2 Ultimate tensile strength, UTS or TS, and defined yield strength at 0.2% offset (inset), TYS or YS. Young's modulus is the slope of the elastic region before plastic deformation begins.

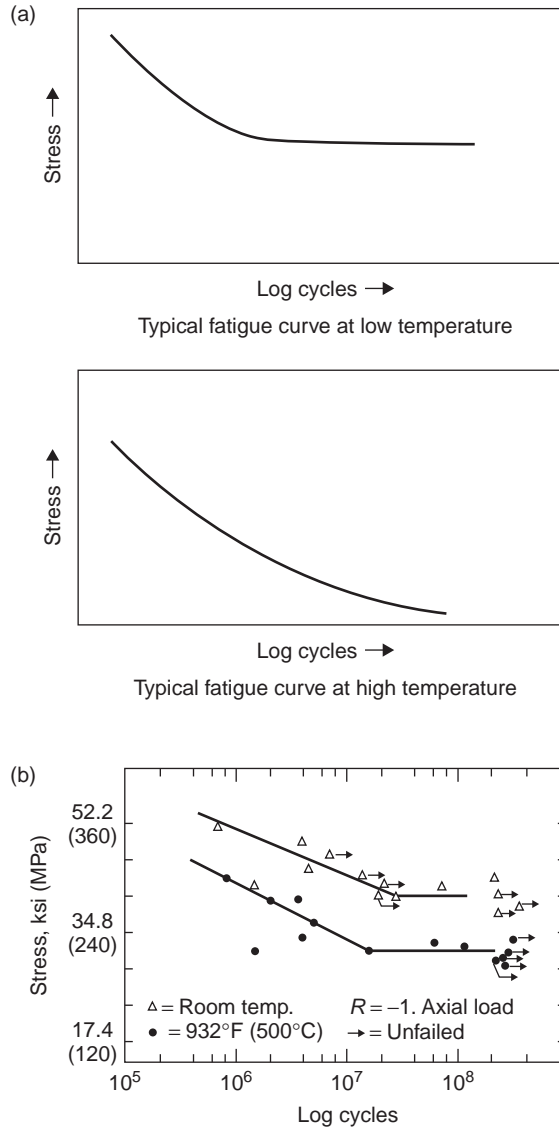

FIGURE 37.3 (a) Typical fatigue response at high temperature versus that at low temperature. (b) Actual fatigue curves at room and one elevated temperature for specific nickel-base superalloy.

as well as a variety of wrought structures. By examining a component under a microscope, microstructure (appearance at $100\times$ magnification and up) can be viewed. Alloys also can be examined at low magnifications for macrostructure (probably $1\times$ to $10\times$ magnification). Subsequent to production of a component, the application of special heating cycles (heat treatment) is often used to convey certain property values or characteristics to alloys. In-process heat treatments may be used during the shaping of the component.

FIGURE 37.4 Time-dependent deformation under constant load at constant high temperature followed by rupture. All loads below short-time yield strength.

37.4 WHAT ARE THE PROPERTIES OF ALLOYS AND HOW ARE ALLOYS STRENGTHENED?

Metals are crystalline as noted above and, in the solid state, the atoms of a metal or alloy may arrange themselves in various crystallographic groupings, often occurring as cubic structures. Some crystal structures tend to be associated with better property characteristics than others. Crystalline structure normally is a characteristic of the major (base) alloy element in an alloy. In addition to basic crystal structure, crystalline aggregates of atoms have orientation relationships in space. As noted, crystalline aggregates are called grains and, in an alloy, there are usually many grains with random orientation directions within each manufactured article. Metal alloy articles with multiple random grain directions are known as polycrystalline (frequently referred to as having equiaxed grain structure), often having roughly equal dimensions in all directions. However, columnar-shaped grains (with one relatively longer axis) are common in polycrystalline cast products.

Properties of alloys may be mechanical, physical, or chemical. Mechanical behavior encompasses the strength properties determined in appropriate tests and tends to be the more important properties for selection of alloys for structural applications. Some mechanical properties of alloys are tensile or compressive strength (e.g., onset of plasticity, yielding strength, and fracture strength under normal stress loading), fatigue strength (i.e., cycles to first crack or fracture or stress for a specific number of failure cycles), modulus of elasticity, and so on, which are measured primarily from lower to intermediate temperatures of operation. In addition, high-temperature mechanical properties such as creep or creep rupture strength, fatigue strength, and thermally induced fatigue capability are of concern but primarily at temperatures above about 0.5 of the absolute melting point of an alloy. At high temperatures, mechanical properties may be influenced by sequences of cyclic loading and time as well as frequency of load application in addition to temperature of testing.

Physical properties include heat capacity, electrical conductivity, thermal conductivity, and magnetic properties. Chemical properties may be of most concern in environmental attack when alloys for structural applications are considered. Intrinsic chemical properties

of alloys are modified (as are mechanical properties) by chemical changes during alloy invention and by heat treatment of alloys during processing. In addition, surface chemical properties are frequently modified by surface changes induced, for example, by coatings.

While the physical properties to a major extent depend on the chemistry of the alloy, the mechanical properties are dependent not only on the chemistry of an alloy but more importantly on the microstructure. Microstructure is assumed to mean grain shape, orientation, grain size, and so on, and the presence, absence, type, and location of new crystal phases in the alloy. The mechanical properties result from the interaction of imperfections such as dislocations with the microstructural components.

The peripheral surface of a grain is called a grain boundary. Aggregates of atoms without grain boundaries are rarely created in nature. However, alloys without internal grain boundaries (i.e., single crystals) or alloys with aligned boundaries (i.e., columnar-grained structures) can be produced in some systems by appropriate manufacturing techniques. The introduction of different atom types and new crystal phases and/or the manipulation of grain boundaries plus the use of stored energy of deformation enable inhibition of the movement of the imperfections (e.g., dislocations) that enable deformation to occur.

It is quite important for the engineer selecting alloys to have a realistic understanding of the strengthening process in alloys as the mechanical properties of alloys can be modified considerably by processing to manipulate the strengthening level achieved. The energy of mechanical deformation (working) can be stored in an alloy (work hardening), producing higher strengths than the unworked (e.g., soft, annealed) alloy. Alloys such as steels (ferrous alloys) can have increased strengths produced by the introduction of fine structure from transformations of crystal lattices. This fine structure usually results from the formation of nonequilibrium martensite phases (in preference to the expected equilibrium phases). The fine structure produced by the martensitic reaction acts to restrict deformation by dislocation movements. This type of hardening often produces very high strengths (as in iron alloys) but much reduced ductility. Subsequent heat treatment (tempering) normally is used to enhance ductility at the expense of strength in transformation-hardened alloys. Industrial use of martensite to strengthen alloys is most prevalent with iron-base alloys (containing carbon) or in titanium alloys.

Dislocation movement at lower temperatures is reduced not only by fine structure but also by smaller grain sizes. Ultimate tensile strength is not particularly affected by grain size changes, although ductility effects are noticed. As operating temperatures increase, finer grain size material usually becomes less strong than coarse-grained material. Increased temperatures and time at high temperatures may cause recrystallization (new grain formation and subsequent loss of stored energy) and/or grain growth. Consequently, work hardening to increase strength has upper limits of application since the high-strength benefits of (cold) work may be lost with time at higher operating temperatures.

Some alloys derive their strength from solid-solution hardeners (elements dissolved in the basis metal) as well as from secondary precipitates that form in the matrix (principal phase and produce precipitation (age) hardening from the dispersed particles. Precipitates may be phases or they may be zones of enrichment in one of the alloy elements present. In lower temperature use alloys, such as aluminum, age hardening may be from zones or phases. In higher temperature use alloys, precipitated phases are the norm. Principal strengthening precipitate phases vary with alloy but in nickel-base and iron-nickel-base super alloys they are ordered particles of γ' , η , and/or γ'' . Phases such as carbides may provide limited direct strengthening (e.g., through dispersion hardening) or, more commonly, indirectly (e.g., by stabilizing grain boundaries against movement at high

temperature). In some instances, ceramic (e.g., silica, yttria) or other phases may be dispersed mechanically instead of metallurgically in a matrix to produce dispersion hardening. Thus, the hardening of alloys can consist of

- solid-solution hardening,
- work hardening,
- dispersion/precipitate hardening (sometimes with ordered precipitates),
- transformation (martensite) hardening,
- grain size/morphology (shape/orientation) hardening.

The results of hardening vary by alloy and by the temperature of testing. Improvements in lower temperature short-time strength may not necessarily be transferred to high-temperature ranges of operation.

Control of grain structure can significantly influence mechanical properties. The extent to which the secondary phases contribute directly to strengthening depends on the alloy and its processing. It should be noted that improper distributions of phases such as carbides and precipitate phases can be detrimental to properties. Work hardening is an important characteristic of alloys since work hardening may be used to strengthen an alloy (Figure 37.5) but also may contribute to the need for intermediate heating (in-process annealing) during forging/forming of an article to prevent cracking of the article or damage to fabrication equipment.

FIGURE 37.5 Terms used in copper industry to indicate the degree of cold working are shown at the top of the plot.

37.5 MANUFACTURE OF ALLOY ARTICLES

Appropriate compositions of most alloy types can be worked, that is, they can be forged, rolled to sheet, or otherwise deformed mechanically into a variety of shapes. More highly alloyed compositions may be processed as castings. Castings may be less costly than equivalent forgings. Large and small castings can be made. Fabricated alloy structures can be built up by combining (joining) separate article pieces, particularly by welding or brazing, but the more highly alloyed the composition, the more difficult it may be to join an alloy.

Many alloys may be available and used in cast or wrought form. In the latter situation, alloys may be available in extruded, forged, or rolled form. Bar stock, strip, sheet, plate, wire, and other wrought forms/sizes may be obtained. Deformation of alloys may be performed hot or cold. Often, higher strength or “exotic” alloys are only able to be produced and used in the cast condition. Powder metallurgy (PM) processing is an accepted method to produce articles of difficult-to-process articles of certain higher strength or demanding alloys in “wrought” conditions. However, simple components of ordinary alloys, particularly of ferrous metals, are often produced by PM for reduced cost compared to conventional cast or wrought processing.

As noted above, cold deformation (work hardening), for example, by cold rolling, may be used to increase short-time strength properties for applications at low to intermediate temperatures. Energy stored by deformation processing is an accepted method for improving alloy mechanical properties below a use temperature of about 0.5 of the absolute melting point. As noted above, heat treatment (heating of components in sometimes multiple and complex steps) is frequently used to obtain desired mechanical property values.

37.6 ALLOY INFORMATION

There is no substitute for consultation with alloy producers or manufacturers about the forms (cast, wrought, and PM), which can be provided and the exact chemistries/properties available in alloys. It should be understood that not all alloys are readily available as off-the-shelf items. Although many thousands of alloy compositions have been evaluated, some for over a century, only a relative handful are routinely produced. Moreover, some alloys are not available for use in all forms and sizes. Sometimes, the highest strength alloys will be useful only as powder metal products or as castings. In many instances, specific alloy compositions may only be available at limited times in a production cycle.

Design data for alloys are not intended to be conveyed here, but Tables 37.1–37.9 offer limited information on some typical properties for a few alloy classes. Design properties should be obtained from internal testing if possible. Data from producers or other validated sources may be substituted if sufficient test data are not available in-house. Typical properties are merely a guide for comparison. Exact alloy chemistry, article section size, heat treatment, and other processing steps must be known to generate adequate property values for design.

The alloy selector needs to be aware that processing treatments such as forging conditions, heat treatment, and coatings for corrosion protection dramatically affect properties of alloys. All data should be reconciled with the actual manufacturing specifications and processing conditions expected. Alloy selectors should work with competent

TABLE 37.1 Elastic Moduli and Tensile Strengths of Selected Representative Metals and Alloys

Material	Elastic Modulus (GPa)		Tensile Strengths (MPa)
	Absolute	Specific

<i>Alloys</i>			
Aluminum	70	26	80–400
Copper	130	14	250–750
Iron	210	27	400–2000
Titanium	120	26	750–1500

metallurgical engineers to establish the validity of data intended for design as well as to specify the processing conditions that will be used for component production.

Application of design data must be taken into consideration the probability of components containing locally inhomogeneous regions under some circumstances. Short-time properties such as tensile strength may be little affected by local inhomogeneities. Time- or cyclic-dependent properties at high temperatures and cyclic properties at low to intermediate temperatures can be detrimentally affected by inhomogeneities. For wrought alloys, the probability of occurrence of such regions (which are highly detrimental to fatigue life) is principally dependent upon the melting method selected to produce the cast ingot for subsequent processing. For alloys, whether used as cast or in the wrought form, the degree of inhomogeneity and the likelihood of defects such as porosity are related to the alloy composition, the casting technique used, and the complexity of the final component. Defects may be detected by metallurgical surface examination, radiography, or sonic inspection, but all methods have limitations on the defect size that can be detected.

For sources of property data other than data from the producers (e.g., melters and forgers) of an alloy or from an alloy selector's own institution, one may refer to organizations such as ASM International, which publish compilations of data that may form a basis for the development of design allowables for many alloys. A list of some trade and professional organizations where alloy information may be obtained is provided at the end of this chapter.

Standards organizations such as the American Society for Testing and Materials (ASTM) publish information about alloys, but that information does not ordinarily contain design data. It is important to note that the same nominal alloy chemistry may have some composition modifications made from one manufacturer or customer to another. Sometimes, this extends from one country to another. Tweaking of the casting or "wroughting" processes or the heat treatment often associated with what seem to be minor

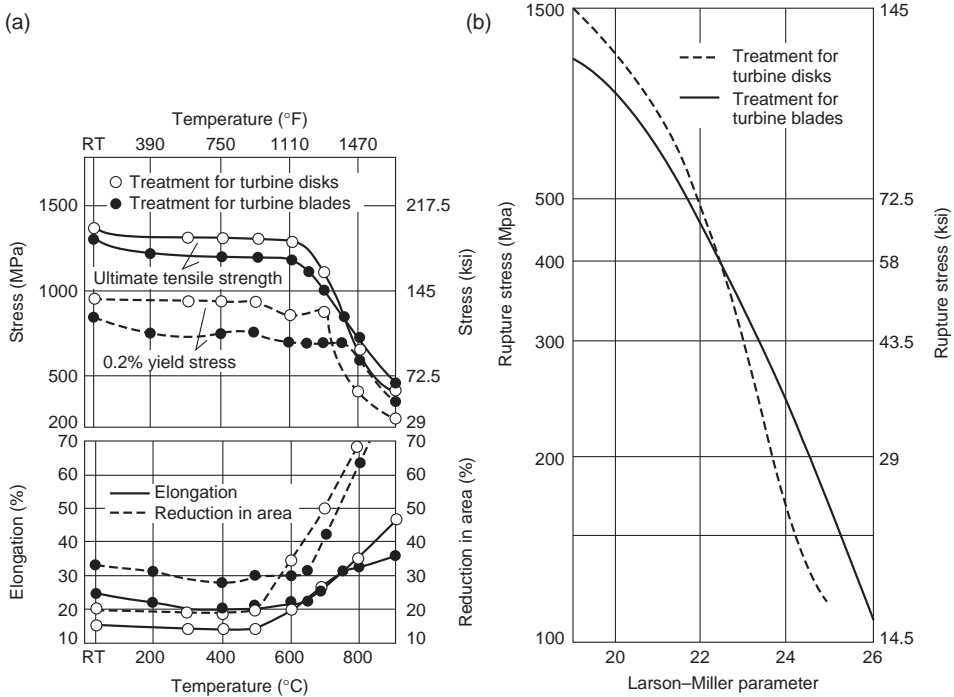

FIGURE 37.6 Heat treatment for two different applications showing how (a) tensile properties and (b) rupture properties differ; $P_{LM} = T(C + \log t)$, where $C = 20$ is Larson–Miller constant, T is absolute temperature (K), and t is time in hours. RT = room temperature.

composition changes can cause significant variations in properties. All facets of chemistry and processing need to be considered when selecting an alloy for an application.

There are instances when different heat treatments may be applied to the same nominal alloy composition with resultant differences in properties. An illustration of this is shown in Figure 37.6 where a wrought superalloy (Waspaloy) was produced for two different gas turbine engine parts, a disk and a turbine blade. Note the changes in properties. It is also not unusual for the heat treatments applied to cast parts of the same alloy composition to differ from the heat treatments for wrought products of the same alloy.

37.7 METALS AT LOWER TEMPERATURES

37.7.1 General

Alloy strengths at lower temperatures (usually considerably below $0.5 T_m$) are not a function of time under normal conditions. Environmental attack (general overall corrosion, selective corrosion, etc.) can be significant and will be a function of time, temperature, and environment. Presence of notches and/or cyclic conditions may cause premature failure of a component. Consequently, in addition to evaluation of tensile (e.g., ultimate, yield strengths) properties, possible environmental considerations should be checked and

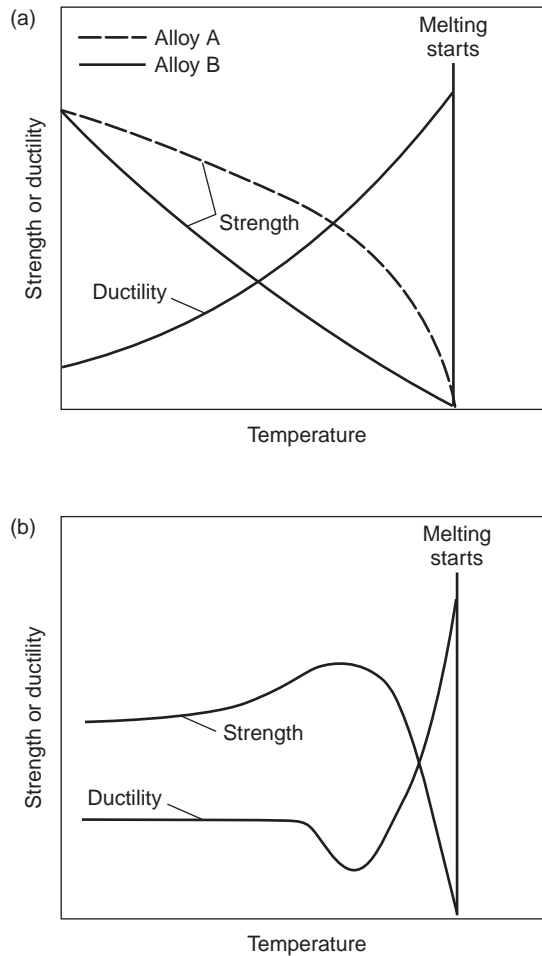

FIGURE 37.7 (a) Most metals and alloys show a decrease in strength and increase in ductility as temperatures increase. (b) Superalloys precipitation hardened by γ' particles often show peak in strength and minimum in ductility as temperatures increase.

the fatigue (low cycle/high cycle, smooth/notched) strengths, crack propagation characteristics, and toughness behavior should be reviewed.

37.7.2 Mechanical Behavior

Temperature or time of load application may influence the property behavior, including failure mode, of an article in mechanical testing. Failure may be defined as initiation of a crack or of fracture of an article into two or more pieces. In case of short-time tensile properties (yield strength, ultimate strength), strengths usually are reduced as temperatures increase from absolute zero to higher temperatures near about 0.5 of the absolute melting temperature. Figure 37.7 illustrates the trends in tensile strength and ductility of alloys as temperatures increase.

FIGURE 37.8 Charpy V-notch energy versus temperature behavior for steel.

Ductility of an alloy, as measured by elongation at fracture or reduction of area in cross section after fracture, tends to increase with temperature. Sometimes, ductility or toughness of an alloy is measured by energy absorbed during impact tests. Strength properties tend to appear in design calculations while ductility values do not. Ductility is considered important in actual alloy use since limited ductility may cause an alloy article to fail with no immediate prior indication of likelihood of failure. The “forgiveness” of higher ductility alloys makes designers more comfortable with application of some alloys. Attempts to build “ductility” considerations into alloy selection and design resulted in various types of fracture toughness property concepts being developed and applied to alloy selection. Fracture toughness (critical fracture toughness) is one concept for which design data may be available for alloys. Higher fracture toughness is most desirable, as is higher ductility.

Some alloys may exhibit a “ductile-to-brittle” transition. This concept occurs when an alloy undergoes a rapid transition to much lower failure ductility over a very small temperature range on cooling of the alloy. Steels, for example, may show a ductile-to-brittle transition, particularly at temperatures below room temperature. Figure 37.8 illustrates how toughness, as measured by ductility, for steels drops as temperature decreases (and carbon content increases).

Hardness properties (usually measured by means of standard indentation tests) may be used to judge an alloy’s strength capability at lower temperatures and confirm the results of heat treatment but play no role in design.

37.8 METALS AT HIGH TEMPERATURES

37.8.1 General

While material strengths at low temperatures are usually not a function of time, the time of load application, at high temperatures, becomes very significant for mechanical properties. Concurrently, environmental attack by oxygen and/or other elements at high temperatures accelerates the conversion of some of the metal atoms to oxides or other compounds. Environmental attack proceeds much more rapidly at high temperatures than at room or lower temperatures. Environmental considerations can vary significantly with different types of environment and different temperatures, in some instances, showing a

greater rate of attack at one temperature than the attack of the same alloy at a higher temperature. As in the case of lower temperatures, presence of notches and/or cyclic conditions may cause premature failure of a component. Thus, in addition to evaluation of short-time tensile (e.g., ultimate, yield strengths) properties, creep rupture properties, fatigue, and thermomechanical fatigue (smooth/notched) strengths, crack propagation characteristics, toughness behavior, and possible environmental considerations should be checked.

37.8.2 Mechanical Behavior

In case of short-time tensile properties (yield strength, ultimate strength), the mechanical behavior of alloys at higher temperatures is similar to that at room temperature, but with alloys becoming weaker as the temperature increases. However, when steady loads below the normal yield or ultimate strength (determined in short-time tests) are applied for prolonged times at higher temperatures, the situation is different. Figure 37.4 illustrates the way in which most alloys respond to steady extended-time loads at high temperatures.

Because of the higher temperature, a time-dependent extension (creep) is noticed under load. If the alloy is exposed for a long time, the alloy eventually fractures (ruptures). The degradation process is called creep or, in the event of failure, creep rupture (sometimes stress rupture) and alloys for elevated temperature use are selected on their ability to resist creep and creep rupture failure. Data for superalloys frequently are provided as the stress, which can be sustained for a fixed time (e.g., 100-h rupture) versus the temperature. Figure 37.9 shows such a plot with ranges of expected performance for various superalloy families.

One of the contributory aspects to elevated temperature failure is that alloys tend to come apart at the grain boundaries when tested for long times above about 0.5 of their absolute melting temperature. Thus, fine-grained alloys that are usually favored for lower temperature applications may not be the best materials for creep-rupture-limited applications at high temperatures. Elimination or reorientation/alignment of grain boundaries is sometimes a key factor in maximizing the higher temperature life of an alloy.

A factor not often recognized in mechanical behavior is that the static modulus (e.g., Young's modulus E) is affected by increases in temperature. This should be obvious from the above discussion about creep. The dynamic modulus of alloys shows a decrease with increasing temperatures. However, dependent on rate of load application, as test temperatures increase, static moduli determined by measurements from a (short time) tensile test tend to gradually fall below moduli determined by dynamic means. Because moduli are used in design and may affect predictions of life and durability, every effort should be made to determine the dynamic, not just static, moduli of alloys for high-temperature applications. Table 37.10 shows dynamic moduli of cast superalloys for illustration.

Moduli of cast alloys also may be affected dramatically by the orientation of grains or by use of single crystals. Thus, a columnar grain nickel-base super alloy will show a dynamic modulus parallel to the growth direction of the columnar grains that is around 18×10^6 psi (124.1 GPa) at 70°F (21°C). This is much lower than the polycrystalline (random-orientation) value of around 30×10^6 psi (206.8 GPa). A more accurate method of depicting moduli would be to use the appropriate single-crystal elastic constants (three needed) of an alloy, but these are rarely available.

Cyclically applied loads that cause failure (fatigue) at lower temperatures also cause failures in shorter times (lesser cycles) at high temperatures. For example, Figure 37.3

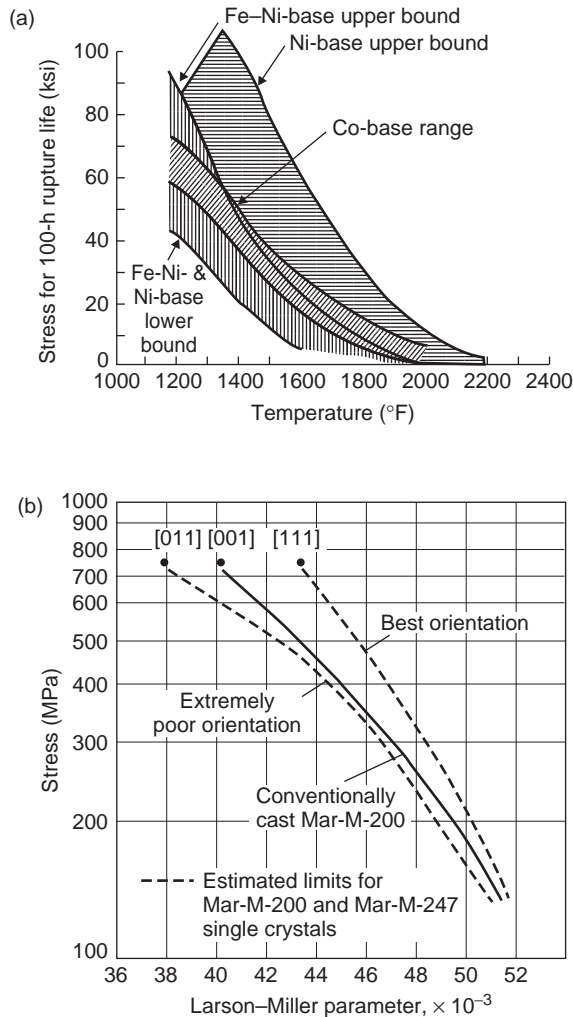

FIGURE 37.9 (a) Stress for 100-h rupture life for three classes of superalloys. (b) Log failure stress versus Larson–Miller parameter for single-crystal nickel-base superalloys in three possible test orientations ($P_{LM} = \text{actual } P_{LM} \times 1.8$). $P_{LM} = T(C + \log t)$, where $C = 20$ is Larson–Miller constant, T is absolute temperature (K), and t is time in hours.

shows schematically how the cyclic resistance is degraded at high temperatures when the locus of failure is plotted as stress versus applied cycles (S – N) of load. From the S – N curves shown, it should be clear that there is not necessarily an endurance limit for metals and alloys at high temperatures.

Cyclic loads can be induced not only by mechanical loads in a structure but also by thermal changes. The combination of thermally induced and mechanically induced loads leads to failure in thermomechanical fatigue (TMF). TMF failures occur in a relatively low number of cycles. Thus, TMF is a low-cycle fatigue (LCF) process (less than about

TABLE 37.10 Dynamic Modulus of Elasticity for Selected Cast Superalloys

Alloy	Dynamic Modulus of Elasticity					
	At 21 °C (70° F)		At 538 °C (1000 °F)		At 1093° C (2000° F)

10⁵ cycles). LCF can be induced by high repeated mechanical loads while lower stress repeated mechanical loads lead to fatigue failure in a high number of cycles (HCF greater than 10⁶ cycles). Dependent on application, LCF failures in structures can be either mechanically induced or TMF type. In airfoils for the hot section of gas turbines, TMF is a major concern. In highly mechanically loaded parts such as gas turbine disks, mechanically induced LCF is the major concern. HCF normally is not a problem with alloys unless a design error occurs and a component is subjected to a high-frequency vibration that forces rapid accumulation of fatigue cycles. Although $S-N$ plots are common, the designer should be aware that data for LCF and TMF behavior frequently are gathered as plastic strain (ϵ_p or $\Delta\epsilon_p$) versus applied cycles. The final component application will determine the preferred method of depicting fatigue behavior.

While life under cyclic load ($S-N$ behavior) is a common criterion for design, resistance to crack propagation is an increasingly desired property. Thus, the crack growth rate (da/dn) versus a fracture toughness parameter is required. The toughness parameter, in this instance, is the stress intensity factor K range ΔK over an incremental distance, which a crack has grown. A plot of the resultant type (da/dn vs. ΔK) is shown schematically in Figure 37.10.

37.9 MELTING AND CASTING PRACTICES

37.9.1 Melting

To produce most alloys, the appropriate chemistries are made liquid; mixing occurs (if more than one element or master alloy is present) and then the liquid is poured into containers (molds) to produce the desired shape. Most alloys have melting points sufficiently

FIGURE 37.10 Three regions of crack growth response.

low that they can be melted and cast to shapes economically and with acceptable purity and quality. Melting consists of providing a furnace with an appropriate (usually ceramic-lined) crucible to contain the molten-metal charge and a power source (usually gas or electricity) to produce the appropriate temperatures for melting. For common industrial alloys (white metals, magnesium, aluminum, copper, steels, and superalloys), the melting range needed probably varies from around 800°F to about 2500°F. Melting temperatures for some alloys such as titanium alloys range higher than this.

As indicated earlier, there are occasions when a primary alloy to eventually be used in a final article shape is cast into an electrode or an ingot one or more times before an article is produced. Electrodes are the precursors to final forged or deformation processed articles. They are intended to be remelted by electrical energy to refine chemistry, microstructure, and so on, prior to being cast as ingots to be delivered to the manufacturer who may cut the ingots to billets from which to make the (raw shape at least) final article by deformation processing. Cast ingots may be remelted without additional processing for use in the direct casting of articles. Alloys produced using the variety of available furnaces in ambient air environments satisfy most common needs. Vacuum melting and similar processes produce higher quality alloys and usually are the production melting methods of choice for applications such as those in aerospace.

For metals such as titanium alloys and superalloys, melting is done under vacuum to retain and/or enhance an alloy's properties. Ordinarily, most alloys to be cast into articles or ingots (which are then processed into billets for wrought processing) are melted open to the atmosphere (air) except for the use of slags on the molten-alloy surface to minimize pickup of gases or loss of elements from the molten alloy or to introduce elements to the alloy from the slag. Furnaces may be resistance wire heated, gas fire heated, arc heated, or induction heated. For more sophisticated melting, especially where vacuum is required, alloys may be heated by induction, arc, electron beam, or plasma. The latter three processes can produce higher local heat input and so may be used to melt alloys such as titanium. The more sophisticated the melting techniques, the higher the cost but, generally, the better the quality.

Vacuum induction melting (VIM) is used for super alloys and, in some instances, stainless steels. The VIM furnace consists of a ceramic-lined crucible built up around water-cooled induction coils. The crucible is mounted in a vacuum chamber. The vacuum chamber may have several vacuum ports (of various sizes) built into it so that, without breaking vacuum,

- charge material may be introduced into the crucible,
- molds may be introduced into the chamber, and
- systems for removing slag from the pour stream (tundish) may be introduced.

Sampling of the molten metal is required for chemistry control in primary alloy production and when the VIM unit is producing ingot for subsequent processing. VIM is more costly than electric arc furnace or other routine processes for melting alloys. A major advantage of VIM is excellent control of chemistry and reduction of impurities such as gases (oxygen and nitrogen) and detrimental tramp elements. Sometimes, in lieu of VIM, an alloy (e.g., of steel) may be vacuum degassed (VD) after melting but before pouring into molds. Improved properties result from VIM or VD processing. The essence of selecting a melting process to create the desired composition and electrode/ingot/cast article structure hinges on the correct choice and adaptation of melting principles and attention to detail in processing.

Consumable vacuum arc remelting (CVAR, most often referred to as VAR) is used to primary melt and to remelt titanium and to remelt superalloys. High heat inputs can be achieved and the alloys are cast into water-cooled molds. No slag is used but rather the ultrahigh vacuum acts to protect the alloy. An electrode is used to strike an arc between the consumable electrode of the alloy and a striker plate in the water-cooled mold. The molten metal produced from the electrode by the arc drips into a pool and solidifies in characteristic ways related to alloy composition, melt rate, mold size, and so on. Generally, the mold is larger than the electrode. Molds for VAR processing are circular. Sometimes, multiple VAR is applied to an alloy.

Another melting process is electroslag remelting (ESR), which uses an arc within the slag to produce heat that melts the face of an electrode. In ESR, current is applied to an electrode situated inside a water-cooled crucible containing a molten-slag charge. The intended circuit of current is from the electrode, through the molten slag, through the solidifying ingot, through the water-cooled stool, and back to the electrode. The molten droplets from the electrode face fall through the slag to a molten pool and then solidify. Changes in chemistry can be effected in ESR to a

greater degree than in VAR processing. There are subtle aspects of the processing for both VAR and ESR, which may be discussed with a knowledgeable alloy producer. For superalloy primary melting, where larger ingot sizes of highly alloyed materials are needed, VAR is used in preference to ESR.

VAR and ESR are secondary melting processes (following primary VIM melting to produce electrodes). Several producers of critical rotating super alloy components in the gas turbine industry have adopted the use of a hybrid secondary melt process. Primary melting by VIM to ensure production of a low-oxygen, precise chemistry, initial electrode is followed by ESR. The ESR electrode will be clean and sound. The clean, sound electrode is then remelted by VAR. The improved cleanliness and soundness of the electrode facilitate VAR control. This product is referred to as “triple melt” and has a much reduced frequency of defect occurrence compared to double-melt (VIM + VAR) superalloy product. The cost of the triple-melt process is clearly higher than double melt (VIM + VAR or VIM + ESR).

As noted, alloy-melting practices may be classified as either primary (the initial melt of elemental materials and/or scrap which sets the composition) or secondary (remelt of a primary melt for the purpose of making larger electrodes, controlling the solidification structure, etc.). The melt type or combination of melt types selected depends on both the alloy composition and intended application (mill form and size desired, properties desired, sensitivity of the final component to localized inhomogeneity in the alloy, economics, etc.).

Although not widely used owing to economic considerations, the use of electron beams or plasma playing on the surface of an electrode and on the molten pool provides an alternate source for clean melting of some specialty alloys.

37.9.2 Casting to Prepare for Subsequent Processing

When alloys are cast, the resulting object may be (a) an electrode for remelting, (b) an ingot to be melted (in whole or in part) later and then cast into articles, (c) a cast article of commerce, or (d) an ingot for processing into billet. This section discusses the casting of ingot for later use, not directly into articles of commerce.

From the billet, wrought-shaped articles may be formed. Also from billet stock, mill products may be produced. Mill products would be bar, plate, sheet, wire, and so on, which might later be deformation processed into a shape or used directly. For example, bar stock might be machined into fasteners while wire might be sold and used with no further processing. Alloys usually not only are available in standard mill forms (plate, sheet, and bar, from which components may be machined) but also may be produced as specific component shapes by the use of forging (or casting). It is critically necessary that the property requirements of a component be fully understood to maximize properties and minimize costs. For instance, a component selected to resist corrosive attack may not need to be melted by a process that assures maximum fatigue resistance.

The most critical feature of melt process selection is the size of the component to be manufactured from an ingot. Larger components require larger ingot sizes. The higher the melting point of an alloy and the more highly alloyed the chemistry of the alloy, the greater may be the restrictions of maximum ingot size. For forged components, consideration must be made not only of the final component size but also of the capability of the ingot to be sufficiently deformed so as to develop the properties characteristic of a forged structure. Internal ingot cleanliness is also a consideration in selecting the melting route.

Many alloys will have no special cyclic requirements and routine melting and casting to ingots is the rule. However, for more sensitive applications (e.g., aircraft structures), more stringent requirements will exist. Generally, for fatigue-sensitive components, a melt practice is selected which will guarantee the best structure. The needs of sensitive applications may require the generation of specific structure in an ingot cast and machined to billet. For example, a specific grain size may be required by the wrought processor to obtain the ultimate customer's specified properties after a forging process and subsequent heat treatment. Specific grain sizes and/or ingot surface finish may be required to maximize the effectiveness of ultrasonic or etch inspections. The processes for producing ingot for sensitive wrought-product applications will require that the alloy selector work closely with the melter and forger on the melt-to-ingot-to-billet-to-article sequence. Those selecting materials for less critical articles may be able to rely on standard "mill" practices to generate adequate product.

37.9.3 Casting Practices for Producing Articles

Generally, cast articles are made by remelting ingots of the desired alloy. Articles may range from grams (ounces) in weight for jewelry (e.g., rings) to tens or hundreds of pounds (machinery, vehicle applications, power turbine components, and aircraft gas turbine components). The casting invariably is done in a foundry. The alloy generally is melted in smaller versions of the furnaces used to do primary/secondary melting to produce ingots. Melting in the furnace is done in crucibles, which are almost always ceramic-lined containers. To cast an article after it has been designed, a copy of the design must be replicated as a negative cavity in a mold. Obviously, the mold must be resistant to attack by the molten alloy to be poured into it.

Multiple molds generally are prepared and dependent on the weight/size of the intended cast article. The molds must be connected in such a way that transfer of liquid alloy to them is easy. Design of molds is critical to successful casting. The cavity in the mold must be slightly larger than the intended article to provide for the shrinkage that occurs in the solidification of alloys. There will be a basin or tundish into which the molten metal is poured and from which the metal is dispersed to the individual molds. To transfer the metal and properly feed the cavities, various channels (sprues, risers, runners, etc.) are needed. The final mold assembly must have sufficient rigidity to be stored and to be moved into place for casting at the appropriate time.

Different media are used for molds. Sand is a common and an inexpensive molding material and plaster and other similar compositions may be used. Surface finish and dimensions are affected by the molding material as is the cost of the casting process. In some instances, molten metal can be melted and injected into water-cooled metal dies producing fine definition with die-cast articles. The alloys used for such processing are lower melting alloys but work has been done to cast high-temperature alloys this way. Cost will be a factor and die casting is more commonly a process for large runs of small-to moderate-size articles such as medals cast in moderate-melting-range alloys.

Complex shapes can be produced by casting. Often, the article shape is such that cores must be added to the negative cavity to produce desired passages and holes in the finished casting. Most routine casting will not require extra thin article walls or extra high tolerances. However, for aircraft or power gas turbine parts, in particular, very high tolerances are required and wall thicknesses (nickel-base superalloys) may drop to 0.040 in. (0.101 cm) or so.

The principal casting practice for high-precision casting is investment casting (also known as the lost-wax process). A reverse-cast model of the desired component is made and wax is solidified in the resultant die. Then, a series of these wax models are joined to a central wax-pouring stem. The assembly is coated (invested) with appropriate ceramic, processed to remove wax, and fired to strengthen the invested ceramic mold. A small percentage of a (VIM) alloy ingot is remelted and cast into the mold. Upon solidification, a series of components in the desired form are created, attached to the central pouring stem. These objects, frequently gas turbine hot-section airfoil components, are removed and then machined and processed to desired dimensions. Superalloy investment-cast cases now are available up to about 40 in. (101.6 cm) in diameter. Titanium alloys similarly can be cast in large sizes using investment-casting techniques. Turbine airfoils can now be cast not only in smaller sizes for aircraft gas turbines but also with airfoil lengths of several feet for land-based power turbines.

Most investment-cast articles are of conventional, polycrystalline structure with more or less randomly oriented grains. Mechanical properties are nominally random but may show some directionality. Increased high-temperature property strength levels have been achieved in nickel-base superalloys by columnar grain directional solidification (CGDS), which removes grain boundaries that are perpendicular to the applied principal load in turbine airfoils. The ultimate solution for optimum high-temperature strength is single-crystal directional solidification (SCDS) to produce a superalloy with no grain boundaries. Maximum creep rupture strength in nickel-base superalloys now is achieved with SCDS alloys. SCDS has been applied not only to aircraft gas turbine engines but also to large-frame land-based gas turbines. Most alloy systems used commercially have not shown a need for increases in the high-temperature strength, which might be produced by single-crystal casting. Such processing would considerably increase cost and property improvements with SCDS depend on alloy chemistry. Certain nickel-base superalloys are the only alloys where acceptable cost-benefit trades are possible.

37.9.4 Casting Considerations in Alloy Selection

Alloy selection for cast articles generally will be on the basis of alloy type needed (e.g., copper and aluminum) and then on specific alloys within the selected type so as to provide the desired properties. Not all alloys are equally good for casting. In many alloys systems, compositions of casting alloys differ from those of alloys used for wrought applications. Depending on the application, there may be more or less tolerance for lesser quality castings. Need for pressure tightness, for example, might dictate a casting process different from that for another application. Casting defects occur and vary with alloy composition, article shape, and dimensions, as well as casting practice. Oxide (dross) carried over from the alloy-melting production process may cause surface and internal inclusion problems in some alloy systems. Porosity is another major concern, especially with large castings. Porosity may be controlled by mold design and pouring modifications. In some alloy systems where articles for critical applications are required, non-surface-connected porosity may be closed by hot isostatic pressing (HIP) of the cast articles. Surface porosity in large castings may be repaired by welding. Other casting concerns may include surface finish, intergranular attack (IGA) caused during chemical removal of molding materials, selectively located coarse grains in PC materials, and so on. Sometimes, alloys may be modified in chemistry to optimize product yield but with a possible compromise in properties. Product yield is an important determinant of final component cost.

37.10 FORGING, FORMING, POWDER METALLURGY, AND JOINING OF ALLOYS

37.10.1 Forging and Forming

Forging is one of the most common methods of producing modest production lots of wrought articles for alloy applications. Mill products such as bar stock and wire generally are produced in greater quantities than forgings but, for the most part, are used to make non-complex shapes. The most demanding applications use wrought forged ingot metallurgy components. One or more intermediate shape stages usually are involved when conventional forging is practiced. Special processing by isothermal (usually superplastic) forging may enable the forging to go directly from billet to final stage in one step using a closed die.

A billet is the precursor to a forging in large-sized articles. Billets are transformed (forged) to shapes approximating the final desired shapes with the approximation dimensions being dependent on the alloy system and known issues in the forging process. Multiple reductions may be needed and blocker dies (open dies) may be needed before closed die forging to final dimension/shape. Forging may be accomplished with one or a group of dies and in open or closed dies. While closed dies better define the finish form of a forging, the cost of using such dies exceeds that of open dies. Some dies may be just flat platens that are used to transfer the forging load. The more complex the dies, the more difficult it becomes to extract heat. Significant costs can be incurred for die design and procurement.

Forging is usually a process carried out at elevated temperatures with the temperature being determined by alloy composition, amount of reduction needed, and so on. Forging always requires significant deformation of the alloy as it is transformed from billet to article. Sometimes, the forging deformation is retained to increase strength; sometimes forging is used to modify the microstructure of the article when forging is combined with appropriate heat treatments. In the case of high-performance superalloys, the objectives of a forging cycle may be:

- uniform grain refinement
- control of second-phase morphology
- controlled grain flow
- structurally sound component

Hot forging is a multistep process with several to many cycles of heating to forge temperature, then forging, followed again by heating, forging, and so on.

Forming, while containing elements of deformation, generally restricts itself mostly to sheet that, for example, may be bent or formed to a mandrel or other forming die. Forming of automotive hoods from sheet metal would be an example. Deformation induced in forming may not be extreme and forming is not used to control microstructure and properties of alloys. Basically, forming produces relatively two-dimensional shapes while forging produces three-dimensional shapes with distinct properties. Roll forming is often used to produce small shapes from bar stock or rod.

There are two major types of forging: open die and closed die. Open-die forgings are less expensive but in general require more stock removal by machining to get to the finish dimensions. Closed-die forgings are more costly but reduce the machining needed to achieve finish dimensions in the article. In forging, alloy billets are squeezed between

two platens or dies using an appropriately sized press. Several to many forging steps may be needed to bring the billet to the approximate article shape and dimensions. A great deal of skill is necessary not only in die design but by the operators of the forge presses in order to achieve optimum properties and cost balances. As alloy strengths increase, it becomes increasingly difficult to move an alloy around during forging. When higher forging pressures are required, defects become more probable.

Superplastic forming became available in the 1960s and was first used to produce aluminum alloy door panels, for example, for high-end automotive vehicles. Superplastic forging was introduced for super alloys when the strengths of alloys were bumping up against metallurgical limits and forging was becoming too difficult. A process called superplastic forming/diffusion bonding was developed in the air frame business to produce large articles with better properties than existing technology could produce. This is a high-technology process without applicability to processing routine materials.

37.10.2 Powder Metallurgy Processing

PM has been in use for many decades, dating back over 50 years. The principal intent of PM was/is to produce alloy articles at less cost. However, since the latter part of the twentieth century, PM also has meant a way to create billets of the highest strength alloys (without casting) and subsequent forging of billets to final parts. Different powder production manufacturing processes exist for alloys. A common practice is gas atomization where a prealloyed ingot is remelted and then blasted by a jet of air/argon/helium to produce powder in a chamber. The powder is recovered and classified for size, for example. Powder production generally is a batch process.

Molds (dies) for making PM parts are made to the shape of the planned article and then filled with powder, tapped, pressed, and sintered (high-temperature heated) or otherwise metallurgically bonded (by heat/pressure) to increase density and properties. The process often can be automated. Dimensions of dies will need to reflect the expansion coefficient of the die material and the alloy powder. There are different process variables in PM, including multiple methods of powder production. Compaction consists of processes such as cold pressing or vacuum hot pressing or HIP, among others. Some high-strength superalloys are made only by PM methods. Because powder articles made by other than HIP are not 100% dense, there will be porosity in the form of very small voids in the powder article compact. For the most part, a small number of defects such as holes do not significantly affect the properties of alloys, at least in static tests. For fatigue-limited applications, higher quality production processes would need to be used.

A relatively new aspect of the use of PM is in the superalloy field where alloys, which can be cast in relatively small parts such as turbine blades, are not workable by cogging, forging, and so on, to produce a billet for disk forging. By using powder of the desired alloy, a compact of the desired article can be made by HIP or extrusion and then the compact can subsequently be worked (usually forged) to final shape and machined to produce a higher strength wrought article than can be produced from conventional wrought-alloy (“ingot metallurgy”) procedures.

37.10.3 Forging/Working Considerations in Alloy Selection

The stronger the alloy to be utilized in design, the more difficult it will be to manipulate by mechanical working forces. In addition to working difficulties, problems with ordinary

forgings can arise from many sources. Poor grain size control, grain size-banded areas, poor second-phase morphology/distribution, internal cracking, and surface cracking are among the sources for rejection of forged parts. Limits exist on the capability of an alloy to be worked without cracking, encountering other defects, or stalling a forge or extrusion press. Some shaping equipment such as rotary forging devices may be better able to change the shape of the stronger alloys than other equipment. PM offers an alternate processing route for high-strength alloys such as superalloys used for rotating disks, shafts, hubs, and so on, in aircraft and power generation turbines. Powder production reflects an art that is not always directly transferable from one producer or one alloy to another. Powder components are best made by producing an ingot from powder and then forging the ingot to component shape. Extensive work with an alloy melt shop and an associated powder producer may be necessary to create a satisfactory metal powder of a high-strength/high-performance alloy selected for design.

37.10.4 Joining

Welding, soldering, and brazing are used to manufacture articles in many instances. Soldering is a lower temperature, less than 800°F (427°C), process of letting molten metal be drawn into a very tight crevice between the components to be joined and then allowing it to be solidified. Brazing is accomplished in the same general way, but the braze alloys melt above about 800°F (427°C). Braze alloys produce stronger bonds than solder alloys. Solder finds extensive use in the electronics industry. Brazing is more often found in structures that require relatively high strength. Such structures might be aircraft gas turbine stator assembly parts, for example.

Welding produces a metallurgical bond between components of an article. There are many welding processes. The simplest definition is solid-state bonding versus fusion welding. Relative to fusion welding, resistance welding techniques are low-cost methods to join parts such as tabs on sheet metal. Arc welding is perhaps the most common fusion welding technique with higher quality associated with gas–tungsten arc or gas–metal arc welding. There are other techniques used for massive structures and also specialized techniques that produce maximum-quality welds. Those techniques use electron beams, laser beams, or plasmas to heat the weld metal. Relative to solid-state welding, a number of techniques exist, including friction or inertia bonding, diffusion bonding, and ultrasonic bonding. The success of these techniques is dependent on clean surfaces and optimum bonding areas.

Many complex articles in devices such as gas or steam turbines were/are combinations of components joined to produce a larger article. In some applications, when the joined article is not too large or complex, efforts have been made to replace such articles with cast components. However, surface-connected defects often are found in large superalloy castings. In addition to large superalloy castings, many articles produced in industry can have production defects. If defects can be repaired, articles may be acceptable for service. Consequently, repair welding is used with great frequency, dependent on the dollar value of the article and other economic and availability aspects.

37.10.5 Considerations in Joining Process Selection

An alloy selector will need to consider the weldability or joinability of an alloy before suggesting initial production use of joining techniques and/or their use in repair. Many

nickel-base superalloys are not weldable. High-performance alloys such as titanium alloys and sheet metal of cobalt-base, solid-solution-strengthened nickel-base and lower hardener content nickel-base alloys can be joined as can iron-nickel-base alloys. Aluminum alloys can be welded with high-heat input welding techniques. Some techniques such as electron beam welding (EBW) may be best for high-performance materials owing to the vacuum environments of the processes and the very narrow fusion zone that is created in the process. High-vacuum EBW and similar joining processes may not find wide use in production of large quantities of consumer goods owing to the cost of the process. On the other hand, the use of nonvacuum electron beam welding (NVEBW) has been shown to be cost effective for steels used in auto frames.

37.11 SURFACE PROTECTION OF MATERIALS

37.11.1 Intrinsic Corrosion Resistance

Most alloys are not intrinsically resistant to surface attack by corrosion. Precious metal alloys containing gold or platinum may be chemically stable. Most alloys consist of metallic elements that want to revert to compounds (e.g., oxides) in chemical states such as those in which the elements are found naturally. Corrosion is the interaction of elements in an alloy with the environment to produce chemical compounds. Surface attack occurs most frequently as the surface is the primary interface with the surroundings of an article in use. Most typically, articles “see” oxygen from the air and a water-based environment owing to humidity in the air. The processes of uniform corrosion in aqueous environments and with selected other environments are fairly well understood. Corrosion also can take place in nonuniform ways through the action of or development of pits, crevices, or cracks. Under some circumstances, individual alloy elements may be selectively removed from an alloy.

Using an understanding of the nature of the corrosion process, metallurgists have developed alloys that have improved resistance to corrosion in a variety of environments. In fact, many alloys containing certain elements such as chromium or aluminum demonstrate natural resistance to corrosion in oxidizing environments. However, alloys that are corrosion resistant in oxidizing environments often are not resistant in reducing environments, especially when attacked in the presence of halide elements such as chlorine. Some alloys/elements are more noble with respect to other alloys/elements. One representation of the corrosion sensitivity of alloys is the “galvanic series of alloys/elements.” Alloys/metals that do not corrode or are more corrosion resistant in aqueous environments are called noble or cathodic while more corrosion prone alloys/elements are called active or anodic. Table 37.11 shows a galvanic series for some commercial alloys and metals in seawater. Note that some more common alloys other than those of the precious elements are near the top. Specifically, titanium and its alloys are very resistant to aqueous corrosion. Similarly, titanium alloys display excellent corrosion resistance in body fluids. Consequently, titanium alloys are often choices for applications such as prostheses for bone implants or in dental work. Commercially, pure titanium finds extensive use in the chemical processing industry.

Although cast iron and steel are near the bottom of the series and so are active (steels rust in most instances of environmental exposure), chromium additions to iron can produce a passive layer that inhibits oxidation. Hence, alloys of iron with sufficient chromium additions became “stainless.” Stainless steels are near the top (cathodic end) of the

galvanic series and perform very well in a variety of commercial applications. Some construction steels are alloyed to produce a rust-resistant finish and are used for uncoated/unpainted steel work on bridges, guard rails, and so on.

Different alloys may display varying behavior dependent on the environment. In some instances, alloys that display good aqueous corrosion resistance (general corrosion attack resistance) show tendencies to selective attack such as that which occurs in stress corrosion. Connections between anodic and cathodic alloys in service invariably lead to accelerated attack of the anodic element/alloy.

Some alloys have moderate resistance to corrosion. That is, they form discolored surface layers but do not have surface recession at a great rate. A case in point would be copper or copper alloy flashing often seen on roofs at chimney lines. The alloys degrade owing to formation of a surface patina, but there is no significant surface recession and the copper retains its cross section and hence strength integrity for a long time.

Some alloys show adequate corrosion resistance so long as the surface of the article is not degraded. However, surface erosion or inadvertent scratching or similar degradation can cause corrosion to accelerate. Pitting and similar corrosion owe their existence to such tendencies.

TABLE 37.11 Galvanic Series of Selected Commercial Metals and Alloys in Seawater^a

Noble or Cathodic	Platinum
	Gold
	Graphite
	Titanium
	Silver
	Stainless steel, austenitic, P (18%Cr, 8%Ni, low C)
	Stainless steel, ferritic, P (10–30% Cr, high C)
	Nickel–chromium–iron alloy, P (80% Ni, 13% Cr, 7% Fe)
	Nickel, P
	Silver solder
	Nickel–copper alloy (70% Ni, 30% Cu)
	Copper–nickel alloys (60–90% Cu)
	Copper–tin bronzes
	Copper–zinc brasses
	Nickel–chromium–iron alloy, A (80% Ni, 13% Cr, 7% Fe)
	Nickel, A
	Tin
	Lead
	Lead–tin solders
	Stainless steel, austenitic, A (18% Cr, 8% Ni, low C)
	Stainless steel, ferritic, A (10–30% Cr, high C)
	Cast iron
	Steel
	Aluminum alloys, precipitation hardened
	Cadmium
	Aluminum, commercially pure
	Zinc
Active, or anodic	Magnesium and magnesium alloys

^aP indicates passive condition; A indicates active condition.

Some alloy elements confer better corrosion resistance in certain temperature/environment regimes than in others. Nickel-base superalloys oxidize at elevated temperatures. Nickel was alloyed with chromium in the early twentieth century to produce oxidation-resistant materials used for electrical resistance wires. In the mid-twentieth century, the nickel–chromium alloys were adapted for use as superalloys for gas turbine engines. In the early years of use, these chromium-containing alloys showed excellent oxidation resistance. Later, as temperatures went higher, alloys with higher amounts of aluminum (and reduced chromium) than in the early superalloys showed improved high-temperature oxidation resistance.

Generally, as temperatures increase, corrosion attack increases. However, for some forms of environmental attack, the kinetics of the attack process may be such that a specific type of attack begins at a certain temperature and increases with increased temperature but then drops again to lower rates at still higher temperatures. Nickel-base superalloys exposed to sulfur and/or halide-containing environments may show lower temperature hot-corrosion rates that are greater than the hot-corrosion attack seen at higher temperatures.

In addition to general corrosion, grain boundary oxidation/corrosion or the selective attack of some secondary phases in an alloy can create notches. Coatings will help protect against such attack. Other types of chemical attack are more subtle. For example, brass (copper–zinc) alloys can be susceptible to stress corrosion cracking. In this instance, the attack may be on/in the grains and cause cracking owing to a residual or applied stress on an article made of the alloy. In the early days of manufacture of cartridge brass (70 Cu and 30 Zn), cases would crack or be embrittled by stress corrosion cracking and would burst on firing. Stress corrosion cracking can be found in titanium alloys and in some stainless steels among other materials. Reduced residual stresses help to alleviate the problem for brass.

37.11.2 Coatings for Protection

From early use of steel, the concept of rust was prevalent. At first, no alloys were made that were rust resistant, but it was discovered that, if one could protect the iron or low-carbon steels from the environment, then there was no attack. In the automotive industry, this concept was applied to bumpers by electroplating coatings onto the bumpers. First, a nickel plate was applied, then a high-reflectivity chromium was plated over the nickel. So long as the nickel did not develop a pore or scratch or suffer a similar breakdown, the steel bumper did not rust. Similarly, before the widespread use of polymer trash cans, steel cans were coated with a sacrificial layer of zinc, an element anodic to iron. The trash cans did not rust because the zinc corroded preferentially to the steel. These two illustrations show the use of impervious coatings or anodic coatings to protect materials.

Corrosion at lower temperatures is not the same as corrosion at high temperatures where the interaction of an alloy with oxygen can cause an oxide to form with consequent reduction in the cross-sectional area of an alloy. If the oxide itself is essentially protective, for example, chromium oxide at temperatures below about 1500–1600°F (186–871°C) or aluminum oxide above about 1800°F (982°C), then the alloy is protected from oxygen attack for some time. It was reasoned that the production of a deliberately introduced chromium-oxide-forming or aluminum-oxide-forming coating on alloys for high-temperature use would increase their resistance to oxidation.

Such coatings were introduced and applied by a number of methods. The early coatings were diffusion coatings on cobalt- or nickel-base superalloys and were created by pack aluminizing or slurry application. The chemistry of the coating was determined by

the chemistry of the alloy. Some high-temperature protective aluminide coatings were applied by painting or by spray processes. Later, (second-generation) coatings were produced by overlaying a specific chemistry of a protective nature on the surface of the component using physical vapor deposition (evaporation of elements of an alloy by using an electron beam and redeposition of the elements on the target alloy's surface). Overlay coatings are generally more expensive than diffusion coatings. However, vapor-transported diffusion-type coatings can coat internal (non-line-of-sight) surfaces while overlay coatings can only coat external line-of-sight surfaces that can be seen by the coating apparatus. Some commercial diffusion coating processes are available, but most overlay coating processes are proprietary, having been developed by users such as aircraft gas turbine manufacturers.

Of course, for lower temperature use, spray or electrodeposited coatings may provide adequate protection for many alloys and overlay coatings might be overkill.

Despite the coatings on high-temperature superalloys, oxidation (or other corrosion) continues but at a markedly lower rate. Since the coating is being used up over time, eventually the coating will not be sufficiently protective and the surface of the alloy must be recoated. This concept of eventual coating degradation will apply at both high temperatures in oxidation and lower temperature corrosion (e.g., aqueous corrosion). Depending on the alloy's structural application, the cost to replace the article that is coated, and the cost of recoating, a decision will need to be made about continued use of the article in its application. Generally, replating or recoating of articles is more apt to occur if the cost of the article's replacement is very high. So, gas turbine airfoils which may cost in the \$100–\$1000 range to make as castings are more apt to be recoated and reused than a car bumper that has rusted.

37.11.3 Coating Selection

Coating selection is based on knowledge of oxidation/corrosion behavior in laboratory, pilot-plant, and field tests. Attributes that are required for successful coating selection include:

- high resistance to general oxidation/corrosion,
- ductility sufficient to provide adequate resistance to thermal mechanical fatigue if the article sees high temperatures since coatings are not particularly ductile and coating cracking/spalling could occur,
- compatibility with the base alloy to be coated (important anywhere but especially for high-temperature operation),
- low rate of interdiffusion with the base alloy (if used at high temperatures),
- ease of application and low cost relative to improvement in component life,
- ability to be stripped and reapplied without significant reduction of base-metal dimensions or degradation of base-metal properties.

37.12 POSTSERVICE REFURBISHMENT AND REPAIR

One important aspect of modern alloy use is the concern for maximizing service life of articles. Manufacturers do not wish articles or devices to fail in less than the warranted life. Selection of alloys for design should include concern for potential early removal and repair or refurbishment. Surface degradation and mechanical property loss are major

economic factors in applications of articles. These factors have become of greater interest as the base cost of materials and subsequent components has risen dramatically over the past 40 years. (Note: As this chapter is being written, for example, the price of nickel, a common base material or alloy element, has risen 10-fold in 3 years!)

Although initial cost has usually prevailed in alloy selection for consumer devices and articles, as the cost of machinery (nonelectronic) has increased owing to various factors, more attention in alloy selection has been given not only to initial ability to produce a viable article but also with regard to future life and refurbishment/repair concerns. In practice, when public safety consideration limits or product integrity design limits are reached, costly components may be withdrawn from use. Some components may appear to be unaffected by service time. For economic reasons, there may be incentives to return these components to service.

Other components after service may have visible changes in appearance. For example, a gas turbine high-pressure turbine blade may be missing a coating in the hottest regions of the airfoil or a crack may develop in a vane airfoil. Seals may be worn. It is highly desirable that damage can be repaired so that the costly parts can be returned to service.

If possible, alloys would be selected on the basis of restoration of capability after initial capability has (apparently) been reduced by service exposure of the component. However, most applications do not permit alloy selection on that basis. Many applications have limited lifetimes to reduce initial cost (and, possibly, to improve the likelihood that new products will be purchased). The best alloy from a property and initial economic viewpoint is usually the choice. However, it is a common practice with certain applications to refurbish or repair many components, which have visible external changes.

Stripping and recoating of turbine airfoils is one example of refurbishment and repair practice. Oxidation- and corrosion-resistant coatings and thermal barrier coatings may be reapplied (after appropriate surface-cleaning treatments) to restore resistance of the surface to heat and gaseous environments. When a high-performance article made of a superalloy is to be refurbished by recoating, all traces of the original coating should be removed before recoating is attempted. In case of missing, eroded, cracked, and/or routed material, welding traditionally has been used to fill the gaps for some alloys and components. Care must be taken to assure that no additional alloy degradation occurs owing to the refurbishment and repair practice.

The restoration of mechanical properties degraded by creep and/or fatigue is not clear-cut. In the laboratory, reheat treatment has been shown to restore the mechanical properties of some superalloys after service exposure. The degree of restoration is a function of the mechanical history of the component. Results of reheat treatment of service-exposed parts are variable. Most postservice procedures for high-cost flight safety articles do not provide for mechanical property restoration.

It is important to recognize that refurbishment or repair may not result in cost-effective performance.

37.13 ALLOY SELECTION: A LOOK AT POSSIBILITIES

37.13.1 General

Selection of alloys for design may require a comprehensive review of the design and potential materials or, as noted below, may rely on prior use to dictate alloy selection. On

the assumption that a design will start from scratch with no preconceived notions of alloy usage, several questions need to be answered:

- What is the expected temperature of use?
- What is the expected environment (gas, liquid, moving, static, etc.)?
- What strength levels are required?
- Is there a cyclic component to any loads?
- Are elastic properties likely to be a criterion?
- Will loading be uniform or will some directions within the article see different loads?
- Are there special characteristics at issue, for example, heat capacity, electrical, magnetic?
- For how long must the article to be designed and manufactured last?
- Will successful operation depend on special cooling or other conditions?
- What weight or dimensional levels must not be exceeded?
- Is there an aesthetic component to the application of the desired article?

Assuming that the above questions can be answered in a definitive way, referral to general alloy characteristics will narrow the choices available. For example, operating temperatures above about 1000°F (538°C) will eliminate aluminum, magnesium, and zinc alloys as alloys of those metals will be molten at such operating temperatures. Elastic modulus concerns might further limit alloys. For example, if it would appear that materials for a given article would need Young's modulus of near 30×10^6 psi (206.8 GPa), then titanium alloys would be eliminated as their moduli are less than 20×10^6 psi (137.9 GPa). Would the application be in oxidizing gases above 1000°F (538°C)? Then iron would be ruled out owing to its lower oxidation resistance compared to other alloys at those temperatures. Stainless steels might be possible but creep rupture strength might be too low, thus moving the likely candidates to superalloys, those of cobalt, iron–nickel, or nickel base.

Now, attention would need to be directed to the manufacturing ability of alloys to be considered. If the alloy is to be mechanically deformed to reach its near final shape, ductility/workability will need to be considered. Is the article complex, with internal cooling passages and thin walls? Then investment casting may be the best production method! Consideration must also be given to the fact that some processing methods produce or permit improved property levels over other processing methods. For example, investment-cast superalloys are superior in creep rupture strength to wrought superalloys and SCDS investment-cast superalloys are superior to polycrystal investment-cast superalloys.

At this point, alloy families will have been reduced considerably from the total matrix of alloys to one or two alloy types, for example, cobalt-base or nickel-base superalloys that can be investment cast. Design now will hinge on strength (static and/or dynamic-cyclic). A review of strength requirements might show creep rupture capability requirements on the order of 24-h life at 1850°F/36 ksi (1010°C/248.2 MPa). Cobalt alloys cannot reach those levels so nickel-base superalloys become the choice. Now the selection may hinge on specific alloy chemistry, past experience with an alloy, and investment-casting experience with the alloys from which selection needs to be made. Economics of the basic alloy chemistry, economics of the investment-casting route (polycrystalline,

columnar grain, and single crystal) to be used, ease of applying surface coatings (if required), minimum alloy properties which are needed, and perhaps other factors need to be considered.

The final selection will need to be verified by actual manufacturing and device testing in simulated or (preferably) actual service. Refurbishment procedures may need to be considered if the article is particularly costly and can have its life extended by suitable and timely refurbishment.

It may be seen that the alloy selection in this instance is not exactly a case of working from “ground zero” to scientifically evaluate the likely candidates. Rather, the selection has depended on real engineering data and judgment and would have involved potential alloy suppliers and manufacturing specialists as soon as possible. A great deal of “alloy selection” that appears in the literature has been done in retrospect, that is after some particular article has been manufactured (e.g., a skateboard), scientific approaches to the evaluation of the actual article show the requirements which were met to produce it. There is nothing in principle wrong with scientific alloy selection. However, the general lack of data (not enough, maybe virtually no, property data), no or limited manufacturing experience, insufficient awareness of the “shop” climate (what furnaces might be available for heat treating the articles and how would the treatment impact the shop schedule), and so on, can cause unacceptable delays or even inability to manufacture an acceptable article.

Assuming that minimum alloy property data will be available, the key to alloy selection is to find knowledgeable engineers in-house and engage them and other knowledgeable persons from the manufacturing pipeline in conversation early on in the selection process.

37.13.2 Impact of Materials’ Data Validity on Selection

There ought to be one basic rule for alloy selection and that is: “Do not believe all you see or hear” (from your fellow employees or from persons purveying new alloys, coatings, or processes). The most common type of statement from alloy/process developers with whom one talks (the “sellers”) at the start of new alloy (or process) evaluation is: “This is our average product/property.” Translated, this statement should probably be treated by the alloy selectors (the “buyers” in this instance) as meaning: “It’s the best we have gotten!” One needs to be skeptical and inquisitive about statements from the seller!

One should be especially wary of selective use of data. There was a situation where an alloy (never used in production) was claimed to have property levels up to 150°F (94°C) better than any other similar alloy then existent. Unfortunately, when a laboratory program was run at a different laboratory (lab 2) than the laboratory (lab 1) of alloy invention, results were troublingly low. On inquiry to the “inventor of the alloy,” the question was raised as to how he got such good results. The answer? The inventor only cut out good material to test.

At that point, it was reported to the manager of lab 2 that, with careful work in the laboratory, one might get a “100°F (62.5°C)” improvement over the best existing alloy but never 150°F (94°C). And, it was said that, in a production shop, the best improvement might be no better than 50°F (31°C). The latter projection was proven true when maximum alloy improvement turned out in production to be only 47°F (29.4°C).

Engineers have been known to discard data that are not as good as what they expect (and occasionally get). There need to be valid reasons for excluding data. When much data (properties, results of processing, etc.) get discarded, the discarded data often come

back to haunt the user of the alloy/production process. Dig into the database for anything you use in your alloy selection. Assure yourself that there are no hidden items that may appear again in production.

In an instance of mechanical property tests of a new wrought nickel-base superalloy to be used for a gas turbine disk, low creep rupture test results were routinely discarded. The alloy (as a disk) went into production and most of the first production run began to fail the creep rupture acceptance tests in the shop, with test values almost identical to those which had been routinely discarded during alloy development. A modification of heat treatment was necessary to bring the alloy creep rupture life back to the range promised in development and much time and money were spent in the recovery operation.

37.14 LEVEL OF PROPERTY DATA

Different organizations have different ways to treat property data. Generally minimum and typical properties are desired by design engineers. Minima can vary in definition (-2σ , -3σ deviations are used). One of the cardinal rules of alloy property development is that enough data will never be generated to truly determine a statistically valid property level over all possible property space. Data cost money! Estimates are made and may often be used in design. If these estimates are conservative and can be justified by alloy data on the alloy of interest and similar alloys, satisfactory designs with the selected alloy usually result.

Not all properties require minimum values. Some property values used for design are typical values. While minima may be used in design, estimates of typical behavior of a component made to track its operation may require typical property values.

37.15 THOUGHTS ON ALLOY SYSTEMS

37.15.1 General

Melting temperatures for homogenous alloys range near but generally below the melting temperature for the major (base) element. Natural segregation of alloy elements during solidification can lead to even lower melting temperatures. The incipient melting temperatures (lowest melting point of an alloy after solidification) can be many tens of degrees less than an alloy's nominal melting temperature. While some homogenization may occur with heat treatment or with wrought processing and heat treatment, it is possible for alloys, particularly cast alloys, to still show incipient melting. This factor needs to be kept in mind during processing and use of a given alloy. Some alloy elements cause significant depression of the melting temperatures of an alloy system while others show relatively little effect. For example, boron, carbon, zirconium, and hafnium depress the melting temperatures of nickel-base superalloys. As these elements were added primarily to enhance grain boundary strength/ductility in cast versions of many alloys, the introduction of single-crystal nickel-base superalloys enabled most or all of those elements to be removed from the alloy chemistry. The resultant melting temperature increase enabled enhanced heat treatments and optimized strength properties in these alloys.

Another aspect of alloys is the effect of alloy elements on the density of the base metal of an alloy. When much lighter elements than the base metal are introduced, significant density reductions occur. Such additions may or may not be beneficial. For example, early

nickel-base superalloys tended to have densities of about 0.3 lb/in.³ (8.3 g/cm³). Some inventors added vanadium, a relatively light metal, to an alloy and reduced the density of the alloy to about 0.28 lb/in.³ (7.75 g/cm³). When first introduced, the vanadium-containing alloy seemed destined to become an excellent turbine blade airfoil performer. However, the introduction of vanadium made the alloy sensitive to hot-corrosion degradation, and it was dropped from consideration. Major changes in alloy density for an application may often be achieved but often only by selecting a different base alloy.

Alloy costs today are much more variable than they have been historically. Alloy selection needs to consider the possibility of alloy and processing cost increases during the lifetime of a component design. Alloy costs can be significantly impacted by local conditions in areas of the world where the base metal ore is found. Dramatic increases in prices have occurred when wars, embargoes, or significant new manufacturing restrictions are imposed. Sometimes, such cost increases have led to changes in alloy selection for a component or to chemistry modifications to reduce the amount of costly or strategic element used in the alloy. In the mid-1970s, the price of cobalt shot up by a factor of 10 (the price eventually dropped). Cobalt was a principal ingredient in many superalloys used for gas turbines. Corporate managements were appalled by this state of affairs and decreed that cobalt be removed as soon as possible from the manufacturing process. As a result, a particular iron-nickel-base superalloy, IN 718 (alloy with no cobalt), became the world standard for applications which previously used cobalt-containing alloys. It behooves the alloy selector to consider strategic and economic conditions when recommending an alloy for design.

As mentioned earlier, there are limited numbers of alloy systems available for structural applications. Iron is the most common and least expensive. Aluminum, copper, magnesium, and titanium follow iron in volume of structural alloy application. Nickel and superalloys are widely used as well. Alloys from all of the systems mentioned can be welded, although some alloys or systems may require special attention. High-strength, high-temperature nickel-base superalloys generally are not weldable owing to a tendency to cracking, particularly in the heat-affected zone.

37.15.2 Iron

Iron alloys consist of cast iron, wrought iron, low-carbon steel, alloy steel, stainless steel, precipitation-hardening steels, and so on. Iron has been around for several millennia. Steel, the name commonly applied to many iron alloys, is the most widely used metallic material. The range of property levels achievable in iron alloys is quite broad and the general availability of iron makes it a relatively inexpensive alloy base for structural design. Steels are hardenable by solid-solution strengthening, grain size hardening, work hardening, precipitation hardening, and transformation hardening (martensite or bainite formation). Very high short-time strengths, up to over 200 ksi (1379 MPa), can be produced in steels. Stainless steels provide significant corrosion protection in many environments. Many steels are forgeable and formable with much steel sheet going into vehicle production. Automobiles can contain nearly 60% of their weight in steel. Steels are ubiquitous, being found in tall buildings, aircraft, cars, trucks, small and large internal combustion engines, hand tools and large machine tools, garden implements, kitchen utensils, pots, pans, and so on. Iron-base super alloys are used in gas and steam turbines. Much iron wire was used to fence the western United States in the late 1800s and iron boilers, rails, and rail cars were standard on trains. Iron has a density of 0.285 lb/in.³ (7.89 g/cm³) but

alloys can range as high as 0.3 lb/in.^3 (8.3 g/cm^3) or above. Steels have elastic moduli in the range of about $30 \times 10^6 \text{ psi}$ (207 GPa). Iron melts at 1220°F (660°C) but steels melt at lower temperatures. Steels can be plated, painted, or coated to enhance corrosion protection. The alloys can be joined with relative ease depending on alloy composition, and economics favors iron alloys as materials of choice in many instances.

Other than for certain stainless grades, steel normally is considered an alloy of iron and carbon plus other elements. Now some modern steels incorporate very important changes, for example, interstitial-free steels where carbon is considered an impurity and vacuum-degassed steels with extra low oxygen content. The application of carbon and alloy steels is related largely to the ability to get the desired mechanical properties ("hardness") where we want it. The selection of steels will need to consider the hardenability (maximum thickness at which one can achieve the desired hardness/strength) of the selected alloy with respect to the requirements for strength in the article being designed. Combinations of alloy content and processing can almost always enable the strength (hardness) to be achieved. There are more steels from which to choose than any other alloy class. Strength in steels is frequently referred to in terms of hardness (e.g., on a Rockwell C scale or some other scale). There are sophisticated tools available to determine the likelihood of success in getting an alloy with the correct hardenability.

The properties of steels are modified not only by chemistry changes but also by heating for various times at various temperatures. This heat treatment of steels is effective because iron has a phase transition as it heats up and the lower (room temperature) body-centered-cubic ferrite phase changes to the face-centered-cubic austenite phase. Of course, carbides continue to exist in steels as appropriate to the temperatures and times at which the steel has been held. On cooling, the steel can change back to the preferred lower temperature structure in many ways (not all ways are possible with all steels). Essentially the austenite, which absorbs a lot of carbon at its high temperature of formation, rejects the carbon and tries to transform back to ferrite. Sometimes the austenite forms a nonequilibrium body-centered-tetragonal phase, martensite. Martensite then exists along with carbides. Sometimes austenite transforms to bainite and carbides and sometimes austenite transforms to pearlite (a special form of ferrite and carbide aggregate). The result of these various possibilities is the ability of steels to possess a range of possible properties. Selection of a particular steel is an exercise in estimating the strength needs for a particular property and finding one steel from the multitude of available steels that will get the properties where they are wanted, along with any other desired properties such as corrosion resistance, and at the lowest cost.

Plain carbon steels are used for routine and lower temperature applications. For elevated-temperature applications (e.g., tubing/piping in a steam turbine), higher alloy contents are needed and carbon content is only a part of the selection process. Chromium is often added in small amounts to low-alloy steels used at moderate temperatures. With sufficient chromium, scaling of steels can be prevented. When corrosion is meant to be almost entirely prevented, chromium is added above about 12 wt%, sometimes going up above 20 wt% for certain stainless steels.

Stainless steels are intended to promote integrity of the surface while retaining reasonable strength at high temperatures. The chromium oxide film that forms on stainless steels conveys a passivity and provides corrosion resistance to the alloy. Stainless steels not only see high-temperature service but also find much use at lower temperatures in aqueous or other nongaseous environments. To an extent, stainless steels for elevated-temperature service form a continuum with the iron-nickel- and nickel-base super alloys as well as

the heat-resistant and nickel-base corrosion-resistant alloys. The so-called precipitation-hardened steels are chromium-containing steels with special additives to bring out precipitates for hardening, much like aluminum alloys or nickel-base super alloys. It is important to note that the stainless nature of stainless steels is promoted by chemically oxidizing environments. Reducing environments, particularly environments containing halogens, can have devastating effects on stainless steels.

37.15.3 Copper

Copper is a system which also has been around for millennia. The bronze age was the age of tin alloyed with copper to produce strong (by the standards of the day) alloys. The bronze age was followed by the iron age. There are many benefits to copper compared to iron-base alloys and other systems. The copper alloy systems do not compete solely on a strength basis since copper alloys normally are weaker than iron alloys. However, there are areas where copper alloys show sufficient strength and unique other properties (corrosion resistance, nonsparking characteristics when struck, etc.) to compete with steels. A major property of pure or relatively pure copper alloys is their high electrical and thermal conductivity. Specially strengthened copper alloys find use as electrodes and similar current-carrying articles where high temperatures and surface wear resistance are significant. Copper has a moderately high melting point, 1981°F (1083°C); this is less than the melting points of iron alloys but much greater than the melting points of aluminum and magnesium alloys.

Copper is strengthened by solid-solution hardening, grain size hardening, work hardening, and precipitation hardening. Copper is moderately abundant and copper alloys such as the brasses offer reasonable strength with good formability and corrosion resistance. The modulus of copper is 17×10^6 psi (115 GPa); this is less than the modulus of steels and nickel alloys, higher than the modulus of aluminum, and comparable to the moduli of titanium alloys. Most wrought alloys are available in work-hardened conditions and typically find use in moderate to small parts such as springs, fasteners, hardware, gears, and cams. Copper is very formable and forgeable though forming is more apt to be used than forging to manufacture articles of copper alloys. Casting can be used to create copper articles as well. A major use is in conductivity devices (e.g., wire). Copper alloys find wide use in plumbing. Copper, brasses, bronzes, and cupronickels are used for pipes, valves, and fittings in transporting water. The density of copper alloys is around 0.32 lb/in.³ (8.86 g/cm³) for many compositions.

37.15.4 Aluminum

The aluminum industry is relatively new and got its start in the late 1800s. Aluminum alloys became available in the early part of the twentieth century. Aluminum melts at 1220°F (660°C) and owes its popularity to corrosion-resistant, moderately high strength alloys with a substantially lower density, 0.098 lb/in.³ (2.77 g/cm³), than most other structural alloys. Strong aluminum alloys can be produced for operation up to about several hundred degrees Fahrenheit. Aluminum is strengthened by solid solution and work hardening but the highest strength aluminum alloys are precipitation (age) hardened. Cast aluminum is often used. Aluminum alloys have become synonymous with lightweight articles of acceptable strength when age-hardened aluminum is used. The density is considerably less than the density of steel. Figure 37.11 shows the effect of density on the

FIGURE 37.11 In certain circumstances, lower densities can make somewhat less strong alloys the materials of choice.

specific strength of several alloy systems. Note that, despite the much greater strength of iron and nickel alloys, at room temperature the specific strength of aluminum alloys makes them competitive with iron alloys.

Aluminum is thermodynamically a reactive metal, as is magnesium. However, it has excellent resistance to corrosion in water (including salt water), atmospheric environments, oils, and many chemicals. Aluminum owes its excellent corrosion resistance to the aluminum oxide films that form naturally but can be enhanced by artificial means. When the excellent corrosion resistance of aluminum alloys in many environments plus the excellent formability/forgability of aluminum alloys is considered, their high specific strength can make them alloys of choice. In weight-sensitive applications at low to moderate temperatures, aluminum alloys perform very well. The modulus of aluminum alloys is about 10×10^6 psi (69 GPa) and so the alloys are not as stiff as iron, copper, or nickel alloys. They find use in aircraft structures, however, and aluminum beams have been used in construction. Aluminum is nontoxic and is found as pots/pans, utensils, and beverage cans and in other uses.

Although aluminum alloys generally are corrosion resistant in atmospheric environments, some alloys are corroded in special localized environments. Exfoliation, intergranular corrosion, stress corrosion cracking, and similar problems can exist. Some alloy types within the aluminum alloy family are less corrosion resistant than other aluminum alloys. However, alloy choice, the availability of anodizing and similar finishing processes, plus the process of cladding aluminum alloys with pure aluminum can provide good corrosion resistance for aluminum alloy systems. Alclad aluminum alloys generally are sheet and tube. Because of the nature of artificially formed aluminum oxide coatings on aluminum alloys, the anodized alloys can be colored. In addition to household goods, aluminum siding provides colorful protection for many homes while resisting denting. Aluminum finds use as ladders and in many outdoor activities where its intrinsic corrosion-resistant oxide surface skin protects it better than iron alloys. Aluminum alloys are extensively used in aircraft structures.

37.15.5 Magnesium

Magnesium alloys became available in the early twentieth century. Magnesium alloy applications are fueled by its density of 0.063 lb/in.³ (1.74 g/cm³), which is the lowest of any commercially used metal. The melting point of magnesium of 1202°F (650°C) is competitive with that of aluminum. The modulus of magnesium is about 6.5×10^6 psi (45 GPa), which is considerably less than aluminum or steel. However, owing to its low density, magnesium can have better specific rigidity than the latter alloys. For rectangular steel, aluminum, and magnesium sections of equal rigidity, calculations show that the magnesium article will weigh only about 71% as much as the aluminum article and 41% as much as the steel article. Magnesium alloys have good strength and very good strength when their density is factored into the selection process. Magnesium alloys generally are forged/formed at elevated temperatures, and forgings can be produced in the same general variety of shapes and sizes as forgings of other metals. However, most magnesium articles are produced as castings. Commercial applications have included luggage, ladders, materials handling equipment, as well as aerospace applications.

Magnesium is the most active element in the galvanic series of elements/alloys and so normally should not be coupled with any more cathodic alloy in an application. (Magnesium is used in hot-water tanks to provide cathodic protection.) Under extreme conditions of galvanic corrosion, rapid corrosion results. However, magnesium alloys generally are used with limited corrosion problems. Magnesium rapidly forms an oxide layer when exposed to corrosion conditions such as atmospheric moisture. The oxide is not too protective but neither is alloy section loss excessive. Use of high-purity magnesium reduces problems and anodizing, chromate coatings, and polymeric coatings have been developed to increase magnesium alloy protection from the environment.

37.15.6 Titanium

Titanium became commercially available at the start of the last half of the twentieth century. Titanium owes its industrial use to two significant factors: it has exceptional room temperature resistance to a variety of corrosive media and a relatively low density of 0.163 lb/in.³ (4.51 g/cm³) and can be strengthened to achieve outstanding properties when compared with competitive materials on a strength-to-density basis. Limited numbers of titanium alloys have been invented and marketed, perhaps owing to the greater cost of the product compared to the metal systems covered thus far. Titanium is produced by a batch process and must be further processed by expensive vacuum-melting techniques if its use is desired for aerospace applications.

There are three main classes of titanium alloys, α , $\alpha-\beta$, and β alloys. Property levels and processing capability vary with class of alloy in addition to specific composition. Titanium has a melting point of 3035°F (1668°C). The high melting point of titanium induced inventors to assume that high-strength alloys comparable to those of iron-, nickel-, and cobalt-base alloys would be capable of being produced. Unfortunately, titanium alloys are not able to operate at very high temperatures. Thus, while titanium and its alloys have melting points higher than those of steels, their maximum upper useful temperatures for structural applications generally range from as low as 800°F (427°C) to the region of about 1000–1100°F (538–595°C), depending on composition. Normally, the alloys are used well below about 1000°F (538°C). However, titanium alloys are capable of being strengthened to high levels and, combined with their reduced densities relative to

iron alloys and excellent corrosion resistance, they were able to replace iron alloys extensively in aircraft gas turbines.

The modulus of titanium is 15.0×10^6 psi (103 GPa). However, titanium undergoes an allotropic transformation on heating and changes from a low-temperature hexagonal-close-packed crystal structure (α) to one that is body-centered cubic (β). On cooling back to lower temperatures, a martensitic reaction can occur or the β can transform to α with varying degrees of fine structure. If a titanium alloy has a β structure at room temperature, the modulus of the alloy will differ from the modulus of an α alloy. The modulus will vary with chemistry and processing. Texturing in rolling processes can further change the effective modulus depending on grain alignment and the amount of β or α present. In addition to the variation of modulus with chemistry and processing, titanium alloy density will vary with the amount and type of alloy elements in a given composition. Many β -forming elements are significantly heavier than titanium while the α -forming element, aluminum, is lighter.

One alloy, Ti-6Al-4V, has been the workhorse of the titanium industry and, for many years, claimed over 50% of the titanium market. This alloy can be used up to the order of 500°F (260°C) to 600°F (316°C). Ti-6Al-4V is an α - β alloy with good all-around properties. Generally, α - β alloys are the most used titanium alloys. However, titanium α alloys have better high-temperature properties and β alloys have superior tensile properties and improved fabricability. Titanium alloys have found use in the chemical processing industry, as golf clubs and eyeglass frames, in dental applications, and as structural implants (e.g., hip replacements) in the human body, in addition to their widespread aerospace use. The alloys have greater high-temperature capability than aluminum alloys and are better in specific strengths than iron alloys, facts which ensure their continued use. A large amount of titanium production is used in aerospace applications. Large fan disks in high-bypass-ratio gas turbines and wing spars for aircraft are made of these alloys.

37.15.7 Nickel

Nickel has been available as an alloy element since the late-nineteenth century. It has exceptional value as an alloy element in steels and other elements as well as being the basis for the high-performance superalloys and heat-resistant alloys used in the aerospace and nuclear industries. Superalloys are covered below. Nickel alloys other than superalloys tend to be more or less relatively pure nickels used in food processing equipment, chemical processing, or some aerospace components. There is another class of nickel alloys which have applications other than those just mentioned—specifically, nickel-copper alloys (trade-names begin with Monel), which are characterized by high strength, good weldability, and excellent corrosion resistance at room temperatures in aqueous conditions. Some of these alloys are age hardened. Monels have applications in pumps, valves, storage tanks, heat exchangers, waveguides, screw machine products, fasteners for nuclear applications, and other uses.

37.15.8 Superalloys

Superalloys came into early use about 1940, with use motivated in large part by military concerns. Stainless steels and cobalt alloys were modified to provide improved creep rupture capability at higher temperatures such as those found in piston engine superchargers. Concurrently, a few nickel-base superalloys such as Inconel X were created and made

available. The terminology “superalloys” did not take hold until the late 1940s when the more widespread use of gas turbine engines prompted a search for improved alloys. Eventually, the addition of more precipitation-creating elements such as aluminum into the basic Nichrome (80 nickel–20 chromium) chemistries plus continued work on modified stainless steels with titanium and other additions led to a class of alloys generally called superalloys. Superalloys are iron-, iron-nickel-, cobalt-, or nickel-based alloys, which have exceptional high-temperature strength properties from about 1000°F (538°C) to about 2000°F (1093°C),

Cast nickel-base superalloys have the best strength in creep rupture at high temperatures above about 1300°F (704°C) while wrought iron–nickel and nickel-base superalloys have the best combination of properties below about 1300°F (704°C). Iron-base superalloys have acceptable properties below about 1000°F (538°C) and are the least expensive superalloys. Cobalt-base superalloys are used for long-time, high-temperature, and somewhat lower stress applications. For highest tensile properties, the nickel- or iron–nickel-base alloys stand out. For best forgeability, iron–nickel-base superalloys such as IN718 are outstanding.

Superalloy articles up to 48 in. (122 cm.) in length are cast as blades for gas turbines by the investment casting process, sometimes using SCDS technology. CGDS blades are made as well. Both types are stronger than polycrystalline castings but decidedly more expensive. Large relatively thin-walled case castings up to nearly 48 in. (122 cm) in diameter are made of IN718. Gas turbine disks up to nearly 36 in. (~1 m) in diameter are forged or PM processed and forged from IN718 and nickel-base alloys. Oxidation/corrosion-resistant coatings are used to protect surfaces of the hottest parts (turbine airfoils) from environmental attack. Superalloys are normally melted with various vacuum-melting techniques using induction or other high-technology furnaces. They may have as many as a dozen or more alloy elements controlled in the alloy and are subject (as is titanium) to extensive surveillance during the melting, casting, and forging operations.

Parts as small as thumb size or as large as gas turbine diffuser cases can be cast in superalloys. Investment-casting techniques produce exceptionally high quality alloy articles with maximum property capability. Most alloys are available to potential customers through normal channels. However, certain manufacturers of gas turbine engine hardware have invented proprietary alloys, and these most likely would not be available for public purchase in the foreseeable future.

37.16 SELECTED ALLOY INFORMATION SOURCES

37.16.1 General

In the selection of alloys for structural applications, selectors may have access to prior-related designs from company records or data from public records that may be applicable to the planned design. Consequently, at least a class of alloys and, possibly, a specific alloy or two may be readily apparent as alloy selection starts. However, more information on alloy types, properties, economics, and availability will most certainly be required eventually. It is beyond the scope of this chapter to provide information on all alloy classes, let alone specific compositions, which might be used for alloy selection within the alloy classes. However, many organizations, technical and sales, exist to promote specific elements and alloys of such elements as well as to promote processes for the manufacture of specific alloys into useful articles.

The number of organizations available to provide alloys, alloy property data, produce articles, and so on, is very large. The following list of websites is provided as a starting point to help alloy selectors determine possible alloy types, properties, economics, and availability. This list almost certainly will change with time and should only be used as a guide to locate potential information providers. Hopefully, the resources at these and similar sites will enable a selector and the designer to come up with an appropriate alloy for a planned design.

It is vital to remember in alloy selection that many alloys are not off-the-shelf consumer items and that properties may vary with material specifications for the alloy. Alloys often are made to user specifications that may vary from user to user and time to time. While a selector may be able to use common readily available alloys, often he or she may not be able to do so. When working with any specialty alloys, diligence in working with the producers will pay dividends in obtaining optimum properties and reducing difficulties for users of alloys. This concept is more costly than buying off the shelf but invariably leads to best quality and more reliable articles in design.

37.16.2 Selected Websites for Alloy Selection

The following is only a partial list. More information as to websites, locations, and so on, may be available. Not all companies or institutions active in any given technology are represented. No recommendation is made or implied by this list.

Polymers are widely used in every day consumer products and engineering applications. They can provide design and manufacturing flexibility, as well as desirable combinations of properties. However, successful implementation of any polymer requires a basic understanding of its mechanical behavior and what factors affect that behavior.

Mechanical properties depend not only on the chemical nature of the macromolecules, but also on a number of variables, which include molecular weight, crosslinking, branching, crystallinity, plasticizers, fillers and other additives, orientation, and processing effects. This is similar to how the mechanical properties of some metallic alloys (i.e., magnesium alloys) can depend on variables such as alloying constituents, grain size, and phase distributions. However, the effects of these variables tend to be much greater in polymers than the analogous effects in metallic alloys.

Also, in comparison to metals, the mechanical properties of polymers are dependent on the application temperature and the timeframe over which the polymer is exposed to load. This dependence on temperature and time is due to the viscoelastic nature of polymers, which means polymers behave in manner that has characteristics of both a viscous liquid and an elastic solid.

This overview of the basic principles of polymer mechanical behavior includes a discussion of the microstructure and morphology of polymers, stress–strain behavior, time–temperature relationships, deformation mechanisms, fracture mechanics, polymer toughening, and reinforced polymers (and composites). The behavior of polymers in load-bearing applications is also described, with introductions to creep, fatigue, and high strain rate performance. References to more detailed information on particular topics are provided.

38.1 MICROSTRUCTURE AND MORPHOLOGY OF POLYMERS—AMORPHOUS VERSUS CRYSTALLINE

Figure 38.1 illustrates the relationship between polymer volume and temperature, from the melt temperature through the use temperature. When cooling from the melt temperature, molecular motion slows. If the polymer is branched, crosslinked, or otherwise

FIGURE 38.1 Specific volume–temperature relationship for polymers. Upper line represents behavior of amorphous material; lower line represents semi-crystalline material behavior.

hindered during this process, it will follow the upper curve; the polymer will experience an abrupt volume change as it hits a sharp thermal transition, called the glass transition temperature (T_g), and will solidify as an amorphous material. In contrast, if the polymer is sufficiently linear, it may pack regularly and follow the lower curve; the polymer will experience an abrupt volume change at the crystallization temperature. This type of polymer will crystallize (and melt) over a temperature range due to incomplete crystallization. The increase in elasticity and solid-like physical properties as a polymer melt cools is associated with the crystallization temperature in semicrystalline materials and with the T_g in amorphous materials.

In semicrystalline materials, the melting range can be very broad. Low molecular weight molecules melt (and crystallize) over a very narrow temperature range, whereas high molecular weight molecules melt over a broad range of temperatures and do not crystallize completely. Most crystallizable polymers contain significant amounts of amorphous material when solidified, and are hence called semicrystalline. Slower cooling leads to higher degrees of crystallinity. Physical properties of these materials are dominated by the crystalline fraction.

The T_g is characteristic of amorphous regions in the polymer, whether or not other regions are crystalline. Like the melting temperature (T_m), the measured value of T_g is dependent on testing conditions. T_g sets an upper limit for the use of amorphous polymers like polymethyl methacrylate (PMMA) or polystyrene (PS) and a lower limit for the rubbery behavior of elastomers. Polymers below T_g are glassy and elastic.

The softening point, which is lower than T_m , is measured as a temperature at which a polymer deforms a given amount under a given load. Semicrystalline polymers are most often used in applications at temperatures between T_g and the softening temperature, and in this region their behavior is described as tough and leathery. Below the T_g , the behavior is described as rigid. These regions are depicted schematically in Figure 38.2 for both amorphous and semicrystalline polymers.

When small molecules crystallize, the crystals have few defects, exhibit well-defined crystal faces and cleavage planes, and often have a single nucleus of growth. In contrast, when large molecules crystallize, a conglomerate of disordered material and clusters of crystallites develop from the growth of many nuclei, the crystal faces are nondistinct, and “tie molecules” traverse more than one crystallite. As with other materials, crystallizable plastics can exhibit more than one crystal form. The form, perfection, orientation, connectivity, and extent of crystals in a plastic affect the observed physical properties.

The morphology of semicrystalline polymers describes the forms that result from crystallization and aggregation of crystallites. The basic units are the crystalline “lamellae,” which consist of folded chain, ribbon-like crystallites (Figure 38.3). The lamellae are typically organized into larger structural features such as spherulites (Figures 38.4 and 38.5). A fibrillar morphology can be created by stretching a crystallizable polymer under temperatures between T_g and T_m , or by stretching spherulites (Figure 38.6). The microstructure and morphology of the polymer control the deformation mechanisms and mechanical properties exhibited in use.

38.2 GENERAL STRESS–STRAIN BEHAVIOR

Mechanical properties refer to the characteristics of a material that describe how it will respond to stress and strain. Stress is the force normalized by the area over which it is

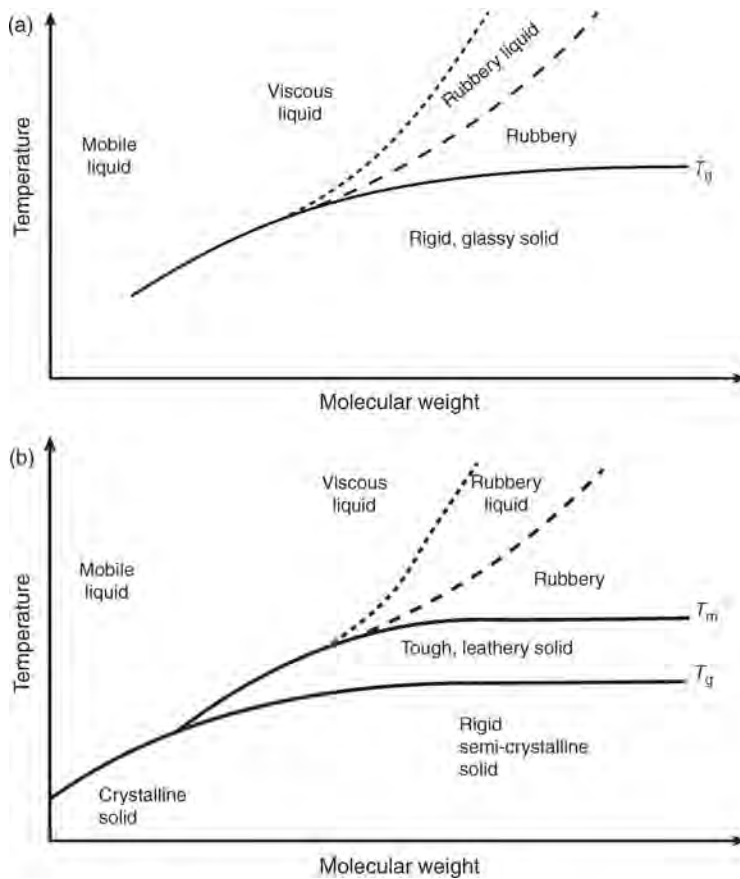

FIGURE 38.2 Relationships between temperature, molecular weight, and physical state.

applied, strain is the deformation normalized by the original dimension of the material. The modulus is the ratio between stress and the corresponding strain. It is easiest to illustrate these concepts by considering uniaxial tensile loading. Figure 38.7 shows monotonic tensile stress–strain curves for a synthetic fiber, a rigid and brittle plastic, a tough plastic, and an elastomer. Of the various forms of plastics, synthetic fibers generally have the highest initial modulus and moderate levels of elongation (strain) to break. Rigid, brittle plastics generally have moderate initial moduli and low elongation to break, whereas tough plastics can exhibit moderate to high initial moduli, a fairly evident yield point, and a larger amount of ductility or post-yield elongation. Elastomers exhibit the greatest amount of elongation to break, which is usually at least several hundred percent and may be more than 1000% as well. Elastomers also exhibit the lowest initial moduli, but the modulus increases rapidly as the elongation increases toward break. These differences arise from the polymer structure and morphology.

When subjected to uniaxial tension, some polymers exhibit (engineering) stress–strain response that appears similar to that of steel, where there is a local maximum yield point,

FIGURE 38.3 Crystal lamellae—Possible conformations of polymer chains at the surfaces of chain-folded single crystals. (a) Adjacent re-entry model with smooth, regular chain folds, (b) adjacent re-entry model with rough fold surface, and (c) random re-entry (switchboard) model.

after which the material necks or flows throughout the specimen gauge section at a lower (engineering) stress until the entire gauge section has necked down; the failure (engineering) stress may or may not be lower than the yield stress (Figure 38.7c).

Both semicrystalline and amorphous polymers can yield. Because of the time–temperature dependency, the yield point can become more pronounced at lower temperatures and higher strain rates, and less pronounced at higher temperature and lower strain rates. A uniaxial applied stress is comprised of both shear stress and dilatational stress, and this yielding behavior seems to be predominantly due to the shear component of the applied stress. Polymers often exhibit higher yield stress in compression than in tension, which indicates the behavior has a dependence on the hydrostatic stress (Dowling, 1999).

If the polymer is not loaded (strained) to failure, the unloading stress–strain behaviors also show significant distinguishing traits. For example, both fibers and plastics exhibit some amount of permanent deformation and some amount of delayed viscous recovery,

FIGURE 38.4 Successive stages in the development of a spherulite by fanning growth from a nucleus (Rudin, 1999).

FIGURE 38.5 Schematic representation of basic structure of a polymer spherulite.

FIGURE 38.6 Schematics of polymer fibril morphology (Rudin, 1999).

but fibers usually exhibit more elastic strain recovery than plastics do. Elastomers, on the other hand, can recover completely and quickly from very high amounts of elongation.

The mechanical behavior of polymers, such as the tensile stress–strain behavior, is dependent on the temperature at which the material is evaluated. Figure 38.8 shows schematically how the tensile modulus changes with temperature for both amorphous and semicrystalline polymers. Thus, a material may be glassy at low temperatures and rubbery at higher temperatures. In the intermediate temperature range, where the modulus changes rapidly (for amorphous and lightly crystalline polymers), the behavior is described as leathery.

In the glassy region, there is no large-scale molecular motion; the material will generally respond elastically to an applied load and fracture under small strains, due to the inability of molecules to flow past each other. As the temperature increases to the T_g , the increased thermal energy permits more coordinated motion, ultimately leading to viscous flow (Table 38.1).

Because the glassy, leathery, and rubbery types of behavior are due to the amount of molecular motions occurring, it is apparent that anything that alters the molecular motions also alters the regions of behavior. Thus, molecular weight, crystallinity, crosslinking and plasticizers, and other factors can affect the temperatures at which these behaviors occur and the magnitude of change in modulus (Rudin, 1999; Hertzberg, 1983). Figure 38.9 illustrates the effects of increasing molecular weight and crosslinking density.

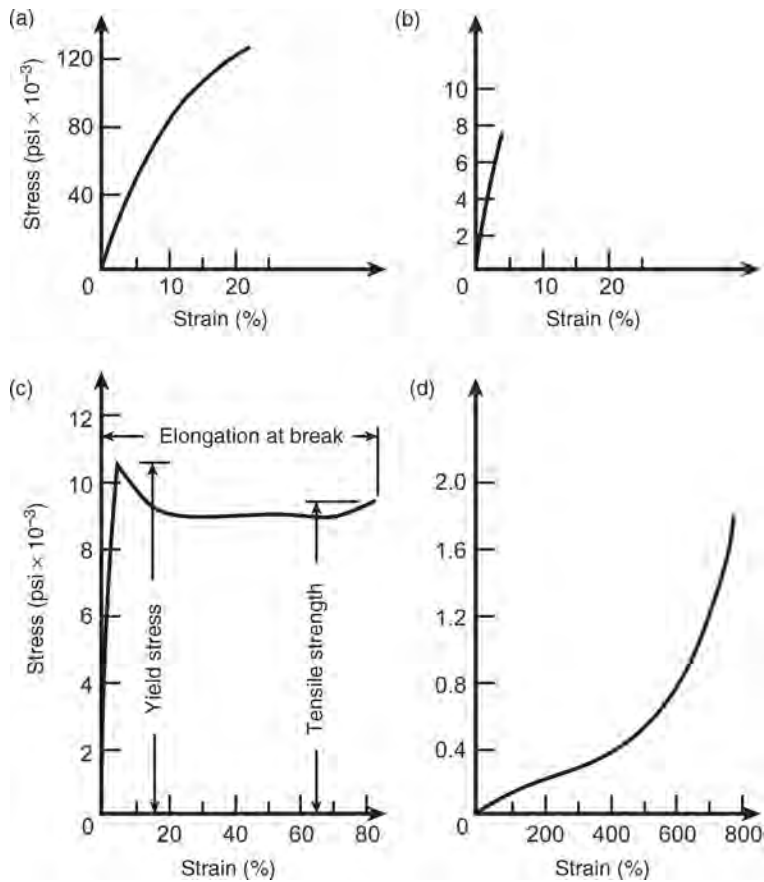

FIGURE 38.7 Monotonic tensile stress-strain curves for (a) a synthetic fiber, (b) a rigid and brittle plastic, (c) a tough plastic, and (d) an elastomer (Rudin, 1999).

FIGURE 38.8 Modulus-temperature relationship for amorphous and semicrystalline polymers.

TABLE 38.1 Molecular Motions at Various Temperatures (Hertzberg, 1983)

Temperature	Molecular Source of Mechanical Behavior
$T \ll T_g$	Believed to be movements of small groups (few atoms only)
$T < T_g$	Believed to be movement of two to three consecutive repeat units
T_g	Believed to be coordinated movements of 10–20 repeat units
$T > T_g$	Large-scale molecular motions

FIGURE 38.9 Effects of molecular weight and crosslink density on relaxation modulus.

38.3 VISCOELASTICITY

Polymeric solids behave in a manner that has characteristics of both Hookean solids and Newtonian fluids; this is called viscoelastic behavior. In an ideal elastic (Hookean) material, there are no time-dependent effects. This means that when stress is applied, the material deforms instantly to a strain that is directly proportional to the amount of stress. When the stress is removed, the deformation is recovered instantly and completely. In contrast, in an ideal Newtonian fluid, no stress can be supported without flow. When shear stress is applied, the fluid instantly responds in viscous flow. For these materials, the viscosity of the fluid is defined as the ratio of shear stress to shear rate.

Figure 38.10 schematically illustrates generic viscoelastic behavior of a crosslinked elastomer, a fiber and an amorphous plastic. Viscoelasticity is evaluated experimentally in creep, stress relaxation, and dynamic mechanical tests. In creep tests, a constant stress is applied and the deformation, which increases over time, is monitored. In stress relaxation tests, a constant deformation is applied and the reaction stress, which decreases over time, is monitored. In dynamic mechanical tests, the response of the material to periodically varying stress (or deformation) is monitored over time (Figure 38.11). In creep and stress relaxation tests, there are difficulties experimentally in measuring the very short-term (elastic) response, and time issues in waiting for the long-term response to occur. Dynamic mechanical tests (also called dynamic mechanical analysis or DMA) were developed to alleviate short- and long-term time

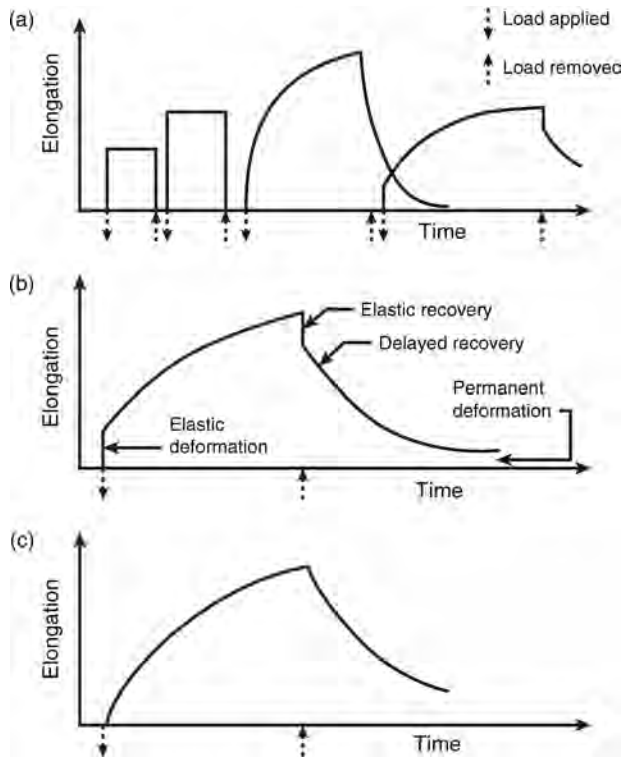

FIGURE 38.10 Elongation-time relationships upon loading/unloading for (a) crosslinked ideal elastomer, (b) fiber, and (c) amorphous plastic.

issues, but are limited to very small amplitude stresses and strains such that linear viscoelasticity methods can be applied. However, a polymer's useful range of stress and strain typically extends beyond the linear region and well into the nonlinear region. Thus, DMA can provide characteristic properties of a polymer, but the response acquired in DMA cannot be directly extended to large strain behavior.

The viscoelastic nature of polymers means that the strain (or stress) response is out-of-phase with the applied stress (or strain). Characteristics of the polymer behavior can be generated from the in-phase and out-of-phase components using vector analysis. The "storage" and "loss" components refer to in-phase and out-of-phase responses, and are linked to recoverable and dissipated energy, which is the result of molecular action. The loss tangent is the ratio of the two components at a particular frequency or temperature, and is often used to identify transitions in the material.

38.4 MECHANICAL MODELS OF VISCOELASTICITY

The viscoelastic behavior of polymers can be thought of as the sum of elastic and viscous behaviors. Elastic behavior of materials is classically modeled with a mechanical linear spring, where the amount of load required to compress the spring is linearly proportional to the amount of compression via a spring constant, k . Viscous behavior of fluids is

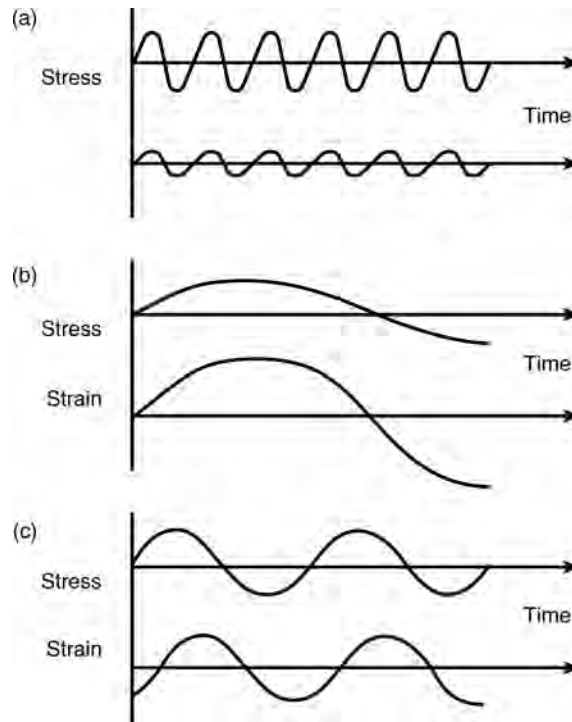

FIGURE 38.11 Effect of frequency on dynamic response of an amorphous, lightly crosslinked polymer: (a) elastic behavior at high frequency with stress and strain in phase, (b) liquidlike behavior at low frequency with stress and strain in phase, and (c) general case with stress and strain out of phase.

classically modeled with a dashpot (in which a piston moves through a vessel of viscous fluid), where the amount of shear stress required to move the piston is directly proportional to the shear rate via the fluid viscosity.

When the spring and dashpot are combined in series, the mechanical model is called a Maxwell element, and the resulting behavior is appropriate for representing stress relaxation. With this model, when load is removed, the model will instantly recover, but will not completely recover its deformation. When the spring and dashpot are combined in parallel, the mechanical model is called a Voigt or Kelvin element, and the resulting behavior is appropriate for representing creep behavior. With this model, when load is applied, the model will deform gradually to an asymptotic value.

The Maxwell and Voigt models are the two simplest mechanical models that are used to describe viscoelastic behavior. Many other, more complex models have been developed to represent certain physical behavior. Rudin (1999), Dowling (1999), and Hertzberg (1983) provide more information on various mechanical models of viscoelastic behavior. Dowling presents the simplest model that is roughly representative of real-world polymer creep, in that it combines elastic, steady-state creep, and transient creep elements; this model consists of a Maxwell element in series with a Voigt or Kelvin element. It is important to remember that the model is simply a tool to mathematically represent a physical behavior.

38.5 TIME-TEMPERATURE DEPENDENCE

There is a time-temperature similarity in the behavior of polymers, which is often called a time-temperature equivalence. The viscoelastic behavior at reduced temperatures is similar to that at reduced time periods, and the behavior at elevated temperatures is similar to that at extended time periods. This similarity or equivalence is related to the mobility of the chains, molecules, side groups, and so on, at a given temperature or time period.

From the work of researchers Williams, Landau, and Ferry, the WLF equation was developed to empirically relate this behavior equivalence in time and temperature. The WLF equation defines a shift factor (a_T) as a function of the T_g and temperature of interest. This shift factor applies to most amorphous polymers in the temperature region between T_g and $T_g + 100^\circ\text{C}$, and is calculated according to the equation below.

$$\log a_T = -\frac{C_1(T - T_g)}{C_2 + (T - T_g)}$$

The constants C_1 and C_2 have generally accepted values of 17.4 and 51.6. A more detailed discussion of this relationship and its link to other descriptions of polymer behavior can be found in Rudin (Rudin, 1999).

Long-term behavior can be determined from short-term behavior at higher temperatures. Master curves for creep and stress relaxation can be created using this equation if the user is cognizant not to apply it at temperatures at which the deformation mechanisms in the material change or at which crystallization can occur.

38.6 DEFORMATION MECHANISMS

38.6.1 Microscopic Deformations

Semicrystalline polymers consist of two distinctive regions: crystalline structure and amorphous structure. Crystalline structure is typically presented as lamellae, which are numerous chain-folded ribbons. Lamellar structures are separated by amorphous materials, which are randomly coiled polymer chains. The term “rigid amorphous phase” is sometimes used to describe the structure intermediate between crystalline and amorphous phases.

When a tensile stress is applied to a polymer, elastic deformation will take place; in that, the polymer chains will elongate along the direction of the stress by stretching of the covalent bonds within the molecular chain. In addition, displacement of adjacent molecules may also be possible, which involves the destruction of Van der Waals bonds between chains.

After the tensile stress reaches the yielding point, permanent, irrecoverable deformation will occur. The deformation mechanisms in amorphous polymers are relatively simple, with the material deforming under load by way of shear yielding or normal yielding (crazing, see Figure 38.12). In contrast, semicrystalline polymers undergo a more complex process of deformation due to their complex morphology.

FIGURE 38.12 Deformation mechanisms in amorphous polymers: (a) normal yielding (crazing) and (b) shear yielding (Hertzberg, 1983).

For a semicrystalline polymer, the plastic deformation is usually a multistep process, which is schematically illustrated in Figure 38.13. In the initial stage of deformation, the tie molecules in the amorphous regions slip past each other and become extended and aligned in the tensile direction, while the lamellae regions maintain their structures as blocks of folded ribbons. In the second stage, as the deformation continues, the lamellae blocks continue to tilt and the chain folds become aligned in the tensile direction. In the next stage, crystalline segments separate from the lamellae and remain attached to each other by tie molecules. Finally, the segments and tie molecules become orientated in the direction of the tensile axis and the polymer produces a fairly large amount of deformation and orientation.

FIGURE 38.13 Multistep process in the plastic deformation of a semicrystalline polymer (Callister, 2003). Sequentially, this entails extension and alignment in the amorphous regions, followed by lamellar disruption and crystalline orientation.

38.6.2 Shear Yielding

One of the important mechanisms leading to plastic deformation in polymers is shear yielding. This process consists of a change in specimen shape at constant volume and is more common in semicrystalline polymers than in glassy polymers. In semicrystalline polymers, shear yielding occurs in forms of slip, twinning, and martensitic-like transformations. In glassy polymers, shear yielding takes place through the formation of shear bands. Example micrographs are shown in Figure 38.14.

Shear yielding is closely related to the process and mechanism of polymer fracture. Tresca and von Mises criteria are the two simplest criteria for yielding. The Tresca criterion states that yield will occur when the maximum shear stress on any plane reaches a critical value. It is expressed as

$$|\sigma_1 - \sigma_3| = 2\tau_y$$

where σ_1 , σ_2 , and σ_3 are principal stresses and $\sigma_1 > \sigma_2 > \sigma_3$. τ_y is the yield stress of the material in pure shear, and is correlated with σ_y , the uniaxial tensile yield stress by

$$2\tau_y = \sigma_y$$

The von Mises criterion states that yield will occur when the elastic shear strain–energy density reaches a critical value. It is expressed as

$$(\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_3 - \sigma_1)^2 = 6\tau_y^2$$

It is noted that both Tresca and von Mises criteria were originally developed for metals, and may not describe the shear yielding of polymers adequately in certain aspects. For example, based on the above criteria, the yield stress measured in uniaxial tension will be equal to that in uniaxial compression; this may not be true for polymers.

FIGURE 38.14 Optical micrographs images (under crossed polarized light) of the shear bands in glass polymers under a plain-strain compression: (a) polystyrene and (b) poly(methyl methacrylate) (Kinloch and Young, 1983).

Shear yielding plays an important role in the initiation and propagation of cracks in polymers. In glassy polymers, highly localized shear bands may lead to the initiation of cracks due to the formation of microvoids at the intersection of shear bands. Upon crack growth, if the plastic deformation is still highly localized at the crack tip, the polymer will exhibit a brittle fracture with a low toughness value. However, if the shear yielding can be homogeneously extended throughout the material, a ductile failure will generally occur and the material will exhibit high toughness, because a significant amount of fracture energy can be absorbed by the extensive plastic deformation. In such a case, shear yielding is an effective toughening mechanism for polymers.

38.7 CRAZING

Another important energy dissipation mechanism in polymer deformation is crazing. A craze can be considered a microcrack bridged by multiple, highly-oriented polymer fibrils. The main difference between shear yielding and crazing is that shear yielding occurs at constant volume, while crazing involves an increase in volume. In other words, shear yielding requires a deviatoric component of the stress tensor, while crazing requires a dilatational component to the stress tensor.

FIGURE 38.15 TEM micrograph of a craze formed in PS (Brostow, 2001).

A transmission electron microscopy (TEM) micrograph of a craze in polystyrene is shown in Figure 38.15. Crazes are typically initiated at sites with defects or molecular inhomogeneities. First, microvoids nucleate at the defects under a tensile stress. Then, the microvoids grow in a plane perpendicular to the maximum principal stress, which is a cavitation process. Next, instead of coalescing and forming a crack, these microvoids are stabilized by the surrounding highly-oriented polymer fibrils spanning the craze. A craze growth mechanism of “meniscus instability” is illustrated in Figure 38.16, showing that the craze tip is broken into a series of “fingers,” and the fibrils are formed behind the craze tip as the fingers pinch together.

FIGURE 38.16 Illustration of craze growth by the “meniscus instability” mechanism.

Crazing has a close relationship with the fracture of glassy polymers, because the breakdown of crazes usually leads to a brittle fracture through microvoid coalescence and crack extension. Like shear yielding, crazing also involves considerable plastic deformation and energy dissipation, and thus can result in improved fracture resistance. In certain polymers, especially multiphase polymers like high impact polystyrene (HIPS) and acrylonitrile butadiene styrene copolymer (ABS), multiple crazing can be an effective mechanism in toughening.

38.8 FRACTURE

38.8.1 Griffith Theory

One important approach to explain the fracture of polymers is the energy balance theory developed by Griffith to model the brittle fracture of a glassy polymer with a pre-existing flaw. The flaw can be a scratch, a notch, or a sharp crack and serves as a stress concentration. The presence of a flaw in a body can be accounted for as an elliptical crack in an infinite plate loaded with a uniform stress, σ_0 , as shown in Figure 38.17. The stress at the tip of the crack, σ_t , can be written as

$$\sigma_t = \sigma_0 \left(1 + 2\sqrt{\frac{a}{\rho}} \right)$$

FIGURE 38.17 Model of an elliptical crack of length $2a$ in an infinite plate loaded with a uniform stress, σ_0 .

where $2a$ is the length of the crack and ρ is the radius of curvature of the tip. The above equation shows that the presence of a sharp crack will cause a large concentration of stress that has its maximum at the tip of the crack.

Griffith calculated the energy released in the fracture process by putting a sharp crack into a plate and related this to the energy required to create new surface. In Griffith's calculation, the critical stress of fracture, σ_c , can be expressed as

$$\sigma_c = \sqrt{\frac{2E\gamma}{\pi a}} \quad (\text{plane stress})$$

or

$$\sigma_c = \sqrt{\frac{2E\gamma}{\pi(1-\nu^2)a}} \quad (\text{plane strain})$$

where E is the Young's modulus, γ is the specific surface energy, and ν is Poisson's ratio. This calculation considers only the energy associated with surfaces and not the energy associated with deformation mechanisms that are often active in polymeric materials. The magnitude of the fracture stress depends strongly on the geometric constraints of the system. In plane strain, one of the three principal strains is equal to zero and the deformation is at constant volume. This is often obtained in the deformation of thick plates or constrained conditions around crack tips. Deformation of thin sheets results in plane stress conditions, in which the two principal stresses that are parallel to the free surfaces are finite and the third principal stress that is normal to the surfaces is zero. Thus, experimentally, thin sheet geometries will result in a higher fracture stress than for the same material with thicker, constrained geometries.

38.8.2 Fracture Mechanics

38.8.2.1 Linear Elastic Fracture Mechanics In the case of glassy polymers undergoing brittle fractures, linear elastic fracture mechanics (LEFM) can be applied. In this case, the material is linearly elastic and any yielding is restricted to a small region around the crack tip. In the LEFM analysis, critical stress intensity factor (K_c) and critical strain energy release rate (G_c) are the two most important parameters.

K_c is defined as

$$K_c = \sigma_c \sqrt{\pi a}$$

in the case of a wide plate sample containing a small crack. As K_c characterizes a material's resistance to brittle fracture, it is called fracture toughness.

The energy term, 2γ , can be replaced by G_c , allowing a correlation between K_c and G_c of

$$G_c = \frac{K_c^2}{E} \quad (\text{plane stress})$$

and

$$G_c = \frac{K_c^2(1-\nu^2)}{E} \quad (\text{plane strain})$$

There are three different modes of crack displacement. Mode I is an opening (or tensile) mode, where the fracture surfaces separate symmetrically with respect to the crack plane; Mode II is a sliding (or in-plane shearing) mode, where the fracture surfaces slide symmetrically with respect to normal, but asymmetrically with respect to the crack plane; Mode III is a tearing (or antiplane shearing) mode, where the fracture surfaces slide asymmetrically with respect to both the crack plane and its normal. Although the fracture of a material may involve either one or a combination of the three crack displacement modes, Mode I is the most commonly encountered and thus the fracture toughness and fracture energy for Mode I are cited for most situations.

For relatively thick samples, K_c is independent of sample thickness; however, for thin plates where sample thickness is comparable to the crack dimensions, K_c becomes dependent on the thickness, as shown in Figure 38.18. The stress condition of the crack in a relatively thick sample is generally plane strain state, so the K_c value at this condition is known as plane strain fracture toughness, K_{Ic} . The subscript “I” denotes that the plane strain fracture toughness is for Mode I crack displacement, as illustrated in Figure 38.19. As K_{Ic} is independent of the sample thickness, it is a well-accepted intrinsic material property to characterize fracture resisting capability. Similarly, the plane strain fracture energy for Mode I is denoted as G_{Ic} .

38.8.2.2 Elastic–Plastic Fracture Mechanics When nonlinear elastic deformation or large-scale plastic deformation has been developed in the vicinity of crack tip, the above LEFM approach no longer applies. Instead, as one form of the elastic–plastic fracture mechanics (EPFM), a J -integral concept was developed to calculate the energy parameter for elastic–plastic materials (Brostow, 2001). The J -integral is defined as the contour line integral which is independent of the integration path and can be expressed as

$$J = -\frac{1}{B} \frac{dU}{da}$$

where B is the thickness and U is the potential energy. The critical J -integral value at crack initiation in Mode I crack displacement is denoted as J_{Ic} , which is an intrinsic material property of resistance to fracture.

FIGURE 38.18 Schematic of the effect of sample thickness on fracture toughness, K_c .

FIGURE 38.19 Three modes of crack displacement: (a) Mode I: opening (or tensile) mode, (b) Mode II: sliding (or in-plane shearing) mode, and (c) Mode III: tearing (or anti-plane shearing) mode.

To experimentally measure the J_{Ic} value, multiple specimens are loaded to various levels to obtain crack extensions, Δa . This procedure is outlined in ASTM E813. For certain types of specimens, the J -integral can be obtained from the load-displacement curve

$$J = \frac{2A}{W - a}$$

where A is the area under the load-displacement curve and $(W - a)$ is the ligament thickness. Then, a crack growth resistance curve (R-curve) can be drawn by plotting the J -integral values against corresponding Δa . In a nonlinear fracture, the crack tip will be blunted before the crack can further extend. The crack blunting line is defined by

$$J = 2\sigma_y \Delta a$$

where σ_y is the yield stress of the material. The intersection of the R-curve and the crack blunting line defines the value of J_{Ic} .

FIGURE 38.20 Schematic of the process zone and the plastic zone around the crack tip in a ductile material.

38.8.2.3 Essential Work of Fracture When the material is extremely ductile, essential work of fracture (EWF) can be used (Brostow, 2001). This method divides the deformation zone around the crack tip into two different regions, the inner process zone and the outer plastic zone, as shown in Figure 38.20. Consequently, the total work of fracture, W_f , can be separated into two parts, the essential work of fracture, W_e , and the plastic work of fracture, W_p , which is written as

$$W_f = W_e + W_p$$

W_e is proportional to the ligament thickness, $W - a$, while W_p is proportional to $(W - a)^2$. Thus, W_f can also be written as

$$W_f = w_f B(W - a) = w_e B(W - a) + \beta w_p B(W - a)^2$$

where w_f is the specific total work of fracture per unit surface area, w_e is the specific essential work of fracture per unit surface area, w_p is the specific plastic work per unit volume, and β is a plastic zone shape factor. The equation can be re-written as

$$w_f = w_e + \beta w_p(W - a)$$

When plotting w_f against $(W - a)$, w_e can be obtained by extrapolating this linear correlation to zero $(W - a)$.

38.9 MODIFYING MECHANICAL PROPERTIES

38.9.1 Toughening of Polymers

Toughening technologies have been researched for decades to improve the fracture toughness of brittle polymers. Shear yielding and crazing are the two most important toughening mechanisms for polymers, but other mechanisms, including croiding (crazing/voiding), crack pinning, bifurcation, crack deflection, crack bridging, and segmental crack growth are recognized (Arends, 1996). To improve fracture toughness, it is important to facilitate deformation processes that can involve toughening mechanisms extensively throughout the material, so more fracture energy can be dissipated.

One toughening technique is molecular flexibilization. This can be achieved by incorporating flexible segments into the macromolecular chains, or increasing the molecular weight between crosslinks for thermosets. The flexibilization of molecular architectures leads to the relaxation of polymer chains or networks, which contributes to the energy dissipation and toughness improvement. However, one of the major drawbacks of this method is compromised strength and T_g , and the effectiveness is limited.

Another popular toughening technique is the incorporation of a second-phase toughening agent. The most widely accepted technique in the industry is adding rubber particles. The industrial production of impact polymers like HIPS and ABS are examples of this type of rubber-toughened polymer. This approach can apply to thermosetting polymers as well. For example, both reactive rubber particles, such as carboxyl terminated butadiene acrylonitrile (CTBN), and nonreactive core-shell particles, such as a butadiene-styrene core with a styrene-methylmethacrylate-acrylonitrile-glycidyl methacrylate shell, have exhibited great toughening effect in matrices of diglycidyl ether of bisphenol A (DGEBA) epoxies (Pearson et al., 2000). Unfortunately, significant increase in viscosity with the addition of rubber particles may largely compromise the processability in certain applications. As an alternate, thermoplastic particles, such as nylon spheres, are sometimes used as toughening agents.

More recently, a novel technique using nanosized amphiphilic di- and tri-block copolymer (BCP) micelles as a toughening agent has shown great effectiveness in improving epoxy fracture toughness. When mixing the BCP with the matrix, the compatible block will dissolve into the matrix, while the incompatible block microphase separates from the mixture, thus forming a micellar structure. Because of the unique structure, extremely small size of the micellar particles, and overall low concentration required, BCP-toughened epoxies retain T_g and modulus, as well as suitable viscosities for processing (Liu,).

38.9.2 Reinforcement of Polymers

The strength and stiffness of polymers can be modified with reinforcements. Depending on the type of the reinforcing agents, polymer composites can be classified as one of three different families: filler-reinforced, fiber-reinforced, and structural composites. In load-bearing applications of polymers, fillers are generally used to increase stiffness and reduce cost, whereas fibers are generally used to increase strength and fatigue performance.

Filler-reinforced composites usually refer to a random dispersion of small, hard fillers in the polymer matrix. The reinforcing fillers can be spherical particles (ZnO , SiO_2 , Al_2O_3 , CaCO_3 , and so on), platelets (montmorillonite, kaolin, zirconium phosphate, graphene, and so on), or randomly oriented small fibers/tubes (halloysite, carbon nanotube, and so on). An isotropic improvement in strength and modulus can be produced in this

case, while sometimes other properties, such as thermal stability, flame retardancy, and barrier property may also be improved. If at least one of the dimensions of these fillers is under 100 nm, this type of composite is referred to as a nanocomposite. For the past two decades, polymer nanocomposites have gained a great deal of interest and effort in both industry and academia for their outstanding performance and light weight (Boo, et al. 2006).

Fiber-reinforced composites usually consist of discontinuous or continuous fibers with an alignment in the polymer matrix. Glass and carbon are the two most popular fiber materials. Composites containing oriented fibers usually exhibit a high anisotropy and a uniaxial stress-strain response. The strength and stiffness in the longitudinal direction (parallel to the fiber orientation) can be significantly improved with the addition of fibers to the matrix, while the transverse strength can be extremely low, sometimes even lower than that of the matrix.

Another family of composites is structural composites, in which the inclusion material has a two-dimensional or three-dimensional structure. Laminate composites are one of the most common structural composites. These use laminated sheets of fabric materials, such as wood, paper, woven glass, or carbon fibers embedded in the polymer matrix. The final properties of the products are dependent not only on the physical properties of the materials of composition, but also on the geometrical design of the structures. Additionally, the processing techniques of structural composites are extremely important, because an improper processing procedure may result in critical defects in the material, such as delamination or air bubbles/pockets. Generally, structural composites can produce very high strength and stiffness, because of their high load transmission and distribution efficiency.

For both fiber-reinforced composites and structural composites, crack growth involves similar processes. Crack initiation usually occurs at the fiber/matrix interface. Then, crack propagation occurs along the interface, leading to debonding, fiber pull-out, and sometimes fiber breakage. Crack propagation can extend through the matrix, and matrix deformation and cavitation can occur.

38.10 LOAD-BEARING APPLICATIONS: CREEP, FATIGUE RESISTANCE, AND HIGH STRAIN RATE BEHAVIOR

38.10.1 Creep and Creep Rupture

At temperatures below T_g , creep effects are small, but as the temperature increases above T_g creep effects become significant. The mechanism of creep in amorphous polymers is reptation, in which the motion of molecules occurs in a time-dependent manner and occurs more rapidly at higher temperatures. These materials behave much like a viscous fluid, with molecules or groups of molecules moving relative to one another over time when stress is applied. Because higher temperatures cause more oscillations at the atomic level, in turn causing more molecular movements that constitute creep, this process can be expressed as an Arrhenius equation. The derived expression for creep due to viscous flow directly relates the strain rate to the applied stress (Dowling, 1999).

For semicrystalline polymers, creep deformation by viscous flow occurs at elevated temperatures, approaching the T_m . This flow of molecules past each other is easier for polymers with lower molecular weights, less crosslinking and fewer side-branches. These considerations are of practical importance to the processing and performance of different grades of polyethylene.

At more moderate temperatures (just above T_g), the molecules cannot move past each other as readily as at higher temperatures. This is due to the secondary bonds between the

polymer chains being more effective at lower temperatures. The result is that the molecules are more easily entangled and create increasing resistance as the creep deformation progresses. These same entanglements act like recovery springs when the load is removed, pulling the stretched molecules toward their original position. The end result is that at temperature moderately above T_g , creep behavior is very different from viscous flow, as the entanglements both limit the amount of creep deformation and provide deformation recovery.

Figure 38.21 schematically depicts typical creep behavior, in terms of strain, as a function of time. There are three stages of creep: an initial transient stage, which contains nearly instantaneous deformation that is predominantly elastic, but may contain some plastic strain; a secondary steady-state region, where there is a more gradual, but steady increase in deformation, and a tertiary unstable region, in which deformation escalates as rupture failure is approached. During the tertiary creep stage, the creep deformation becomes localized through formation crazes, cracks and void coalescence, or formation of a neck in the case of ductile polymers. The creep strain–time curve for a polymer is affected by the magnitude of applied stress and temperature.

Dowling (1999) presents the development of isochronous stress–strain curves and secant modulus curves, which are often used in component design for polymers. Material suppliers often provide such information. However, differences in polymer composition or processing affect these data, and it is recommended that data specific to the material and process of interest be obtained.

In engineering applications where creep occurs, the design and material selection must ensure that neither excessive deformation nor rupture occur within the design life. Creep data can be used to generate stress life curves for the stress and time required to reach a given limiting amount of deformation or rupture, as dictated by the design criteria.

FIGURE 38.21 Three stages of creep behavior under constant engineering stress.

38.10.2 Fatigue Resistance

In most load-bearing applications, the applied stress does not remain constant. If the stress changes are infrequent and small, stress–life and time–temperature data can still provide reasonably accurate life estimates. However, if the stress changes are frequent enough, fatigue damage can start to occur. Fatigue of polymers is more complex than for metals, due to that fact that there is almost always a creep component involved due to the intrinsic viscoelasticity of polymers. Depending on the loading frequency, there can also be thermal damage generated in addition to the mechanical damage.

Dowling (1999), Atkins and Mai (1988), and Hertzberg (1983) provide both excellent background and details on fatigue of materials. The rest of this section touches on areas of fatigue behavior and analysis that are pertinent to polymers. Topics such as strain life versus stress life, the effect of mean stress, variable amplitude loading and overloads, which are all very important in plastics, are too complex to introduce here, but are aptly covered in the aforementioned texts.

38.10.3 Creep-Fatigue Interaction

The time–temperature dependence of polymers means that creep-relaxation phenomena occur in combination with cyclic loading. The slower the test frequency and higher the temperature, the more significant the creep component. This means that loading waveforms (sinusoidal versus square versus ramp) directly influence the overall resulting creep-fatigue behavior.

There are three main approaches to handling creep-fatigue interaction to assess long-term life:

- Sum of life fractions due to creep (time-fraction) and fatigue (Palmgren–Miner rule), which is expressed as $\sum \Delta t_i / t_{ri} + \sum \Delta N_i / N_{fi} = 1$. This method can also be based on attaining a given amount of strain.
- Frequency-modified fatigue approach by Coffin, in which the cyclic stress–strain and strain–life relations are generalized and material constants are functions of temperature and frequency.
- Strain-range partitioning method by Manson, which considers life fractions spent in each of the following four types of loading: plastic deformation with little creep, creep in tension, creep in compression, and creep in both tension and compression.

38.10.4 Fatigue Resistance of Polymers

Fatigue resistance of polymers is assessed by one of the following three methods: crack propagation until fracture; accumulation of damage, which is commonly used for fiber-reinforced polymers; and degradation of a mechanical property, such as modulus, yield, or unrecovered strain.

Similar to metals, polymers can exhibit fatigue striations. At high stress intensity (ΔK) levels, striations generally correspond to crack advancement due to one load cycle. However, in polymers, especially at low ΔK levels, striations generally correspond to discontinuous crack advancement following several hundred load cycles, during which the crack front remains stationary. Thus, macroscopic growth rate data or other supplemental

information is necessary to distinguish between fatigue markings created by a single cycle and markings created by up to hundreds or thousands of cycles.

Semicrystalline polymers have superior fatigue crack propagation (FCP) resistance over amorphous polymers. This is a direct consequence of the microstructure and morphology of semicrystalline polymers. Energy is dissipated by deforming crystallites; the reformed crystalline structure is strong; and the two-phase structure (crystalline and amorphous) impedes crack propagation. Many amorphous polymers, such as PS, PMMA, and polycarbonate (PC), can have an endurance limit of only one-fifth the static fracture stress, whereas crystalline polymers, such as polyethylene, polypropylene, and polytetrafluoroethylene (PTFE), can have an endurance limit of one-third to one-half the static fracture stress, and sometimes higher. These are generalized endurance limit values and actual values depend on the testing conditions under which they were obtained (strain-control or stress-control, loading waveform and frequency, and so on) and on the particular composition of the polymer.

There are several compositional factors that affect the fatigue resistance of polymers. Fatigue resistance is greater for higher molecular weights (MW) due to greater entanglement density and orientation hardening. The T_g and modulus of a polymer can plateau at higher MW (100,000 to 200,000), but fatigue life and strength can continue to improve (as can creep resistance). This applies to both amorphous and crystalline polymers. Fatigue resistance can also be improved with a broader molecular weight distribution (MWD), and particularly those with high-MW tails. Because chain ends can be sources of submicron cracks, fewer chain ends can lead to improved fatigue resistance.

A lower T_g of the amorphous region makes a polymer less sensitive to flaws at its use temperature, because of the increased chain and molecular mobility. Similarly, a polymer with a lower melt flow index will have improved fatigue resistance over its higher melt flow counterpart, because of entanglements that limit creep and crack propagation.

Crosslinking increase rigidity, reduces ductility, inhibits crazing and creep, and inhibits local plastic deformation and crack tip blunting. Consequently, less crosslinking leads to improved fatigue resistance.

Rubbery additions generally do not have as significant an effect on fatigue resistance as they do on impact resistance and toughness. However, the effect can depend on MW and amount added.

Fillers, such as talc and other minerals, can delay cyclic softening until near the end of life, but the lifetime is affected very little. Thus, caution should be used when measuring property degradation to assess fatigue life of filled polymers.

The environment in which the polymer is exposed to fatigue can also strongly affect fatigue performance. For example, testing a polymer in an unreactive, but volatile (evaporative) liquid (e.g., nylon in water or alcohol) can improve apparent fatigue resistance due to cooling. Likewise, testing under a nitrogen blanket as opposed to air can double the life of PS; PS is not sensitive to oxygen but fatigue fracture may include some bond fracture as craze fibrils rupture, and these free radicals interact with oxygen to produce oxidative degradation. Finally, crazing or cracking agents can be used to accelerate testing, for example, alcohols on PS or Igepal on high density polyethylene (HDPE).

Fatigue loading waveforms (shape and frequency) can strongly affect FCP rates due to associated strain rate and creep-relaxation phenomena. For un-notched specimens, hysteretic heating at higher test frequencies leads to a reduction in fatigue resistance due to the high capacity for energy absorption and low thermal conductivity (worse for thicker samples), and reduced elastic modulus from generalized heating. However, with notched

specimens, fatigue resistance can increase with increased test frequency; this is related to the frequency of movement of the main chain segments responsible for transition peak (resonance-like condition) at the temperature of concern, with localized crack tip heating leading to crack tip blunting. With regards to strain rate effects resulting from the loading waveform, higher frequencies and faster loading rates (ramp versus sinusoidal) result in faster rates of strain, which can affect the polymer differently.

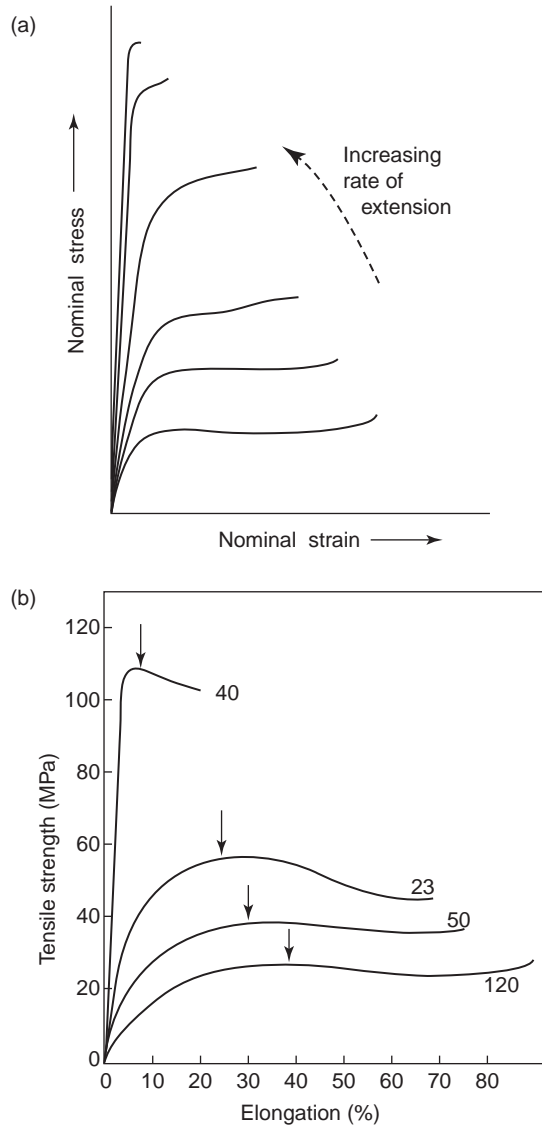

FIGURE 38.22 Stress-strain behavior of a polymer at different (a) strain rates and (b) temperatures (Rudin, 1999).

38.10.5 High Strain Rate Behavior

Because of the time–temperature dependence of polymers, it is understood that changes in behavior with decreasing temperature are similar to the change in behavior with decreasing time periods, or increasing strain rate. Figure 38.22 illustrates the general effects of decreasing temperature and increasing strain rate on the stress–strain response.

The deformation mechanisms in polymers depend on molecular mobility. At high strain rates (or loading rates), there is less time available for molecules to stretch, twist, and slide, and thus there is less resulting molecular movement. This is exhibited by the material response becoming stiffer and more brittle in nature. The most pronounced effect is often on the failure strain, with it becoming significantly lower with increasing strain rate. The failure stress and yield stress (if the polymer exhibits one) increase with increasing strain rate and the initial modulus often increases as well. Most polymers have a strain rate range over which the rate effects are most pronounced, and below and above that range the effects are more moderate.

It is difficult to acquire high quality stress–strain data for polymers at high strain rates, particularly if covering the entire range of behavior, from initial elastic modulus through yield and plastic deformation, to strain at failure. Numerous research activities have been underway to address these difficulties and provide protocol for experimental testing of polymers under high strain rates (Hill, 2005; Xiao, 2007; Pinnell, 2008). SAE J7149 provides guidance in experimentally determining high strain rate tensile behavior of polymers.

39.1 INTRODUCTORY REMARKS

Polymers are large molecules or macromolecules made up of repeating structural units usually connected by covalent chemical bonds. Polymers with structural units of the same type are called homopolymers and copolymers otherwise. Most skeletal bonds in macromolecules fluctuate between energy wells or rotational states giving rise to a nearly unlimited number of macromolecular conformations. As a result, the macromolecular nature of polymers vastly broadens the time scale for molecular adjustments to external

force fields. A relevant characteristic of polymers is their ability to withstand high electric fields with negligible conduction due to the high energy gap between the localized valence electronic states and the conduction band. This characteristic coupled with favorable processing properties makes polymers the obvious choice for insulating applications. The versatility of design of polymer chains has expanded the use of these materials to unexpected applications. Thus, polymers can be designed to be used as solid electrolytes for batteries and low temperature fuel cells, piezoelectric and pyroelectric sensors, electronic and ionic conductors, NLO materials, and so on. This chapter is focused on the description of the influence of the chemical structure on the polarity of molecular chains. Special attention is paid to the analysis of the influence of the physical nature of polymers (rubbery, glassy, crystalline, and liquid crystal) on their response to electrical force fields in wide temperature/frequency windows. Also chemical structures are described in relation with polymers capability to be used in ionic and electronic applications of great interest.

39.2 POLARITY AND PERMITTIVITY

A dipole is defined as an entity in which a positive charge q is separated by a distance \mathbf{r} from a charge of equal magnitude, but negative sign. The dipole moment is a first-order tensor or vector defined as $\boldsymbol{\mu} = q\mathbf{r}$. By convention, the direction of a dipole points from the negative toward the positive charge. Traditionally, the dipole moment resulting from two charges of 10^{-10} statc, separated by a distance of 1 Å, named Debye, is used as the dipole moment unit in the cgs system. Then, $1 \text{ D} = 10^{-18} \text{ stat C cm}$ and $3.338 \times 10^{-33} \text{ cm}$ expressed in cgs and SI units, respectively. Two electronic charges of different sign ($q = 1.6022 \times 10^{-19} \text{ C}$) separated by a distance of 1 Å have a dipole moment of 4.8 D. The dipole moment of rigid polyatomic molecules depends on their geometric structure and can be calculated as first approximation from the vectorial sum of bond dipoles.

In the International System of units, the electrical force lines crossing a surface S surrounding a positive electric charge q are given by (Jackson, 1974)

$$\oint_S \mathbf{E} \cdot d\mathbf{S} = \frac{q}{\epsilon_0 \epsilon} \quad (39.1)$$

where E is the electric field in V/m, ϵ_0 ($= 8.854 \text{ pF/m}$) is the permittivity in vacuum, and ϵ ($= \epsilon_a / \epsilon_0$) is the relative permittivity, ϵ_a being the absolute dielectric permittivity of the isotropic medium or dielectric under the electric force field. For a parallel capacitor containing a dielectric of relative permittivity, ϵ , Equation (39.1) becomes

$$E = \frac{q}{\epsilon \epsilon_0 S} = \frac{\sigma}{\epsilon \epsilon_0} \quad (39.2)$$

where q and S are, respectively, the charge and area of the capacitor arm plates and σ the surface-charge density. The decrease of the electric field in the capacitor by effect of the dielectric is given by

$$E_0 - E = \frac{\sigma}{\epsilon_0} \left(\frac{\epsilon - 1}{\epsilon} \right) \quad (39.3)$$

The reduction of the electric field arising from the decrease of the charge density in the capacitor, called polarization, can be written as

$$P = \sigma(\varepsilon - 1)/\varepsilon \quad (39.4)$$

The polarization of capacitors is caused by the alignment of the individual dipoles of the dielectric medium with the electric field. A parallel plate capacitor with polarization P , area of each arm plate S , and distance between plates d has a dipole moment given by $\mu = \mathbf{P}(\mathbf{S} \times \mathbf{d}) = \mathbf{P} V$, where V is the volume of the dielectric. Then the polarization can be defined as the dipole moment of the dielectric per volume unit.

Taking into account Equations (39.2) and (39.3), the polarization of an isotropic dielectric under an electric field E can be written in SI units as

$$\mathbf{P} = \sum_i \mu_i = e_0(\varepsilon - 1)\mathbf{E} \quad (39.5)$$

where μ_i is the dipole moment associated with the dipole of the molecular entity i of the dielectric. Then the electric susceptibility is given by

$$\chi = P/E = e_0(\varepsilon - 1) \quad (39.6)$$

Another important magnitude is the dielectric displacement, \mathbf{D} , defined as the charge density σ in the capacitor. From Equation (39.2), it follows that

$$\mathbf{D} = e_0\varepsilon\mathbf{E} \quad (39.7)$$

For anisotropic dielectrics, the relative dielectric permittivity becomes a second-order tensor and \mathbf{P} and \mathbf{D} should be written as

$$P_i = e_0(\varepsilon_{ij} - 1)E_j \text{ and } D_i = e_0\varepsilon_{ij}E_j \quad (39.8)$$

The SI units of \mathbf{P} and \mathbf{D} are C/m^2 . Notice that in the cgs system the factor $1/(4\pi)$ should replace the symbol e_0 in the equations indicated above. The units of electrical charge, electric field, voltage and capacity in the cgs system, and their equivalences with the respective SI units are, respectively, statc ($1 \text{ C} = 3 \times 10^9 \text{ statc}$), dyne/statc ($1 \text{ N/C} = 3.3 \times 10^{-5} \text{ dyne/statc}$), statv ($1 \text{ V} = 3.3 \times 10^{-3} \text{ statv}$), and statF ($1 \text{ F} = 9.1 \times 10^{11} \text{ statF}$).

39.3 MEASUREMENTS OF DIELECTRIC PERMITTIVITY

Since $E = -\text{grad } V$, where V is the electrical potential, and bearing in mind that the capacity of a capacitor is $C = q/\Delta V$, Equation (39.2) shows that the capacity of capacitors having parallel and cylindrical geometries are, respectively, $C = e_0\varepsilon S/d$ and $C = 2\pi e_0\varepsilon L/\ln(r_2/r_1)$. In these expressions, S and d are, respectively, the area of a single arm plate and the distance between the plates for parallel capacitors, whereas r_1 and r_2 are, respectively, the radii of the internal and external cylinders of length L for capacitors with cylindrical geometry. Notice that if $r_2 - r_1 = d$ is very small, $\ln(r_2/r_1) = \ln[1 + (r_2 - r_1)/r_1] \cong (r_2 - r_1)/r_1$. Since $2\pi r_1 L = S$, where S is

the lateral area of the cylinder, the formula for the capacity of a cylindrical capacitor is also $\epsilon_0 \epsilon S/d$. The SI units of the voltage, electric field, and capacity are, respectively, V, V/m, and F. The relative dielectric permittivity ϵ of a dielectric is C/C_0 , where C and C_0 are the capacitance of a capacitor containing, respectively, the dielectric material and vacuum.

It is an experimental fact that most capacitors with dielectrics between their arm plates lose a fraction of energy under an alternating electric current. The simplest model for a capacitor with a lossy dielectric is a capacitor with a perfect dielectric ($\epsilon = 1$) in parallel with a resistor accounting for the power dissipation (Figure 39.1a). The admittance of the circuit under an alternate voltage $V = V_0 \exp(j\omega t)$, where ω is the angular frequency of the force field, is a complex quantity that can be written as $Y^* = 1/R - j\omega C$. Since the current intensity flowing in the circuit is $C_0 \epsilon^*(\omega) dV/dt = VY^*$, where ϵ^* is the relative complex permittivity and C_0 is the capacity of the capacitor in vacuum, the values of the real ϵ' and imaginary ϵ'' components of ϵ^* are given by

$$\epsilon' = \frac{C}{C_0}; \quad \epsilon'' = \frac{1}{\omega RC_0} \quad (39.9)$$

The loss $\tan \delta$ for the equivalent parallel circuit is given by

$$\tan \delta = \epsilon''/\epsilon' = (\omega RC)^{-1} \quad (39.10)$$

An alternative model to the equivalent parallel circuit is an ideal capacitor ($\epsilon = 1$) in series with a resistor (Figure 39.1b). After pertinent calculations carried out following the procedure outlined above, ϵ' and ϵ'' are expressed by

FIGURE 39.1 Schemes of the equivalent electric circuits for dielectrics: (a) in parallel and (b) in series.

$$\varepsilon' = \frac{C_s/C_0}{1 + \omega^2 R_s^2 C_s^2}$$

$$\varepsilon'' = \frac{\omega R_s C_s^2}{C_0 [1 + \omega^2 R_s^2 C_s^2]}$$
(39.11)

The subscript s reminds that the ideal capacitor and the ohmic resistance are in series in the circuit. The loss $\tan \delta_s$ can be written as

$$\tan \delta_s = \omega R_s C_s \quad (39.12)$$

The study of the electric behavior of the condensed matter in general, and polymers in particular, can be carried out in the frequency window $10^{-4} < f < 10^{11}$ Hz where $f = \omega/2\pi$ (Kremer and Arndt, 1997). However, this wide range of frequencies cannot be covered by a single apparatus. In the frequency range 10^{-4} –10 Hz, the permittivity can be measured using lumped circuit transient response. The dielectric permittivity in the intermediate frequencies range 10^{-1} – 10^6 Hz has traditionally been measured with an experimental device based on the Wheatstone bridge principle where the arms of the bridge are capacitance-resistance networks (Figure 39.2a).

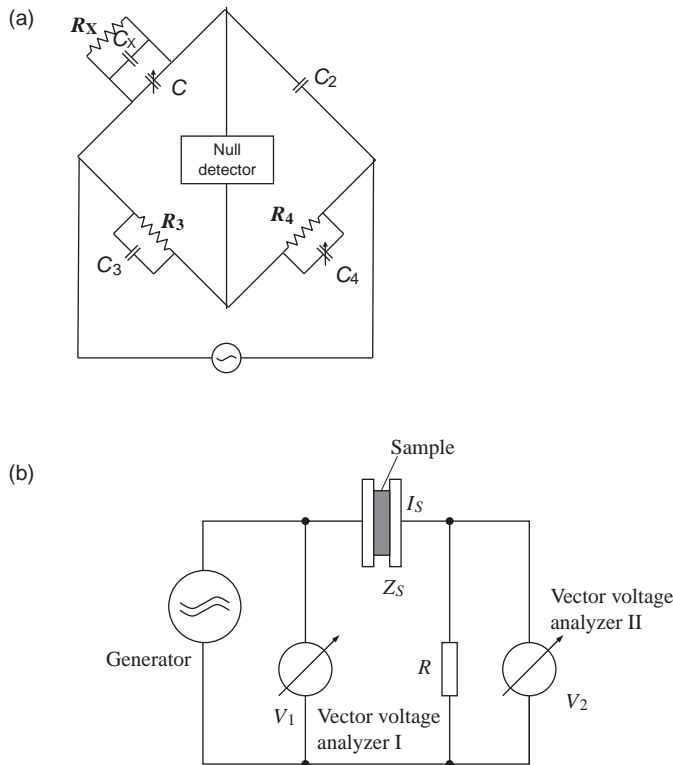

FIGURE 39.2 Schemes of (a) capacitance bridge (the resistance and capacitance of the equivalent circuit of the sample are indicated by R_x and C_x) and (b) impedance spectrometer.

The frequency range 10^{-2} – 10^6 Hz can also be covered utilizing impedance bridge devices. A scheme of a frequency response analyzer of this kind is shown in Figure 39.2b (Kremer and Arndt, 1997). An AC voltage V_1 is applied to the sample, and a resistor R or a current-to-voltage converter for low frequencies converts the sample current I_S into a voltage V_2 . By comparing the amplitude and the phase angle between these two voltages, the complex impedance of the sample is given by

$$Z_S^* = \frac{V_1 - V_2}{I_S} = \frac{V_1 - V_2}{V_2} R \quad (39.13)$$

For frequencies higher than 10^5 Hz, a buffer amplifier decouples the sample current of the analyzer and the current-to-voltage converter by means of an impedance variable. Owing to parasitic inductances, the high frequency limit is about 1 MHz.

At frequencies in the range 1 MHz–10 GHz, the inductance of the connecting cables contributes to the measured impedance. Resonance circuits have been used in the past in the range 10^5 – 10^8 Hz. The measurements performed in a broad range of temperatures require the lengths of the electric wires connecting the sample and the resonance circuit to be as short as possible. This problem can be circumvented by placing the sample capacitor as the termination of a high precision coaxial line.

A technique often used to obtain dielectric spectra at high frequencies is time domain reflectometry (Cole, 1975, 1977; Cole et al., 1980; Mopsik, 1984; Feldman, 1996). The technique is based on the reflection of an electric wave transported through a coaxial line in a dielectric sample cell attached to the end of the line. If the reflected wave corresponding to a step-pulse voltage incident signal is measured in the time domain, the ratio of the Fourier transforms of the reflected wave and the incident pulse is a function of the complex permittivity of the sample.

For frequencies above 1 GHz, the experimental devices move from interference optics to geometrical optics. Network analysis is used and the dielectric properties of materials from infrared to ultraviolet are studied in terms of the amplitude and phase of reflected and transmitted waves. A scheme of the range of frequencies covered by different experimental devices is shown in Figure 39.3.

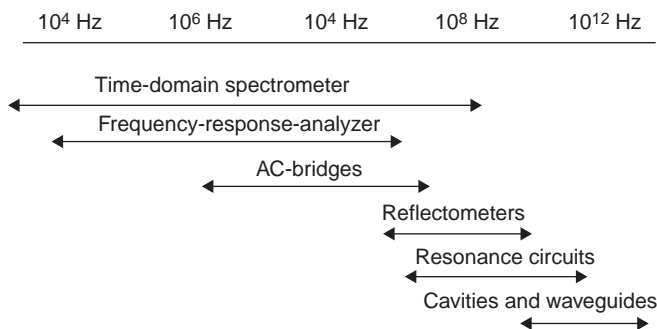

FIGURE 39.3 Experimental devices for dielectric spectroscopic measurements in different ranges of frequency.

39.4 POLARIZATION AND DIPOLE MOMENTS IN ISOTROPIC SYSTEMS

Let us consider a gas with randomly oriented N molecules per unit volume, each of them having permanent dipole moment μ_p . An electric field E produces a partial orientation of the permanent dipoles together with the separation of the residual charges in such a way that the dipole moment of the molecules is $\mu = \mu_p + \mu_d$, where μ_d arises from the residual charges displacement in the direction of the electric field. The parameter μ_d is related to E by $\mu_d = \alpha_d E$, where α_d is the molecular polarizability. In the cgs system, used in this section, the units of μ and α are, respectively, the Debye and cm^3 . The calculation of the dipolar contribution to the polarization was firstly proposed by Debye (1936). If E has the z -axis direction of the reference frame, the total polarization can be expressed by

$$\mathbf{P} = N(\mu_p \langle \cos \theta \rangle + \mu_d) \mathbf{k} \quad (39.14)$$

where \mathbf{k} is the vector unit along the z axis, and $\langle \cos \theta \rangle$ is the average of the cosine of the angle the permanent dipoles form with the electric field. This average can be obtained using the Boltzmann distribution for the dipoles at temperature T to yield $\langle \cos \theta \rangle = \mu_p E / 3k_B T$, where k_B is the Boltzmann constant. Then Equation (39.14) becomes

$$\mathbf{P} = N \left(\mu_p^2 E / 3k_B T + \mu_d \right) \mathbf{k} = N(\alpha_0 + \alpha_d) \mathbf{E}_1 \quad (39.15)$$

where $\alpha_0 = \mu_p^2 E / 3k_B T$ is the orientation polarizability and \mathbf{E}_1 is the true electric field acting on each molecule in the \mathbf{k} direction arising from the external electric field E together with the field E_{sph} produced by the charges surrounding the cavity where the molecule is located. Pertinent calculations find that $E_{\text{sph}} = (4/3)\pi P$ and the real field acting on the molecule in the \mathbf{k} direction is $E_1 = E + E_{\text{sph}}$. Since in the cgs system, the appropriate expression for Equation (39.6) is $\chi = P/E = (\epsilon - 1)/4\pi$, Equation (39.14) leads to

$$\frac{\epsilon - 1}{\epsilon + 2} = \frac{4\pi\rho N_A}{3M} (\alpha_0 + \alpha_d) = P_o + P_d \quad (39.16)$$

where ρ and M are, respectively, the density and molecular mass of the gas, and N_A is Avogadro's number. Moreover, $P_o = 4\pi\rho N_A \alpha_0 / 3M$ and $P_d = 4\pi\rho N_A \alpha_d / 3M$ are called, respectively, the orientation and induced molar polarizations. Notice that the molar polarization evidently differs from the polarization \mathbf{P} or dipole moment per volume unit. The parameter $\alpha_d (= \alpha_e + \alpha_a)$ arises from the distortion of the electronic cloud (electronic polarizability, α_e) and the small displacement of the atoms of the molecule (atomic polarizability, α_a) caused by the electric field. The molecular polarizability α_d can be obtained by writing $\alpha_0 = 0$ in Equation (39.16). Then the electronic polarizability α_e is usually calculated by utilizing the Maxwell relationship $\epsilon(\lambda) = n^2(\lambda)$. Owing to the fact that Equation (39.15) corresponds to a static electric field, n should be obtained at different wavelengths and its value extrapolated to $1/\lambda \rightarrow 0$. Except for silicon compounds, the parameter α_a is rather small, approximately $0.15\alpha_e$, and its contribution to the polarization is neglected. In these circumstances, Equation (39.16) can be written as

$$\frac{\varepsilon - 1}{\varepsilon + 2} - \frac{n^2 - 1}{n^2 + 2} = \frac{4\pi\rho N_A \mu_p^2}{3k_B T M} \quad (39.17)$$

This expression, known as Debye equation, holds for a variety of gases and vapors at ordinary pressures. However, Equation (39.17) presents some shortcomings, among them the prediction of a Curie temperature at which the material becomes ferroelectric. Moreover, Equation (39.17) fails for polar liquids. These facts led Onsager (1936) to reexamine the internal field in the cavity model introducing the concept of reaction field. Onsager succeeded in developing a fundamental modification of Debye's equation that gives a good account of the dipole moment of liquids in absence of real association between molecules. Kirkwood (1939) and Fröhlich (1948, 1958) refined even more Debye's formalism by taking into account short-range interactions between neighboring molecules.

By separating polar molecules from one another in the liquid state with nonpolar ones, the dielectric behavior of the solution resembles that of a gaseous condition. In this situation, the Debye model can be used to obtain the dipole moment of isolated polar molecules from their solutions in nonpolar solvents such as benzene, toluene, cyclohexane, and so on. In this case Equation (39.16) becomes (Guggenheim, 1949, 1951; Smith, 1950)

$$\mu_p^2 = \frac{27k_B T M}{4\pi\rho N_A (\varepsilon_1 + 2)^2} \lim_{w \rightarrow 0} \left(\frac{d\varepsilon}{dw} - \frac{dn^2}{dw} \right) \quad (39.18)$$

where M is the molecular weight of the polymer, ε and n are, respectively, the static dielectric permittivity and the index of refraction of the solution in which the weight fraction of polymer is w ; ρ and ε_1 are, respectively, the density and the dielectric permittivity of the solvent whereas N_A and k_B are, respectively, Avogadro's number and Boltzmann's constant. Notice that using cgs units in Equation (39.18), μ_p is given in Debye's equation.

Whereas rigid simple molecules have similar permanent dipole moments, flexible oligomers and polymers are continuously changing their spatial conformations. Actually, molecular chains are made up of thousands and even hundred of thousands of skeletal bonds. Each skeletal bond fluctuates in energy wells separated from contiguous wells by barrier energies. The energy wells are associated with discrete rotational states. By effect of the thermal energy $k_B T$, a fluctuating skeletal bond can overcome the barrier energy that separates it from another rotational state and a conformational transition takes place. Then conformational transitions can be considered to be produced by discrete rotations about skeletal bonds. For most skeletal bonds, the rotational states with minimum energy are *trans* (t), *gauche* positive (g^+), and *gauche* negative (g^-) (Figure 39.4). Accordingly, a

FIGURE 39.4 Conformations arising from rotations about skeletal bond i : *trans* (t , all the methylene groups are on the plane), *gauche* positive (g^+ , the last methylene group located behind the plane), and *gauche* negative (g^- , the last methylene group in front of the plane).

chain of N skeletal bonds has accessibility to 3^{N-2} spatial conformations, a nearly unlimited number of spatial conformations for large values of N . The dipole moment associated with each conformation may differ from that of another one, and μ_p^2 obtained for polymers using Equation (39.18) is an average value, currently written as $\langle \mu^2 \rangle$, where bracket angles mean average. Mean-square dipole moments obtained for polymers and oligomers using Equation (39.18), also known as the equation of Guggenheim (1949, 1951) and Smith (1950) show consistency among them, presumably because intra-molecular dipole-dipole interactions fade away among dipoles separated by four or more skeletal bonds. Then Equation (39.18) becomes one of the most reliable methods that can be used to determine mean-square dipole moments for isolated molecular chains.

Dipoles in molecular chains can be rigidly attached to the skeletal bonds and to flexible side chains. In the first case, dipoles can be classified into two types: (a) dipoles parallel to the chain contour (type A dipoles) and (b) dipoles bisecting skeletal bond angles, and therefore perpendicular to the chain contour (type B dipoles). Dipoles separated from the main chain by flexible segments are called type C dipoles (Stockmayer, 1967; Stockmayer and Burke, 1969). Dipoles of type A are correlated with the end-to-end distance of the chain, \mathbf{r} , in such a way that $\langle \boldsymbol{\mu} \times \mathbf{r} \rangle \propto \langle r^2 \rangle$, where $\langle r^2 \rangle$ is the mean-square end-to-end distance of the chains. As a consequence, the mean-square dipole moment measured in solution for this type of polymers is subject to the same excluded volume effects as $\langle r^2 \rangle$. For macromolecules with B and C type dipoles $\langle \boldsymbol{\mu} \times \mathbf{r} \rangle = 0$, and therefore, $\boldsymbol{\mu}$ and \mathbf{r} are uncorrelated parameters. This means that the mean-square dipole moment measured in solution does not present excluded volume effects for polymers containing either B or C type dipoles. The dipoles of most polymers are of types B or C.

The mean-square dipole moment of a chain of N skeletal bonds is given by

$$\langle \mu^2 \rangle = \langle \boldsymbol{\mu}_i \times \boldsymbol{\mu}_j \rangle = \left\langle \sum_i \mathbf{m}_i \times \sum_j \mathbf{m}_j \right\rangle = \sum_i m_i^2 + 2 \left\langle \sum_i \sum_{j < i} m_i m_j \cos \theta_{ij} \right\rangle \quad (39.19)$$

where m_i and m_j represent, respectively, the dipole moments of the skeletal bonds i j , whereas θ_{ij} is the angle between these two bonds. Dipole moments associated with skeletal or groups of skeletal bonds can be obtained from simple molecules. For example, from the dipole moments of dimethyl ether and dimethyl thioether, the dipole moments of ether ($\text{CH}_2\text{—O}$), thioether ($\text{CH}_2\text{—S}$), and $\text{CH}_2\text{—CH}_2$ skeletal bonds are found to be, respectively, 1.07, 1.21, and 0.00 D. For polyvinyl chloride, polyvinyl bromide and aliphatic polyesters, the dipole moments of ethyl chloride, ethyl bromide, and methyl acetate are used as dipole moments of the respective structural units. Detailed information concerning dipole moments of low molecular weight molecules used as models for molecular chains can be found elsewhere (McClellan, 1974).

For a freely jointed chain $\langle \cos \theta_{ij} \rangle = 0$ and $\langle \mu^2 \rangle = \sum_i m_i^2$. In general mean-square dipole moments are expressed in terms of the dipole moment ratio $g = \langle \mu^2 \rangle / \sum_i m_i^2$. The parameter g such as the characteristic ratio $\langle r^2 \rangle \langle r^2 \rangle_0 / \sum_i l_i^2$, where $\langle r^2 \rangle_0$ and l_i are, respectively, the unperturbed mean square end-to-end distance of the chains and the length of the skeletal bond i , depends on molecular weight for short chains. However, both ratios are independent on molecular weight for large chains.

Both the dipole moment ratio and its temperature dependence expressed as $d \ln \langle \mu^2 \rangle / dt$ may be very sensitive to the chemical structure of polymer chains (Riande and Mark, 1978). For example, polyoxymethylene (POM) exhibits a low polarity ($g = 0.2$) whereas syndiotactic polyvinyl chloride (PVC) presents a rather high polarity ($g \cong 4$)

FIGURE 39.5 Conformational transition $g^+g^+ \rightarrow tt$ for four oxymethylene skeletal bonds. Arrows indicate dipoles associated with CH_2OCH_2 skeletal bonds.

(Riande and Saiz, 1992; Díaz-Calleja and Riande, 1997). The low value of g for POM arises from the fact that *gauche* states of the same sign are favored over the alternative *trans* states. In the former case, dipoles are in antiparallel direction (low polarity), whereas in the latter are in parallel direction (high polarity). An increase in temperature causes conformational transitions from *gauche* to *trans* states and, as a result, the dipole ratio of POM chains exhibit an unusually high temperature dependence, of the order of $6 \times 10^{-3} \text{ K}^{-1}$ (Figure 39.5) (Riande and Mark, 1978).

The stereochemical composition of vinyl polymers containing polar groups in their structure affects the total polarity of the chains (Mark, 1971, 1972; Blasco Cantera et al., 1981; Saiz et al., 1982; Salmerón et al., 1984). For example, syndiotactic PVC is formed by $ttt \dots t$ sequences occasionally separated by *gauche* states. In $ttt \dots t$ conformations the dipole moments associated with the repeating units of syndiotactic PVC are in nearly parallel direction and as a result the dipole moment ratio of the polymer is rather high, of the order of 4. However, isotactic PVC is formed by $tg^+tg^+ \dots tg^+$ (or $tg^-tg^- \dots tg^-$) sequences, occasionally separated by *trans* states. In these conformations, the dipoles associated with the repeating units of the isotactic chains are in nearly opposite direction; hence, the low dipole moment ratio of isotactic PVC is rather low, of the order of 0.5.

The Rotational isomeric state (RIS) (Volkenstein, 1963; Flory, 1969) model, which assumes that each skeletal bond has accessibility to a limited series of rotational angles of minimum energy, has proved to be a useful tool to predict the polarity of molecular chains as a function of the chemical structure (Suter and Mattice, 1994). Also, the model is useful to determine the conformational energy of *gauche* states relative to the corresponding *trans* states by comparing experimental mean-square dipole moments with theoretical ones calculated using the RIS model. For illustrative purposes, the variation of the dipole moment ratio with the energy of *gauche* states about $\text{OCH}_2\text{—OCH}_2$ bonds in the case of alternating copolymers of methylene oxide and ethylene oxide are shown in Figure 39.6 (Riande and Saiz, 1992) Notice that as the energy decreases the fraction of low polarity $g^\pm g^\pm$ conformations increases at expenses of the high polarity tt conformations (see Figure 39.5). Good agreement between theoretical and experimental results is found for values of $E(g^\pm) - E(t) = -1.2 \text{ kcal/mol}$.

39.4.1 Dielectric Relaxations

In response to electric field perturbations, the dipoles of polar molecules of liquids rotate toward the direction of the field until an equilibrium distribution of the dipoles around the direction of the field is accomplished. The dielectric polarization decreases with the molecular size, the viscosity of the medium and the frequency of the electric field. All these variables hinder the orientation of the molecules in the field. As a result, the

FIGURE 39.6 Dependence of the dipole moment ratio of poly(1,3-dioxane) on the energy of gauche states relative to trans about oxymethylene skeletal bonds (Riande and Mark, 1978).

polarization is a complex quantity with a capacitance perpendicular to the field, and another component, in phase with the field, accounting for the displacement current that gives rise to thermal dissipation of energy. Theories have been developed (Fatuzzo and Mason, 1967; Titulaer and Deutch, 1974) relating the polarization with the frequency force field, but here only a phenomenological approach will be described.

In linear conditions, experimental evidence (Riande and Díaz-Calleja, 2005) indicates that the dielectric displacement under a constant force field, E , varies with time as $D(t) = e_0[\varepsilon_\infty + (\varepsilon_0 - \varepsilon_\infty)\varphi(t)]E$, where $\varphi(t)$ is a normalized continuous monotonously increasing function or buildup function that describes the orientation of the dipoles with time, whereas ε_0 and ε_∞ are the dielectric permittivities at time ∞ and zero, respectively. The limit values of $\varphi(t)$ are $\varphi(0)=0$ and $\varphi(\infty)=1$. In linear systems, the Boltzmann superposition principle holds so that the total dielectric displacement at time t caused by a variable electric field $E(\theta)$ can be written as (Riande and Díaz-Calleja, 2005; MacCrum et al., 1967)

$$D(t)/e_0 = \int_{-\infty}^t \varepsilon(t-\theta)[dE(\theta)/d\theta]d\theta = \varepsilon_\infty E(t) + (\varepsilon_0 - \varepsilon_\infty) \int_0^\infty E(t-u)[d\varphi(u)/du]du \quad (39.20)$$

Under an alternating electric field $E(t)=E_0 \operatorname{Im} \exp(j\omega t)$, where ω is the angular frequency of the electric field, Equation (39.20) leads to

$$\varepsilon^*(\omega) = D(t)/(e_0 E(t)) = \varepsilon_\infty + (\varepsilon_0 - \varepsilon_\infty) \int_0^\infty \exp(-j\omega u)[-d\varphi(u)/du]du \quad (39.21)$$

In this expression, $\varphi(t)$ is a continuous monotonously decreasing function or memory function whose limit values are $\varphi(0)=1$ and $\varphi(\infty)=0$; moreover, $d\varphi(t)/dt + d\varphi(t)/dt = 0$. Hence, Equation (39.21) can be rewritten in the following way

$$\frac{\varepsilon^*(\omega) - \varepsilon_\infty}{\varepsilon_0 - \varepsilon_\infty} = L \left[-\frac{d\phi(t)}{dt} \right] \quad (39.22)$$

where the symbol L represents the Laplace transform (Williams, 1979). Notice that ε_0 and ε_∞ in the frequency domain represent the relaxed ($\omega = 0$, $t \rightarrow \infty$) and unrelaxed ($\omega \rightarrow \infty$, $t = 0$) dielectric permittivities. The right-hand side of Equation (39.22) is $\phi(0) - s\phi(s) = 1 - s\phi(s)$, where $\phi(s)$ is the Laplace transform of $\phi(t)$. Then Equation (39.22) can be written as $f(\omega) = 1 - s\phi(s)$, where $f(\omega)$ represents the left-hand side of this equation. In the complex plane, $s = j\omega$ and taking into account that $\phi(t) = \phi^{-1}(s)$, the memory function can be expressed in terms of the complex permittivity by

$$\phi(t) = \frac{1}{2\pi} \lim_{R \rightarrow \infty} \int_{-R}^R \frac{\varepsilon_0 - \varepsilon^*(\omega)}{\varepsilon_0 - \varepsilon_\infty} \exp(j\omega t) d \ln \omega \quad (39.23)$$

For a simple system defined by a single relaxation time, the rate of return to equilibrium of an observable property depending on time, $X(t)$, is proportional to the distance of the observable from its value at equilibrium represented by X_{eq} . As a first order approximation, $(X(t) - X_{eq})/(X(0) - X_{eq}) = \exp(-kt)$, where the proportionality constant k must be the reciprocal of time, that is, $k = 1/\tau$, τ being the so-called relaxation time. The relaxation time is defined as the time necessary for the observable quantity X to reduce $1/e$ the value it had at $t = 0$. Then, the time dependence of the normalized relaxation function with a single relaxation time is $\phi(t) = \exp(-t/\tau)$. By substituting this expression into Equation (39.22), the real and loss components of the complex dielectric permittivity for systems with a single relaxation time or Debye systems are obtained as

$$\varepsilon'(\omega) = \varepsilon_\infty + (\varepsilon_0 - \varepsilon_\infty)/(1 + \omega^2 \tau^2) \quad (39.24)$$

$$\varepsilon''(\omega) = (\varepsilon_0 - \varepsilon_\infty)\omega\tau/(1 + \omega^2 \tau^2) \quad (39.25)$$

According to Equation (39.24), the real component of the complex dielectric permittivity is a continuous decreasing function of ω , its limit values being ε_0 and ε_∞ at $\omega \rightarrow 0$ and $\omega \rightarrow \infty$, respectively. Illustrative plots for the components of the complex permittivity are shown as a function of $\omega\tau$ in Figure 39.7a. Three regions can be observed in the isotherm corresponding to ε' . In the high frequency region, ε' undergoes only a slight increase as frequency decreases. This region is followed by another one where ε' substantially increases with decreasing frequency. In the low frequencies region, ε' is nearly independent on frequency. The dielectric loss ε'' is an absorption that reaches a maximum at $\omega\tau = 1$, just at the inflexion point of the ε' versus $\omega\tau$ curve. The values of ε'' at the frequency limits ($\omega \rightarrow 0$, and $\omega \rightarrow \infty$) are zero.

The so-called complex electric modulus $M^*(\omega)$ is the reciprocal of the complex permittivity. Its components expressed in terms of those of $\varepsilon^*(\omega)$ are

$$M'(\omega) = \varepsilon'(\omega)/[\varepsilon'^2(\omega) + \varepsilon''^2(\omega)]; \quad |M''(\omega)| = \varepsilon''(\omega)/[\varepsilon'^2(\omega) + \varepsilon''^2(\omega)] \quad (39.26)$$

Plots with the components of $M^*(\omega)$ for a material with a single relaxation time are presented in Figure 39.7b. In the low frequency region, the value of the real component M'

FIGURE 39.7 (a) Real and imaginary components of the complex dielectric permittivity ϵ^* against $\log \omega\tau$ for a system described by the following parameters: $\epsilon_0 - \epsilon_\infty = 3$, and $\epsilon_\infty = 2.5$. (b) Components of the complex relaxation modulus M^* for the same system.

slightly increases with increasing frequency until a frequency is reached at which the modulus undergoes a sharp increase, remaining nearly constant in the high frequencies region. On the other hand, the shape of M'' versus $\omega\tau$ is similar to that of ϵ'' reaching a maximum at the inflexion point of the curve M' versus $\omega\tau$. It is worth noting that the shapes of ϵ' and M' remind those of the creep compliance function (J') and relaxation modulus (G') in mechanical dynamic experiments.

For most systems, including low molecular weight liquids and polymers, dielectric dispersions in the frequency domain cover more than the 2.29 decades predicted by Debye systems. This fact suggests that a multitude of dielectric mechanisms i may intervene in the relaxations of real systems, each of them associated with a different relaxation time τ_i . Accordingly, the normalized decay function should be expressed as a weighted sum of exponential decay functions, $\phi(t) = \sum_i w_i \exp(-t/\tau_i)$ where w_i is the mass fraction of the mechanism i and $\sum_i w_i = 1$. Then Equation (39.22) can be written as

$$[\epsilon^*(\omega) - \epsilon_\infty]/(\epsilon_0 - \epsilon_\infty) = \sum_i w_i / (1 + \omega^2 \tau_i^2) \quad (39.27)$$

The integral analogue of Equation (39.27) involves a continuous distribution of retardation times $L(\ln \tau)$, and Equations (39.24) and 39.25 become

$$[\epsilon'(\omega) - \epsilon_\infty]/(\epsilon_0 - \epsilon_\infty) = \int_{-\infty}^{\infty} L(\ln \tau) d\ln \tau / (1 + \omega^2 \tau^2) \quad (39.28)$$

$$\epsilon''(\omega)/(\epsilon_0 - \epsilon_\infty) = \int_{-\infty}^{\infty} L(\ln \tau) \omega \tau d\ln \tau / (1 + \omega^2 \tau^2) \quad (39.29)$$

These equations can directly be obtained by taking into account that a continuous monotonously decreasing function of time, such as the memory function $\phi(t)$, can be expressed in terms of the Laplace transform of an unknown function $N(s)$ (see Riande and Díaz-Calleja, 2005 for details). Following the same strategy, the dielectric permittivity in the time domain can be written in terms of the retardation spectrum as

$$\varepsilon(t) = \varepsilon_{\infty} + (\varepsilon_0 - \varepsilon_{\infty}) \int_{-\infty}^{\infty} L(\ln \tau) (1 - e^{-t/\tau}) d \ln \tau \quad (39.30)$$

In Equations (39.28–39.30), $L(\ln \tau)$ is the normalized retardation times spectrum. It has been emphasized that the numerical fitting of weighted sum of different exponential decays to the decay function does not necessarily mean that a distribution of relaxation times really exists. The substitution of a decay function with a stretch exponent $\bar{\beta}$ lying in the range $0 < \bar{\beta} \leq 1$ into Equation (39.22) also gives a good account of relaxation processes of complex molecules (Williams and Watts, 1971).

The loss component of the complex dielectric permittivity for amorphous polymers, at a given frequency, can be represented as a function of temperature. The resulting isochrone presents a prominent absorption or α relaxation associated with the glass transition temperature T_g , named glass–rubber relaxation. Below T_g , one or more secondary absorptions appear, which in decreasing order of temperature are called β , γ , δ , . . . (Figure 39.8) (Diaz-Calleja et al., 1992). The dipoles of polymers, such as poly(propylene oxide), poly(propylene sulfide), and trans poly(*cis*-1,4 isoprene), have a component of the dipole associated with the repeat unit parallel to the chain contour. As result, a relaxation appears associated with chains length, named normal mode process, located at higher temperature than the α relaxation (Figure 39.9) (Boese and Kremer, 1990). As

FIGURE 39.8 Dependence of the dielectric loss on temperature for poly(cyclohexyl acrylate) at several frequencies: (●) 0.1, (◆) 1, (▲) 10, (○) 10^2 , (▼) 10^3 , and (◇) 10^4 Hz. The repeat unit of the polymer is shown in the figure (Diaz-Calleja et al., 1992).

FIGURE 39.9 Isochrones, at 100 Hz, showing the dependence of the dielectric loss on temperature for several fractions of poly(cis-1,4-isoprene), the molecular weights of which are given in the figure (Boese and Kremer, 1990).

molecular weight increases, the location of the normal mode process in the isochrones shifts to higher temperatures, whereas the location of the glass–rubber relaxation and secondary processes are not affected by molecular weight. It is worth noting that the statement “the location of the α relaxation is independent on molecular weight” only holds if the molecular weight of the chains is high enough so that the T_g of the system is independent on molecular weight.

For polymers in the glassy state, the imaginary component or dielectric loss ϵ'' of the complex permittivity in the frequency domain exhibits one or more peaks associated with secondary or subglass relaxation processes named in increasing order of frequency β , γ , δ Above T_g , an ostensible absorption in most systems appears, just in the frequency region where a significant change in the value of ϵ' occurs, named α or glass–rubber relaxation. The α relaxation is followed at higher frequencies by the secondary absorptions, also detected in the glassy state, called in increasing order of frequency β , γ , δ An increase in temperature shifts the locations of the α relaxation and the secondary absorptions to higher frequencies. As the activation energy associated with the α relaxation is higher than that of the β , the distance between the peaks of both relaxations decreases with increasing temperature until a temperature is reached at which a single relaxation, named $\alpha\beta$ relaxation, appears. This behavior is presented in Figure 39.10 where dielectric loss in the frequency domain for poly(5-ethyl-1,3-dioxacyclohexane acrylate) (Huang et al., 2002), at several temperatures, is shown. Below the glass transition temperature of the polymer, 285 K, the isotherms show a single relaxation, named β process. However, at temperatures slightly above T_g , the isotherms present the α relaxation well separated from the β process appearing at higher frequency. As temperature increases, the intensity of the β relaxation increases and that of the α decreases. Moreover, the degree of overlapping between the α and β relaxations increases forming the $\alpha\beta$ relaxation in the vicinity of 343 K.

FIGURE 39.10 Dielectric loss in the frequency domain for poly(5-ethyl-1,3-dioxacyclohexane acrylate) at the temperatures indicated in the figure. The isotherms below 293 K correspond to the polymer in the glassy state. The T_g of the polymer lies in the vicinity of 290 K. The chemical structure of the repeat unit of the polymer is shown in the figure (Huang et al., 2002).

In the low frequency side of the α relaxation, the dielectric loss in polymeric systems may undergo a relevant increase with decreasing frequency caused by humidity and ionic impurities in the materials. In this case, the ionic contribution to the dielectric loss becomes dominant, and the scaling law $\varepsilon''(\omega) \sim \omega^{-1}$ holds. To account for this ionic conductive contribution, Equation (39.30) should be written as

$$\varepsilon''(\omega) = (\varepsilon_0 - \varepsilon_\infty) \int_{-\infty}^{\infty} L(\ln \tau) \omega \tau / (1 + \omega^2 \tau^2) + \sigma / (e_0 \omega) \quad (39.31)$$

where σ is the ionic conductivity in S/m. The ionic conductivity contribution to the dielectric loss is negligible at high frequencies.

In the low frequency region, the loss spectra of polymers containing dipoles of type A or type AB display the normal mode relaxation associated with chains disentanglement and flow (Adachi and Kotaka, 1993). As shown in Figure 39.11, the normal mode at a given temperature shifts to lower frequencies as molecular weight increases, while the location of the α relaxation in the loss spectra is nearly independent on molecular weight.

The energy dissipated per cycle and per volume unit by the dipoles under the electric field is $\pi \omega E_0^2 \varepsilon''$, where E_0 is the amplitude of the alternate electric field.

Owing to the fact that a Debye type process in the relaxation spectra extends over more two decades in the frequency domain, whereas it is a Dirac delta in the time domain, the retardation time spectra $L(\ln \tau)$ are better defined than the loss relaxation spectra in the frequency domain. This behavior can be observed in Figure 39.12 where the loss dielectric spectra and the retardation time spectra for poly(3-methylbenzyl methacrylate),

FIGURE 39.11 Dependence of the dielectric loss on frequency for fractions of poly(cis-1,4-isoprene) of different molecular weights. The peak associated with the normal process shifts to lower frequencies as molecular weight increases (Adachi and Kotaka, 1993).

poly(3-fluorobenzyl methacrylate), and poly(3-chlorobenzyl methacrylate) are shown. The better definition of the retardation spectra facilitates the deconvolution of overlapped α and β relaxations (Domínguez-Espinosa et al., 2005, 2006a, 2008; Diaz-Calleja et al., 2007; Alvarez et al., 2005). Since the buildup function $\varphi(t)$ corresponds to the integral of Equation (39.30) and taking into account that $\phi(t) + \varphi(t) = 1$, the normalized memory function can be obtained from the non-normalized retardation time spectra by means of the following expression

FIGURE 39.12 Dielectric loss spectra (left) and retardation time spectra (right) for poly(3-methylbenzyl methacrylate) (top), poly(3-fluorobenzyl methacrylate) (middle), and poly(3-chlorobenzyl methacrylate) in the temperature ranges 283–403, 313–423, and 293–403 K, respectively, at 10 K steps (Domínguez-Espinosa et al., 2005, 2006a; Diaz-Calleja et al., 2007; Alvarez et al. 2005).

$$\phi(t) = \frac{\int_{-\infty}^{\infty} L(\ln \tau) e^{-t/\tau} d \ln \tau}{\int_{-\infty}^{\infty} L(\ln \tau) d \ln \tau} \quad (39.32)$$

The shapes of both the glass–rubber relaxation and secondary processes in the frequency domain are described by empirical Havriliak–Negami type equations (Havriliak and Negami, 1987; Havriliak and Havriliak, 1997)

$$[\varepsilon^*(\omega) - \varepsilon_{\infty}]/(\varepsilon_0 - \varepsilon_{\infty}) = [1 + (\omega\tau)^b]^{-a} \quad (39.33)$$

The parameters a and b are shape parameters that lie in the range $0 < a, ab \leq 1$. For secondary relaxations $a = 1$ and the complex plots are arcs. For glass–rubber relaxations, the complex ε'' versus ε' plots are skewed arcs that fit to a straight line intersecting with the abscissa axis in the high frequency region. As the complexity of the relaxation system increases, the values of the shape parameters decrease.

The temperature dependence of the secondary absorptions obeys to Arrhenius behavior. The Arrhenius plots for the β absorptions of many flexible polymers lie in straight lines that intercept the ordinate axis at $f_0 = 1/2\pi\tau_0 \cong 13.5$. Then the activation energy can be estimated as $E_a \cong 0.258 T_{\max}$, where T_{\max} is the absolute temperature at the peak maximum of the β relaxation, at 1 Hz (Heijboer, 1972). Accordingly, the higher the activation energy of the β absorption, the higher the temperature at which the relaxation is centered.

The glass–rubber relaxation is governed by the volume and its temperature dependence is described by the Vogel–Fulcher–Tammann–Hesse (VFTH) equation (Vogel, 1921; Fulcher, 1925; Tammann et al., 1926)

$$\log \tau_{\max} = -\log(1/2\pi f_{\max}) = A + m/(T - T_V) \quad (39.34)$$

where T_V is the Vogel temperature, about 50 K below T_g , considered as the temperature at which the configurational entropy of the glassy system vanishes. Illustrative plots showing the temperature dependence of the α and β relaxations for poly(5-ethyl-1,3-dioxacyclohexane acrylate) (Huang et al., 2002) are shown in Figure 39.13. Notice that the activation energy associated with the β process above and below the glass transition temperature seems to have the same value. The temperature dependence of the ionic conductivity follows Arrhenius behavior and the activation energy associated with this process is rather high (about 30 kcal/mol).

The normalized glass–rubber relaxation in the time domain inevitably obeys to a stretch exponential, called the Kohlrausch–Williams–Watts (KWW) equation (Williams, 1979; Williams and Watts, 1971; Kohlrausch, 1847).

$$\phi_{\alpha}(t) = \exp[-(t/\tau_{\text{KWW}})^{\bar{\beta}}]; \quad 0 < \bar{\beta} \leq 1 \quad (39.35)$$

where $\bar{\beta}$ is the stretch exponent and τ_{KWW} is a characteristic relaxation time whose temperature dependence obeys to Equation (39.34). The lower $\bar{\beta}$, the higher the complexity of the relaxation process is. Illustrative plots showing the normalized memory functions for the total ($\phi(t)$) and $\alpha(\phi_{\alpha})$ relaxations of poly(2,4-difluorobenzyl methacrylate) are shown in Figure 39.14 (Domínguez-Espinosa et al., 2006a). The

FIGURE 39.13 Temperature dependence of the relaxation times associated with the α and β relaxations for poly(5-ethyl-1,3-dioxacyclohexane acrylate) (Huang et al., 2002).

decrease of $\phi(t)$ at short times is caused by the β relaxation and that taking place at longer time arises from the glass–rubber relaxation. Notice that whereas the memory function corresponding to the glass–rubber relaxation is described by Equation (39.35), the total memory function is not.

FIGURE 39.14 Memory relaxation function for the whole spectrum ($\phi(t)$, continuous line) and the α relaxation ($\phi_\alpha(t)$, open circles) for poly(2,4-difluorobenzyl methacrylate) (Domínguez-Espinosa et al., 2006a).

The fact that the relaxation times associated with secondary or subglass absorptions, such as the β process, are independent on molecular weight suggests that these absorptions arise from motions in the side groups of the molecular chains. For polymers without side groups, such as polyvinyl chloride and poly(oxyethylene), secondary absorptions are produced by local motions in the main chain. The mean relaxation time associated with the glass–rubber relaxation is also independent on the chains length for moderate and high weight polymers in which the concentration of chain ends is negligible. This behavior suggests that the glass–rubber relaxation is produced by cooperative micro-Brownian motions, or segmental motions, involving a significant number of skeletal bonds (~ 40 – 50 in flexible polymers) (Adachi and Kotaka, 1993; Schonhals, 1997; Kremer, 2003; Ferry, 1980). The secondary β absorption and the α relaxation are general phenomena in dynamics of supercooled liquids, independently of their molecular weight. The relaxation time associated with the dielectric normal mode process scales with molecular weight as $\tau \sim M^{3.4}$ for $M > M_c$ where $M_c \cong 2M_e$, M_e being the molecular weight between entanglements. For $M < M_c$, $\tau \sim M$ (Schonhals, 1997; Kremer, 2003; Ferry, 1980). The temperature dependence of the normal mode process is also described by the VFTH equation.

The dielectric strength of relaxation processes can be obtained from Equation (39.23) taking into account that $\phi(0) = 1$. The pertinent expression is $\epsilon_{0,i} - \epsilon_{\infty,i} = (2/\pi) \int_{-\infty}^{\infty} \epsilon''(\omega) d \ln \omega$, where the subscript i represents the type of relaxation α , β , In general, the relaxation strength of secondary relaxations increases with increasing temperature because new polar mechanisms associated with the process become available. However, the dielectric strength of the glass–rubber relaxation decreases with increasing temperature owing to the fact that the thermal energy hinders the alignment with the electric field of the dipoles intervening in the segmental motions. This behavior is depicted in Figure 39.15 where the dielectric strengths of the α and β relaxations for poly(5-ethyl-1,3-dioxacyclohexane acrylate) (Huang et al., 2002) are shown.

FIGURE 39.15 Dependence of the dielectric strength for β (filled squares) and α (filled circles) relaxations of poly(5-ethyl-1,3-dioxacyclohexyl acrylate) (Huang et al., 2002).

The dielectric strengths of relaxation processes can also be obtained from complex dielectric plots ϵ'' versus ϵ' , described by Equation (39.29). The intersection of the curves with abscissa axis at low and high frequencies gives, respectively, the relaxed (ϵ_0) and unrelaxed (ϵ_∞) dielectric permittivities. The strength of the relaxation i can be expressed in terms of the mean-square dipole moments by means of the Fröhlich equation (Fröhlich, 1948)

$$\epsilon_{0;i} - \epsilon_{\infty;i} = \frac{\epsilon_{0;i}(\epsilon_{\infty;i} + 2)^2}{(2\epsilon_{0;i} + \epsilon_{\infty;i})} \frac{4\pi\rho N_A g_i \mu_u^2}{9Mk_B T} \quad (39.36)$$

where μ_u^2 and M are, respectively, the square of the dipole moment and the molecular mass of the repeat unit, k_B and N_A are, respectively, the Boltzman constant and Avogadro's number, ρ is the density of the polymer, and T is the absolute temperature. The product $g_i \mu_u^2$ denotes the fraction of μ_u^2 relaxing through the relaxation process i . By obtaining the extreme values of the permittivity for the relaxation i from the experimental results using pertinent complex dielectric plots, the amount of μ_u^2 relaxed in each relaxation can be estimated.

The dielectric loss spectra are very sensitive to structure. Figure 39.16 shows the isochrones of the components of the complex dielectric permittivity of conventional (methylacrylate) (PMMA), at 10 Hz, in the temperature range -100 – 140°C . As temperature increases, the real component of the dielectric permittivity increases reaching a plateau; then ϵ' increases again, reaching a second plateau (Schönhals, 1997; Kremer, 2003; Ferry, 1980). The dielectric loss isochrone presents a prominent β relaxation below T_g ($\sim 105^\circ\text{C}$) which is believed to be associated with molecular motions about the $\text{CH}(\text{CH}_3)\text{—CO}(\text{O})$ bonds of the side groups. Above T_g , the isochrone shows a less developed absorption associated with the α or glass–rubber relaxation (Tetsutani et al., 1982). The fact that the β relaxation is more prominent than the α in conventional PMMA is caused by the methyl group of the repeat unit that hinders the cooperative conformational transitions in the

FIGURE 39.16 Real and imaginary isochrones for conventional poly(methyl methacrylate) at 10 Hz. Notice that the strength of the β relaxation (left peak) is significantly larger than that of the glass–rubber relaxation (right peak). The arrow in the inset indicates the dipole associated with the ester group (Tetsutani et al., 1982).

FIGURE 39.17 Dielectric loss factor as a function of temperature for conventional (2), isotactic (3), and syndio (1) polymethyl methacrylate. Curve 4 corresponds to a mixture (50/50) of iso and syndio poly(methyl methacrylate) (Mikhailov and Borisova, 1961).

segmental motions. As a result, the T_g rises from about 0°C for poly(methyl acrylate) (PMA) to ca. 105°C for PMMA. It is worth noting that the stereoregularity of the chains affects the response of PMMA to perturbation fields as Figure 39.17 shows (Mikhailov and Borisova, 1961). For example, the spectrum of iso-poly(methyl methacrylate) is similar to that of conventional PMMA. However, the α relaxation for syndio-PMMA is much more prominent than the β . As usual, the β relaxation of PMA and poly(n -alkyl methacrylates) with $n \geq 2$ is weaker than the α .

Aside from the chemical nature and the flexibility of the main chain, the chemical structure of the side groups of molecular chains has a rather high influence on the secondary dielectric relaxations of polymers. For example, the ratio between the strengths of the β and α relaxations $\Delta\epsilon_\beta/\Delta\epsilon_\alpha$, for poly(chlorophenyl acrylate) depends of the location of the chlorine atom in the phenyl group (Díaz-Calleja et al., 1991a, 1991b). The ratio decreases in the order P2CMA > P3CMA > P4CMA, where the numbers in the acronyms denote the location of the chlorine atom in the phenyl group of the side-chains. This behavior can be explained taking into account that dielectric activity in these polymers arises from motions about $\text{CH}(\text{CH}_3)\text{—CO}(\text{O})$ bonds coupled with motions about the $\text{O—C}_6\text{H}_5\text{Cl}$ bonds. For each $\text{CH}(\text{CH}_3)\text{—CO}(\text{O})$ conformation, significant changes in polarity come from rotations about $\text{O—C}_6\text{H}_5\text{Cl}$ bonds, that decrease in the order P2CMA > P3CMA > P4CMA. This fact suggests that motions about $\text{O—C}_6\text{H}_5\text{Cl}$ bonds play an important role in the development of the β relaxation of these poly(chlorophenyl acrylates).

The dielectric relaxation behavior of polymers is strongly influenced by the crystallinity that in turn depends on the undercooling $\Delta T = T_m - T_c$, where T_m and T_c are, respectively, the thermodynamic melting temperature and the crystallization temperature. The crystallization rate is small at low undercoolings, being zero for $\Delta T = 0$. On the other hand, the crystallization rate also tends to zero at high undercoolings where molecular transport governs the crystallization process (Mandelkern, 2004). Then by quenching from the melt semicrystalline polymers with low crystallization rate, such as poly(ethylene terephthalate) (PET) and aromatic polycarbonates, amorphous materials are obtained. Polymers of this type do not reach crystallization extents beyond 50%. There are also

FIGURE 39.18 Isochrones representing the temperature dependence of the dielectric loss for polyethylene with 68% crystallinity. The frequencies of the isochrones are 5×10^2 , 10^3 , 2×10^3 , 5×10^3 , and 10^4 (Hz) (Ribes-Greus and Diaz-Calleja, 1989).

polymers that are difficult to crystallize to extents higher than 60%, but they are not quenchable to the amorphous state. Examples of these medium crystallinity polymers are aliphatic polyamides and polyesters. A third kind of semicrystalline polymers integrated by polyethylene, polyethers, and so on exhibit crystallinity after quenching hardly below 50%. The crystallinity of these polymers lies in the range 60–80%.

Figure 39.18 shows the isochrones for the dielectric loss of polyethylene with 68% crystalline content (Ribes-Greus and Diaz-Calleja, 1989). The relaxation appearing at higher temperature, named α process, is connected with motions in the crystalline entities of the material. In decreasing order of temperature appears the so-called β absorption, developed in the amorphous fraction of the material, which is associated with the glass–rubber relaxation. The intensity of this relaxation decreases as crystallinity increases. The lower temperature process, called γ absorption, emerges from molecular local motions in the amorphous phase though the assumption that it may have an important component from the crystalline phase should not be ruled out. Notice that in semicrystalline polymers the glass–rubber relaxation is denoted β relaxation instead of α , the nomenclature used for this process in amorphous polymers.

The effect of the crystallinity on the dielectric relaxation behavior is made evident in PET, and other semicrystalline polymers that can be obtained in the amorphous state. Illustrative plots showing the components of the complex dielectric permittivity in the frequency domain for both amorphous PET and 50% crystalline PET are presented in Figure 39.19 (Boyd, 1985, 1997). An inspection of the curves shows that the relaxation strength of the dielectric glass–rubber or β relaxation is smaller than that of the same process or α relaxation in the amorphous polymer. Moreover, the width of the β peak increases with the presence of crystalline entities, and therefore, the relaxation processes are less defined in semicrystalline polymers than in amorphous ones. The presence of crystallites entities in PET shifts to lower frequencies the location of the dielectric glass–rubber β process. The strength of the secondary γ absorption, not shown here, decreases as the crystallinity increases, but its location in the frequency domain is independent on the degree of crystallization. The comparatively low dielectric strengths of the β

FIGURE 39.19 Components of the complex dielectric permittivity in the frequency domain for amorphous PET (a) and PET with crystallinity 50% (b). Open and filled symbols represent, respectively, the real and loss components of ϵ^* (Boyd, 1985, 1997).

relaxations of semicrystalline polymers arise from the fact that crystalline entities hinder segmental and local motions in the amorphous regions.

Besides the amorphous and crystalline state, condensed matter presents an additional state of aggregation, called liquid crystalline order (Collins, 1990; de Gennes and Prost, 1995). In this state molecular rods are free to move as a liquid, though as doing so they spend a little more time pointing toward a definite direction than along some other direction. An arrow, called the director, represents the direction along which the rod molecules or segments tend to align. Poly(*n*-alkyl isocyanates) having a planar or helicoidal rigid backbone, to which relatively flexible side groups are attached, develop liquid crystalline order in solution at room temperature and in bulk at elevated temperatures (Aharoni and Walsh, 1979; Aharoni, 1979). Thorough studies (Moscicki et al., 1982) on the dependence of the dielectric behavior of poly(*n*-alkyl isocyanates) on toluene concentration show that for concentrations lying in the range $0 < c < 15\%$, the relaxed dielectric permittivity ϵ_0 increases with concentration, ϵ_0 being a linear function of concentration. In this region, the system is isotropic because all the molecules through the Brownian motion randomize the dipole vectors associated with the highly polar rods into a 4π solid angle. In the concentration range $15\% < c < 25\%$, ϵ_0 increase with concentration, but this quantity falls below the linear relation because the orientation of the rods is hindered by the viscosity of the medium. In the range $22\% < c < 35\%$, a critical concentration is reached at which liquid crystalline phase coexisting with an isotropic phase appears. The component of the biphasic displaying liquid crystalline order is much larger than that of the isotropic component. As a result, a severe drop in ϵ_0 occurs because the permittivity of the biphasic may be considered as the weighted sum of the relaxed dielectric permittivities corresponding to the amorphous region, which is high, and the ordered region, which is low.

Most dielectric studies on liquid crystalline polymers were carried out on polymers containing mesogenic groups in the side chains with capability to develop mesomorphic order. In these polymers, called side chain liquid crystalline polymers (SCLCP), the mesogenic groups can be aligned by magnetic or electric fields. Obtaining SCLCP thermotropic polymers requires the placement of a flexible spacer between the main chain and the mesogenic group. These polymers develop smectic mesophases. The isochrones of

FIGURE 39.20 Illustrative isochrones showing the temperature dependence of the components of the complex dielectric permittivity for a thermotropic SCLC polymer at several frequencies: (filled circles) 1 Hz, (open triangles) 10^2 Hz, and (filled squares) 10^4 Hz (Díaz-Calleja et al., 1999).

SCLCP polymers present subglass absorptions followed in increasing order of temperature by two overlapped relaxations formed by the glass–rubber relaxation or α process and the δ peak (Figure 39.20) (Díaz-Calleja et al., 1999; Attard et al., 1988). The latter peak is assigned to librational fluctuations of the mesogen around the short molecular axis. Different extents of alignment between fully homeotropic and fully planar (homogeneous) structures can be achieved by slowly cooling the isotropic material back into the liquid crystalline state in the presence of AC fields of given amplitude and frequency. Whereas the loss dielectric curve is bimodal for the isotropic material, the loss curve seems to be made up of a δ process with only a small intensity α relaxation for the homeotropic aligned material.

To develop ferroelectric behavior, the mesogenic group in SCLCPs must contain a dipole perpendicular to the main axis of that group. Moreover, a chiral moiety must be attached to the end of the mesogenic group or to the spacer. To facilitate mesogenic alignment, the polymer backbone should be a flexible polymer, such as polyacrylates or polysiloxanes. A representative polymer of a ferroelectric SCLCP polymer is shown in Figure 39.21. The relaxation spectra of ferroelectric SCLCPs in the frequency domain present a strong absorption below 1 MHz, called Goldstone mode, typical of S_C^* mesophases, arising from fluctuations of the phase of helical structures. By imposing a DC field, the Goldstone mode decreases, eventually disappearing. With the suppression of the Goldstone mode, the soft mode emerges at higher frequencies associated with unwound state (Figure 39.22) (Schönfeld et al., 1994; Kremer, 1997). It is worth noting that dielectric spectroscopy is a useful tool to study mesophase transitions as a function of temperature in ferroelectric polymers.

FIGURE 39.21 Scheme of a SCLC polymer with the requirements necessary to display ferroelectric behavior. Notice that the asterisk in the carbon of the end segments denotes chirality.

39.5 THERMOSTIMULATED DEPOLARIZATION CURRENTS

Electrical charges are virtually immobile at low temperatures in glassy systems. To stimulate their motion and eventually produce dipole libration, which is the origin of the dielectric relaxation, polymers must be heated. If an electrical field is applied during cooling, and then removed at the lowest temperature, the motions of the dipoles in the system can be thermally stimulated. This procedure gives rise to a thermogram in which depolarization peaks of current appear. Illustrative thermograms are shown in Figure 39.23 (Domínguez-Espinosa et al., 2006b). The thermograms exhibit secondary peaks followed by a prominent peak corresponding to the glass–rubber relaxation. The molecular origin of the peaks in the thermograms, especially at temperatures below the glass transition, is the same as that observed for loss peaks in broadband dielectric spectroscopy. The conversion of TSDC into ϵ'' data has been described elsewhere (Hino, 1975).

FIGURE 39.22 Dielectric loss in the frequency domain for a thermotropic SCLC thermotropic polymer under orientation promoted by the electric voltages indicated in the inset (Schönfeld et al., 1994; Kremer, 1997).

FIGURE 39.23 Global thermo stimulated depolarization current (TSDC) curves for poly(2,4-difluorobenzyl methacrylate) (open squares) and poly(3-fluorobenzyl methacrylate) (open triangles). The inset shows partial TSDC curves for P24FM obtained at poling temperatures from 273 to 298 K (5 K step) (Domínguez-Espinosa et al., 2006b).

Another convenient way to obtain the dielectric permittivity from TSDC results, called thermal windowing, is described elsewhere (Perlman and Unger, 1974; Shimizu and Nakayama, 1991). The method essentially consists in performing partial depolarizations in the material in the glassy state, in small temperature windows covering the experimental range of temperatures where the relaxation peaks appear. Illustrative partial thermal stimulated depolarization curves are shown in the inset of Figure 39.23. The real and imaginary parts of the complex permittivity can be obtained from the partial depolarization curves by

$$\begin{aligned}\varepsilon'(\omega) &= \varepsilon_{\infty} + \sum_{i=1}^n \frac{\Delta\varepsilon_i}{1 + \omega^2\tau_i^2} \\ \varepsilon''(\omega) &= \sum_{i=1}^n \frac{\Delta\varepsilon_i(\omega\tau_i)}{1 + \omega^2\tau_i^2}\end{aligned}\quad (39.37)$$

where τ_i are given by the following equation (van Turnhout, 1972)

$$\tau_i = \frac{\int_0^t i(t') dt'}{i(t)} = \frac{\int_{T_i}^T i(T') dT'}{hi(T)} \quad (39.38)$$

where T is the absolute temperature, T_i is the initial temperature of each individual depolarization curve, and h is the inverse of the heating rate or $1/(dT/dt)$. The dielectric strength $\Delta\varepsilon_i$ of partial depolarization curves used in Equations (39.37) are obtained as

$$\Delta\varepsilon_i(T_p) = \frac{1}{e_0 h E} \int_{T_0}^{T_f} i(T') dT' \quad (39.39)$$

From partial depolarization curves, the frequency dependence of the components of the complex dielectric permittivity can be estimated for glassy polymers in the region of very low frequencies.

39.6 CONDUCTIVITY IN POLYELECTROLYTES AND POLYMER-ELECTROLYTES AS SEPARATORS FOR LOW TEMPERATURE FUEL CELLS AND ELECTRICAL BATTERIES

Polymers with anionic or cationic groups covalently anchored to the structure of molecular chains are called, respectively, cation- and anion-exchange polyelectrolytes. For strong cation-exchange resins, the fixed ionic groups can be $-\text{SO}_3\text{H}$ or $-\text{PO}_3\text{H}_2$ and $-\text{N}(\text{CH}_3)_3\text{OH}$ for anionic-exchange resins. The fixed groups dissociate in water as $-\text{SO}_3\text{H} \rightarrow -\text{SO}_3^- + \text{H}^+$, $-\text{PO}_3\text{H}_2 \rightarrow -\text{PO}_3\text{H}^- + \text{H}^+$, $-\text{N}(\text{CH}_3)_3\text{OH} \rightarrow -\text{N}(\text{CH}_3)_3^+ + \text{OH}^-$ (Sata, 2004).

Usually, ion-exchange membranes are cast from polyelectrolyte solutions. The characteristics of ion-exchange membranes are: (a) ionic conductivity, (b) hydrophilicity, and (c) the existence of a fixed carrier (ion-exchange group). Mobile ions with opposite sign to that of the ionic fixed groups (anions and cations, respectively, for cation and anion-exchange membranes) are called counterions, whereas those with the same sign are coions. Traditionally, ion-exchange membranes have been used in electrodialysis, demineralization being the most promising application of this technique. Two cases can be distinguished in the use of electrodialysis: (a) demineralization of solutions containing only electrodialysable electrolyte solutes and (b) demineralization of solutions containing an electrolyte and a nondialysable electrolyte, such as a protein. The experimental devices for electrodialysis are made up of electrolytic cell groups, each of them separated from the two contiguous ones by a cation-exchange membrane at one side and an anion-exchange membrane, at the other side (Sata, 2004). Anion- and cation-exchange membranes to be used in electrodialysis must have high conductivity and high permselectivity. In an ideal permselective membrane, each Faraday of current carries one equivalent of counterions across the membrane.

Owing to the ever increasing demand of new kinds of energy sources for portable electronic products, such as cellular phones, and the stringent environmental regulations requiring zero emission traction vehicles, academic and industrial research laboratories are focused their interests on the development of electrochemical power sources that can provide high energy density and long cyclability. Moreover, the power sources must be reliable and safe. Two new sources of energy that use polyelectrolytes and electrolytes solvated in polymers are, respectively, low temperature fuel cells and rechargeable lithium batteries.

Low temperature fuel cells are energy source devices in which fuel (hydrogen, methanol, etc.) is reduced in the anode of the cell producing protons that travel across a separator, usually an acidic ion-exchange membrane, to the cathode where they react with reduced oxygen forming water as subproduct. The configuration of a fuel cell is anode (catalyst, i.e., platinum, dispersed in an electronic conducting substrate), | fuel (hydrogen, methanol), | cation-exchange membrane in the acid form | oxygen or air | cathode (catalyst, i.e., platinum dispersed in an electronic conducting substrate). Electrons travel from the anode to the cathode by an external circuit, whereas protons do that across a cation-exchange membrane in the acid form. Using hydrogen as fuel, the overall chemical reaction is $2\text{H}_2 + (1/2)\text{O}_2 \rightarrow \text{H}_2\text{O}$. Taking into account that $\Delta g^0 = -2FE_0$, where Δg^0 , F and E_0 are, respectively, the change in standard free energy of the redox reaction, Faraday's constant and standard electromotive force of the cell, the value of E_0 is 1.24 V. The voltage of the fuel cell can be expressed in terms of the current density by (O'Hayre et al., 2006; Larminie and Dicks, 2003).

$$V = E_0 - A \ln \frac{i}{i_0} - ir + m \ln(n \cdot i) \quad (39.40)$$

The second term on the right-hand side of Equation (39.40) denotes the reduction in voltage due to the redox reactions at the electrodes. The third term ir ($r = RS$, where R and S are, respectively, the resistance and area of the acidic membrane acting as separator) represents the loss in voltage caused by the transport of protons across the membrane. The last term in Equation (39.40) is a correction in the voltage arising from the slight reduction of reactants at the electrodes. An illustrative curve showing the variation of the voltage of a fuel cell with the current density is shown in Figure 39.24.

The solid polyelectrolyte separating the anode from the cathode in fuel cells is a cation exchange membrane in the acid form. Acidic membranes should exhibit high proton conductivity and good chemical stability at the operating fuel cell conditions, about 80°C in available low temperature fuel cells. However, to reduce platinum poisoning by effect of traces of CO in the fuel, it would be necessary to develop membranes with good chemical and mechanical properties in the vicinity of 150°C. This is one of the major problems facing the commercial development of fuel cells technology as a source of energy. There are many reviews that address membranes performance in relation with their chemical stability and proton conductivity (Hickner et al., 2004; Kreuer, 1996; Rozière and Jones, 2003; Schuster and Meyer, 2003; Rikukawa and Sanui, 2000). Up to now, the most successful membranes are based on perfluorosulfonate electrolytes, Nafion being the principal one. Nafion, the chemical structure of which is shown in Figure 39.25, exhibits rather high proton conductivity lying in the range 0.01–0.1 S/cm at 25°C. However, Nafion membranes present some drawbacks such as high permeability to methanol, high cost, environmental problems and a decrease in both chemical stability and mechanical properties at temperatures above 100°C. Proton exchange membranes are being developed based on high chemical stability polymers such as polysulfones, poly(ether-ketone), and polyimides (Hickner et al., 2004; Kreuer, 1996; Rozière and Jones, 2003; Schuster and Meyer, 2003; Rikukawa and Sanui, 2000). Illustrative sulfonated

FIGURE 39.24 Illustrative curve (continuous line) showing the dependence of the voltage on the current density. The activation loss (discontinuous line) represents the loss of voltage caused by the reactions at the electrodes.

**FIGURE 39.25** Chemical structure of Nafion.

structures are shown in Figure 39.26. Conductivities lying in the range 10^{-3} – 10^{-2} S/cm, at room temperature, have been reported for membranes of this type.

Proton conduction in acidic membranes is very sensitive to the ion exchange capacity and water uptake. Water promotes segregation of the fixed acid groups forming hydrophilic nano-size domains and hydrophobic domains that contains the amorphous part of the chains. In this way, hydrophilic percolation paths are formed through which protons transport takes place. The conductivity of membranes is strongly dependent on the water content. Dry acidic membranes have conductivity lower than 10^{-8} S/cm as a consequence of the fact that dissociation reaction $-\text{SO}_3\text{H} \leftrightarrow -\text{SO}_3^- + \text{H}^+$ does not take place in the fixed $-\text{SO}_3\text{H}$ groups unless the membrane contains about 2 moles or more of water/ $-\text{SO}_3\text{H}$ group (Paddison, 2003). A dramatic increase of several decades occur in proton conductivity as the water content in the membrane increases. Proton transport in acidic membranes is a rather complex process that is discussed in detail elsewhere (Kreuer et al., 2004).

**FIGURE 39.26** Structures of representative cation-exchange membranes prepared from high chemical stability polymers: (a) polyarylene ether sulfone; (b) naphthalenic copolyimide; (c) polyetherether ketone.

FIGURE 39.27 Equivalent electric circuit for a cation-exchange membrane in the acid form.

The conductivity of acidic membranes is usually measured by impedance spectroscopy. To carry out the measurements, the membrane is sandwiched between two blocking electrodes. The equivalent electrical circuit of the acidic membrane consists of a resistance accounting for the proton resistance of the acidic membrane in series with circuit made up of a resistance, R_p , in parallel with a capacitor that describe polymer-electrode polarizations (see Figure 39.27). The impedance of the circuit is given by

$$Z^* = R_{H^+} + \frac{R_p}{1 + j\omega R_p C} = R_{H^+} + \frac{R_p}{1 + (\omega R_p C)^2} - j \frac{\omega R_p^2 C}{1 + (\omega R_p C)^2} \quad (39.41)$$

The plot Z' versus Z'' , called Nyquist diagram, is an arc (Figure 39.28) displaced from the origin of the coordinate axis by R_{H^+} . Notice that $\lim_{\omega \rightarrow \infty} Z'(\omega) = R_{H^+}$ and $\lim_{\omega \rightarrow 0} Z'(\omega) = R_{H^+} + R_p$, whereas in both limit situations $Z'' = 0$. This analysis assumes that the polarization process has a single relaxation time given by $\tau = R_p C$. Real Nyquist diagrams are not described by Equation (39.41) as Figure 39.28 shows owing to the fact that polarization processes are associated with a wide distribution of relaxation times (Compañ et al., 2007). Fitting the data would require an equivalent circuit formed by N circuits in series, each of them formed by a resistance R_{pi} in parallel with a constant phase element of admittance $Y_i^* = Y_{0i}(j\omega\tau_i)^{n_i}$ where $0 < n_i \leq 1$. The impedance of the circuit is given by

$$Z^*(\omega) = R_{H^+} + \sum_{i=1}^N \frac{R_{pi}}{1 + R_{pi}Y_{0i}(j\omega\tau_i)^{n_i}} \quad (39.42)$$

In the extreme frequency limits $Z'' = 0$, whereas $Z' = R_{H^+}$ and $Z' = R_{H^+} + \sum_{i=1}^N R_{pi}$ as $\omega \rightarrow \infty$ and $\omega \rightarrow 0$, respectively. At high frequencies, the contribution of the polarization to the impedance is negligible and Equation (39.41) can be used to estimate the proton resistance of cation-exchange membranes. The proton conductivity of membranes is given by

$$\sigma = \frac{l}{R_{H^+} S} \quad (39.43)$$

where l and S are, respectively, the thickness and area of the membrane whose resistance is R_{H^+} . The dependence of the proton conductivity on temperature in acidic membranes follows Arrhenius behavior with 2–3 kcal/mol of activation energy.

Proton transport across acidic membranes is accompanied by water molecules, and the water thus transported is called electro-osmotic water. The electro-osmotic process dries

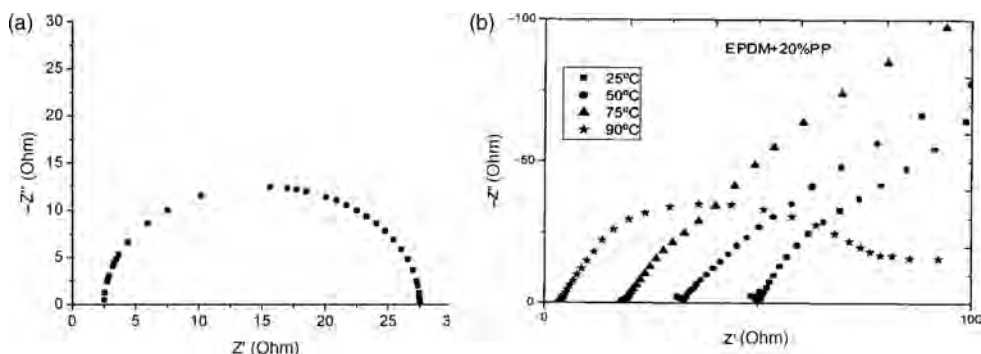

FIGURE 39.28 Nyquist diagram for a Debye type polyelectrolyte (a) and a real acidic membrane formed by blends of sulfonated EPDM and poly(propylene) (b). (Notice that the frequency increases from right to left) (Compañ et al., 2007).

the membrane in the anode side and as a result decreases the proton conductivity. Then besides high conductivity, membranes should exhibit low electro-osmosis (Lakshminarayanan, 1966; Riande, 1972).

Another recent breakthrough in power electric sources development in which polymers may play an important role has been the development of rechargeable commercial lithium batteries. These devices can exhibit high level of performance driven by their high volumetric and gravimetric energy density. Moreover, the environmental friendly condition of these power source devices makes them an attractive alternative to traditional battery technologies involving toxic metals (Pb/PbO₂, Ni/Cd). In principle, the anode of the battery is made up of Li or carbon–Li intercalation compound separated by means of an organic conducting electrolyte from the cathode, usually an inorganic compound with an open structure, that is, layered structure (i.e., LiCoO₂, V₂O₅) or a tunnel structure (i.e., V₆O₁₃, MnO₂) (Scrosati, 2001). Using carbon–Li intercalations in the anode, the typical electrochemical reactions are

The state of the art in Lithium batteries can be found in literature publications and reviews (Scrosati, 2001; MacCallum, 1987; Meyer, 1998; Koksang et al., 1994; Stephan and Nahm, 2006; Wright, 2002; Appetechi and Croce, 1998). The reasonable low conductivity, of the order of 10⁻² S/cm at room temperature, exhibited by rechargeable lithium batteries based on lithium metal electrodes and liquid organic electrolytes, is tarnished by safety problems these cells present. Safety problems could be circumvented using “plastics” electrolytes such as polyethylene oxide (PEO) complexed with a lithium salt. PEO crystallizes in helicoidal form and its melting point is about 70°C. At room temperature, the conductivity of PEO–LiX electrolytes is only about 10⁻⁷ S/cm, because only the amorphous phase of the semicrystalline polymer intervenes in the transport process. Complexes of type (PEO)_xLiClO₄ and (PEO)_xLiCF₃SO₃, with *x* in the range 8–50 salt molecules, exhibit an acceptable level of ionic conductivity, of the order of 10⁻³ S/cm at temperatures slightly above the melting temperature of PEO (Cairns and McLaren, 1993; Armand, 1987). Transport of Li⁺ in PEO involves ion solvation in the melt polymer and

further motion across the chains as Figure 39.29 illustrates (Meyer, 1998; Armand, 1987). In this context, molecular dynamics simulations suggest that Li^+ ions are solvated by PEO through five ether groups (Müller-Plathe and van Gunsteren, 1995), and the mobility of the ions in the chains is related to the motions of the complexing segments of the PEO chains. Notice that the electrolyte is not covalently bound to the polymer chains as occurs in the solid polyelectrolytes used as separators in low temperature fuel cells. The temperature dependence of the conductivity in the melt ($T > 70^\circ\text{C}$) obeys to the phenomenological Vogel–Fulcher–Tammann–Hesse (VFTH) equation (Armand, 1987) $\sigma(T) = AT^{-1/2} \exp[-m/(T - T_V)]$.

Power density is rather high for lithium polymer batteries as result of the thin laminate construction used. Owing to the fact that poly(propylene oxide) (PPO) is amorphous, and its T_g is below room temperature, one could think that this polymer could be used as complexing agent for Li^+ salts. However, the polymer exhibits limited solvation properties as a result of the fact that the rigidity of the chains promoted by the methyl solvation groups predominates over the increased donor power of the oxygen atoms linked to a secondary carbon. The conductivity of PPO–Li complexes lies in the range 10^{-5} – 10^{-6} S/cm (Watanabe and Ogata, 1987).

The preparation of separators with suitable conductivity at room temperature and below room temperature can be accomplished by adding organic liquids or plasticizers (i.e., propylene carbonate, ethylene carbonate, ethylene glycols of low molecular weight) to PEO. However, the liquid additives produce loss of mechanical stability, and moreover, they can react with lithium metal. Dispersion of nanoscale particles of selected ceramic powders, such as TiO_2 , SiO_2 , and Al_2O_3 , in the PEO–LiX matrix increases the amorphicity of the system without affecting the mechanical and interfacial properties of the electrolyte (Croce et al., 1998, 1999, 2000). The disperse ceramics prevents the crystallization of PEO and enhances the conductivity of the electrolyte composite that can reach values of 10^{-5} S/cm at room temperature.

The preparation of the electrolyte for lithium batteries involves the trapping in a polymer matrix of lithium salt solutions in organic solvent mixtures. Polymers commonly studied are polyacrylonitrile (PAN), poly(methylmethacrylate) (PMMA), or

FIGURE 39.29 Scheme of the solvation and transport of Li^+ cations in amorphous poly(ethylene oxide).

poly(vinylidene fluoride) (PVDF) (Scrosati, 1997, 1998). Liquid immobilization of the Li^+ salts may involve UV cross-linking, casting, or gelation, the latter being the most widely used method. In this case, the gel membranes are not true polymer electrolytes, but hybrid systems containing a liquid phase within the polymer matrix. Ionic conductivities in a range 10^{-2} – 10^{-3} S/cm at 25°C have been reported for the gel formed by immobilizing an ethylene carbonate-dimethyl carbonate lithium hexafluorophosphate solution in polyacrylonitrile.

Lithium batteries can also be designed in which the cathode is an electronic conducting polymer. The cell configuration could be $\text{Li}|\text{electrolyte separator}(\text{A}^-\text{Li}^+)|\text{P}^+\text{A}^-$ where P^+ indicates p-type doping. Other configurations have been described but none of them is commercially available (Müller et al., 1997).

The conductivity of polymer electrolytes can be measured by impedance spectroscopy by sandwiching the electrolyte between two parallel blocking electrodes, such as platinum electrodes. Under the action of an alternating electric field, the lithium ions migrate back and forth in phase with the voltage. The migration of the lithium ions is represented by the resistance R_{Li} , whereas the polarization of the immobile polymer chains may be represented by a capacitor C in parallel with the resistor. Each electrode–electrolyte interface is similar to a parallel-plate electrode of capacitance C_e in such a way that the total capacitance of the two in series condensers is $1/C_e = 1/C_1 + 1/C_2$. The admittance of the parallel circuit is

$$Y^* = \frac{1}{R_{\text{Li}}} + j\omega C \quad (39.44)$$

where ω is the angular frequency of the alternating voltage. Since the C_e , capacitor is in series with the $R_{\text{Li}}-C$ parallel circuit, the complex impedance for the equivalent circuit of the electrolyte–electrodes system is

$$Z^* = \frac{1}{Y^*} + \frac{1}{j\omega C_e} = R_{\text{Li}^+} \left[\frac{1}{1 + (\omega R_{\text{Li}^+} C)^2} \right] - j \left[\frac{\omega R_{\text{Li}^+}^2 C}{1 + (\omega R_{\text{Li}^+} C)^2} + \frac{1}{\omega C_e} \right] \quad (39.45)$$

At high frequencies, $1/\omega C_e \cong 0$ and the complex Z'' versus Z' plot is an arc intersecting the abscissa axis at $Z' = 0$ ($\omega \rightarrow \infty$) and $Z' = R_{\text{Li}}$ (in the low frequency region). Then the conductivity, σ , of the polyelectrolyte separator can be obtained from

$$\sigma = \frac{l}{R_{\text{Li}^+} S} \quad (39.46)$$

where l is the thickness of the electrolyte and S is the area of the electrodes.

39.7 SEMICONDUCTORS AND ELECTRONIC CONDUCTING POLYMERS

Traditionally, semiconductors are of inorganic nature. However, the high flexibility, high impact resistance, and low density of polymers make these materials an attractive option to prepare semiconductors. Owing to the fact that each carbon is sp^2 hybridized in polydienes, polymers such as polyacetylene can be considered one-dimensional analogues of

graphite, an electronic conducting material. However, whereas the C—C bond lengths are equivalent in graphite, the backbone bond lengths of polydienes, such as trans-polyacetylene, are alternatively slightly longer and slightly shorter. This effect, known as Peierls distortion, opens a gap between the HOMO level of the fully occupied π bond (valence band) and the LUMO level corresponding to the empty π^* bond (conduction band) (Kohlman et al., 1996). These facts are illustrated in Figure 39.30. Trans-polyacetylene can be considered a semiconductor with an energy band of 1.5 eV.

Semiconductor character is not only exhibited by polymers of polyene type but also exhibited by conjugated aromatic polymers. For illustrative purposes, some of these polymers are shown in Figure 39.31 (Pron and Rannou, 2002; Frommer and Chance, 1996; Moratti, 1998). Under electric perturbations, these materials emit light, phenomenon known as electroluminescence. An electroluminescent diode in its simplest form consists of a single layer of polymer semiconductor sandwiched between two electrodes. The anode, which is a hole injector usually, is a thin layer of indium-tin oxide (ITO) transparent to the light, whereas the cathode, an electron injector, is a metal with a low work function such as calcium and magnesium (Yang and Pei, 1995; Kido et al., 1994). After application of an electric field, holes and electrons are injected, respectively, in the π and π^* orbitals. Injected charge carriers of different sign drift in opposite direction in the conjugated polymer matrix to form excited species, namely, singlet or triplet polaron-excitons. The radioactive decay of singlet excitons produces light whose frequency depends on the π – π^* energy gap. In increasing the energy gap, for example, by functionalization of the semiconductor polymer, the emitting light shifts to short-wave light (see Figure 39.32). The name of electroluminescent-diode given to these devices arises from

FIGURE 39.30 Schemes showing the sp^2 hybridization character of polydienes and the energy gap between the valence and conduction bands.

FIGURE 39.31 Representative conjugated polymers that exhibit semiconductor character.

the fact that no electroluminescence occurs until a voltage is reached above which electroluminescence rapidly increases with increasing voltage (Friend and Greenham, 1998; Leising et al., 1998). Conjugated polymers can also be used to construct photovoltaic cells (Yu et al., 1995; Hide et al., 1997; Tressler, 1999; McGehee and Heeger, 2000), polymer-based photopumped lasers, and polymer-based field-effect transistors (FET) (Würthner, 2001; Kraft, 2001; Sirringhaus et al., 1990). It is worth noting that functionalization of semiconductor polymers with moieties that increase the solubility is often performed to facilitate their processability.

In the early 1970s, Shirikawa and Ikeda (1971, 1974) reported the possibility of preparing strong, self-supporting films of polyacetylene by direct polymerization of

FIGURE 39.32 Scheme of a light-emitting diode.

FIGURE 39.33 Electronic conductivities reported for doped poly(trans acetylene), polyaniline (protonated emeraldine, PAN), poly(pyrrol) (PPy), poly(thiophene) (PT), and others (Epstein, 1997).

acetylene. This finding attracted little attention until 1977 when Shirikawa et al. (1977) rediscovered that the treatment of polyacetylene with a Lewis acid or bases can increase its conductivity by up to 13 orders of magnitude. This process involves removal or addition of electrons. Then by oxidation or reduction of conjugated polymers using, respectively, an electron acceptor or an electron donor electronic conductor polymers are obtained. This process is called “doping.” Whereas the amount of dopant in inorganic semiconductors is of the order of parts per million, this amount can be up to 50% of the total weight in organic semiconductors. Trans-polyacetylene doping can change the conductivity of the polymer from 10^{-12} S/cm (undoped form) up to 10^5 S/cm (highly doped polymer), more than 14 orders of magnitude. Conductivities that present some conjugated polymers in different doping conditions are shown in Figure 39.33 (Epstein, 1997). Molecular order favors electronic conductivity of conjugated polymers (Joo et al., 1994). Atomic or molecular dopant ions are located interstitially between chains forming new three-dimensional structures. For polymers with degenerate ground states such as trans-polyacetylene, the charge transport added to the backbone can be described by the motion of a solitary wave, called a soliton in field theory notation (Mizes and Conwell, 1994; Yan et al., 1994). For nondegenerate systems (i.e., polypyrrole, polythiophene, poly(*p*-phenylene), etc.) the charges introduced at low doping process are stored as charged polarons (a radical cation or a radical anion plus a lattice distortion around the charges) or bipolarons (see Figure 39.34) (Bredas et al., 1982, 1984). The one-dimensionality of polymers leads to the localization of the electron wave functions. Then though experimental evidence suggests that the metallic states are three-dimensional, the transport properties are highly anisotropic. Macroscopic transport in conducting materials containing well-ordered

FIGURE 39.34 Electronic transport species in doped polyacetylene and doped poly(*p*-phenylene).

polymer chains is not possible unless the carriers are able to hop to an adjacent chain, otherwise resonant back staggering between chain ends confine electrons in one dimension.

Conducting polymers can be used for charge dissipation in textiles, resistive heaters provided that rather low power per m^2 is required, electromagnetic interference shielding, electrochromic applications, and so on. Other applications involve deposition of conducting polymers, for example neutral or doped polyaniline (protonated emeraldine), on metal surfaces to protect them against corrosion. In principle, conducting polymers can be used as electrodes in rechargeable batteries (Müller et al., 1997).

Carbon black mixed with an insulating material form a semiconducting layer that placed between the metallic conductor and the insulating layer in the technology of high-voltage coaxial cables. This configuration avoids electrical breakdown. Carbon black can be replaced by undoped polyaniline. For low-electric fields, polyaniline behaves like an insulator, whereas under electric fields exceeding 1 kV/mm the intensity is no longer a linear function of the voltage, leading to a significant increase in polymer conductivity. In the areas in which the field locally increases owing to imperfections of the material, polyaniline becomes conductive and the accumulation of charge is dissipated.

39.8 FERROELECTRICITY, PYROELECTRICITY, AND PIEZOELECTRICITY IN POLYMERS

Ferroelectric crystals such as pyroelectric crystals exhibit spontaneous polarization, whereas piezoelectric crystals become polarized only under stress. Centrosymmetric crystals and isotropic systems present neither piezoelectric nor pyroelectric effects. The conditions that anisotropic systems must hold to display ferroelectric behavior are described elsewhere (Nye, 1987).

For piezoelectric systems $dP_i = d_{ijk} d\sigma_{jk}$ where P and σ are, respectively, the tensors of first and second order representing the polarization and the stress whereas d_{ijk} is a third-order tensor whose number of independent components due to the symmetry of the stress tensor reduces from 27 to 18. As the symmetry of the crystals augments, the number

of components of the system equal to zero increases (Tashiro, 1995; Riande and Díaz-Calleja, 2005). Making reduction of indices ($11 \rightarrow 1$, $22 \rightarrow 2$, $33 \rightarrow 3$, $3 \rightarrow 4$, $13 \rightarrow 5$, and $12 \rightarrow 6$) the polarization can be written as $dP_i = d_{ij}d\sigma_j$. For pyroelectric systems, $dP_i = p_i dT$, where \mathbf{p} is the pyroelectric vector, and T is the temperature. The SI units of d_{ij} and p_i are, respectively, C/N and C/(m²K). Ferroelectric crystals present the additional property of reversing their polarization by applying a sufficient large electric field. Ferroelectric materials exhibit also pyroelectricity and piezoelectricity, and pyroelectric polymers also present piezoelectric behavior. Ferroelectric materials present a limit temperature, named Curie temperature, above that the ferroelectric effect is lost.

Although piezoelectricity and pyroelectricity were firstly studied in inorganic crystals, polyvinylidene fluoride (PVDF) is one of the most important ferroelectric materials. The preparation of ferroelectric PVDF films involves stretching the film and then poling. During the uniaxial or biaxial orientation, usually carried out in the range 60–100° C, crystallites in the α form (dipoles in antiparallel direction) are converted into the high polarity β form (dipoles in parallel direction) (Tashiro, 1995). The structures of the α and β crystallite forms are shown in Figure 39.35. Let us assume that there are N dipoles of moment μ dispersed in film of area A and thickness of a poled sample of PVDF or any other ferroelectric polymer. The remnant polarization is $P_r = N\mu\langle\cos\theta\rangle/Al$, where $\langle\cos\theta\rangle$ is the average of the angles between the dipoles and the orientation axis (Furukawa, 1989). By applying a pressure perpendicular to the film, P_r changes as a result of the variation of the film dimensions and, as a result, the system exhibits piezoelectricity.

Change in dimensions has little effect on the pyroelectric behavior of ferroelectric materials. In this case, disorder of the orientation of dipoles by change in temperature is the main responsible for the pyroelectric effect that these materials present.

Polymers with flexible backbone with chiral side groups containing mesogenic moieties with a dipole moment perpendicular to the rod may display ferroelectric behavior

FIGURE 39.35 Configurations of PVDF chains in the α (a) and β (b) crystalline forms.

(Scherowsky, 1995). A scheme of a liquid crystal polymer displaying ferroelectric behavior is shown in Figure 39.21. Piezoelectric systems can also be prepared from amorphous polar polymers such as polyvinyl chloride and poly(vinyl acetate). At $T > T_g$, the dipoles of the polymer chains are oriented under the effect of an electric field, and then the temperature is lowered below T_g thus accomplishing frozen-in dipole orientation. The remnant polarization of the films in SI units is $P_r = \epsilon_0 \Delta \epsilon E_p$ where ϵ_0 is the dielectric permittivity in vacuum, $\Delta \epsilon$ is the dielectric relaxation strength and E_p is the polarization electric field.

Piezoelectricity is also displayed by uniaxial-oriented polymer chains containing chiral moieties. Systems of this kind include a variety of polymers such as poly(γ -benzyl-L-glutamate), cyanoethylcellulose, and isotactic polypropylene oxide. For illustrative purposes, the values of piezoelectric and pyroelectric coefficients for several polymers are shown in Table 39.1. PVDF and the VDF/TFE copolymers exhibit rather high piezoelectric and pyroelectric coefficients in comparison with other polymers. These polymers provide an alternate way to fabricate high quality ultra thin crystalline ferroelectric films (Bune, 1998; Duan, 2004).

The piezoelectric and pyroelectric properties of polymers are inferior to those exhibited by ceramic materials such as barium titanate and lead zirconate titanate (PZT). However, their brittle nature and inflexibility of inorganic materials limits their use (Mazur, 1995; Dias and Das-Gupta, 1996). A homogenous mixture of highly piezoelectric and pyroelectric ceramic material with a polymeric material, such as PVDF or PVDV, and Nylon, allows to obtain a composite that exhibits the piezoelectric and pyroelectric coefficients of ceramics with the flexibility, strength, and lightness of the polymer.

TABLE 39.1 Piezoelectric, Pyroelectric, and Permittivity Coefficients for Some Polymers (Furukawa, 1989)

Class 1: Poled Polymers		d_{31} (pC/N ⁻¹)	ϵ_{33}	p_3 (μ /Cm ² /K ⁻¹)
A. Ferroelectric polymers	PVDF ^a	30	0.2	35
	VDF/TrFE ^b	30	0.3	50
	VDF/TFE ^c	30	0.25	35
B. Polar polymers	VDCN/VAc ^d	8	0.25	20
	Nylon 11	4		5

^fLead zirconate titanate-PVDF composite.

^gLead zirconate titanate.

^hPoly(benzyl glutamate).

ⁱCyanoethyl cellulose.

^jPoly(β -hydroxy butyrate).

39.9 NONLINEAR POLARIZATION IN POLYMERS

Experiments indicate that the induced polarization of molecules easily polarizable is not a linear function of the electric field E and can be approximated by a Taylor series expansion (Buckingham, 1967)

$$P = \alpha E + (1/2)\beta EE + (1/6)\gamma EEE + \dots \quad (39.47)$$

where α is a second-order tensor, whereas β and γ named first and second hyperpolarizabilities, respectively, are third and fourth-order tensors, respectively.

Under electric fields of high intensity, second and third harmonics of polarization accompany the first or fundamental harmonic. Accordingly, a monochromatic laser beam at frequency ω traveling through a crystal produces a polarization 2ω , which radiates an electromagnetic wave of the same frequency (2ω), that propagates with the same velocity, monochromaticity and direction as the incident electromagnetic radiation of frequency ω . Symmetry operations dictate that neither isotropic system nor centrosymmetric crystals produce second-order harmonics. However, third-order harmonics can appear in isotropic systems.

It became clear in the 1980s that polymers with chromophore groups in their structure can display nonlinear optical behavior. However, owing to the fact that these polymers are amorphous, it is necessary to convert them into anisotropic materials in order that they can generate second-order harmonics or display electro-optical properties (see below). This can be accomplished by orientation of the dipoles of the chromophores in an electric field at temperatures well above T_g .

It has been suggested that a two-state model could be used to guide the design of second-order NLO chromophores (Buckingham, 1967). In the study of the hyperpolarizabilities, it was found (Oudar and Chemla, 1977) that $\beta = (\mu_{ee} - \mu_{gg})\mu_{ge}^2/E_{ge}^2$, where μ and E are the dipole matrix element and transition energy, respectively, between the ground state (g) and the excited state (e). In general (Chia-Cheng et al., 2005), molecules for second-order NLO applications were based simply on aromatic π -electron systems asymmetrically end-capped with electron donating and accepting groups to impart the directional bias. For example, 4-(*N,N*-dimethylamino)-4'-nitrostilbene (DANS). In DANS, $(\mu_\beta = (446 \sim 580) \times 10^{-48} \text{ esu})$ is a typical NLO chromophore. In this molecule, the two benzene rings and the double bond provide the conjugated π -system and the polarizable electrons; the dimethylamino group acts as the donor, and the nitro group acts as the acceptor.

NLO polymers exhibit large optical nonlinearities, which have ultrafast response because the electronic polarization is nearly instantaneous. At the macroscopic level, second-order harmonic generation under an electric field $E = E_0 \cos \omega t$ can be written as (Burland et al., 1994; Riande and Díaz-Calleja, 2005)

$$P_i(2\omega) = (1/2)e_0\chi_{ijk}(-2\omega, \omega, \omega)E_j(\omega)E_k(\omega) = e_0d_{ijk}(-2\omega, \omega, \omega)E_j(\omega)E_k(\omega) \quad (39.48)$$

where χ_{ijk} is the electro-optic susceptibility. Notice that χ_{ijk} is related to the first hyperpolarizability by

$$\chi_{ijk}(-2\omega, \omega, \omega) = (1/2)e_0Nf_i(-2\omega)f_j(\omega)f_k(\omega) < \beta_{ijk}(-2\omega, \omega, \omega) >_{ijk} \quad (39.49)$$

where N is the number of chromophores groups, f_i is the Lorentz field factor and the angular brackets denote the weighted sum of the polarizability of the molecule over all its orientations in the polymer. In SI units, the third-order susceptibility tensor χ is given in m/V.

Polymers containing chromophore groups with their dipoles duly oriented display the electro-optic effect, that is, the dielectric permittivity of the polymer changes by effect of an electric field. This phenomenon is known as Pockells effect. The change in permittivity is reflected in the index of refraction so that (Kaminov, 1974)

$$\Delta n_{IJ} = -(n^3/2)r_{IJK}E_K \quad (39.50)$$

where r_{IJK} is the electro-optic coefficient. Change in the permittivity (index of refraction) causes a change in the frequency of an electromagnetic radiation traveling through the poled material. Then the electro-optic effect plays an important role in the transmission of codified information, whereas the second-order effect is important in information storage. Making the reduction of indices $11 \rightarrow 1$, $22 \rightarrow 2$, $33 \rightarrow 3$, $3 \rightarrow 4$, $13 \rightarrow 5$, and $12 \rightarrow 6$, the d_{IJK} and r_{IJK} tensors are expressed as d_{IJ} and r_{IJ} , respectively. NLO chromophore that possesses a large first hyperpolarizability β is essential to ensure large optical nonlinearities in bulk polymers. The second harmonic coefficient d_{33} and the linear EO coefficient r_{33} are directly related to the second-order NLO susceptibility and EO susceptibility, respectively.

In the glassy state, micro-Brownian motions freeze and dipolar orientation is preserved. Therefore, to maintain the anisotropy of the system, the glass transition temperature of the poled polymers should be high. On the other hand, during devices processing, the temperatures of NLO polymers can be up to 300°C. Moreover, these materials may endure temperatures of the order of 100°C for long times during operation conditions (Kaminov, 1974; Samyn et al., 2001). As a result, NLO polymers should exhibit good mechanical and thermal properties. For frequency doubling devices, the second-order susceptibility should be of the order of 60 pm/V, whereas the electro-optical coefficient for electro-optical applications should be larger than 10 pm/V. Chromophore moieties often used in the preparation of NLO polymers based on poly(metacrylic acid) are shown in Figure 39.36. Values of the susceptibility and electro-optical polymers for copolymers with different chromophores are given in Table 39.2.

NLO polymers with suitable mechanical and thermal properties can be prepared from polyimides containing both rigid segments and chromophore groups in the main chain. However, the rigidity of this configuration hinders the orientation of the dipole associated with the chromophore in an electric field, the necessary step to convert the material into an anisotropic one. A better molecular design is the use of rigid segments in the backbone and chromophore groups as lateral substituents (Peng and Yu, 1994; Yang et al., 1994, 1996; Yu and Yu, 1994). A representative structure of this kind is shown in Figure 39.37. NLO polymers can also be obtained from epoxy resins (Jungbauer et al., 1990) and cross-linked polyurethanes (Chen et al., 1992; Shi et al., 1992) containing in both cases chromophore groups. Since molecular mobility in thermosets is severely hindered, orientation of the dipoles associated with the chromophore groups must be performed before gelification takes place. This can be accomplished by carrying out the cross-linking reaction under poling (see Figure 39.38). Dendrimeric structures containing NLO moieties with different configurations have also been reported (Ma et al., 2001; Kajzar et al., 2002).

FIGURE 39.36 Copolymers of methyl methacrylate with methacrylates containing chromophore groups.

Ferroelectric polymers such as poly(vinylidene fluoride) and its copolymers vinylidene/fluoride, vinylidene cyanide copolymers and ferroelectric liquid crystalline polymers exhibit interesting nonoptical properties. For a survey with the description of NLO polymers (see Chia-Cheng et al., 2005).

39.10 ELASTOMERS FOR ACTUATORS AND SENSORS

Well above the glass transition temperature, cross-linked polymers or elastomers behave such as rubber materials, displaying large deformations under mechanical force fields. In this situation, stress-strain relationships in the elastomer become nonlinear. In the linear theory of elasticity, solutions of traction boundary problems are unique and the stress

fields are also unique. This is a consequence of the linearity of the constitutive equations. However, under finite deformations, those relations are nonlinear and the uniqueness of the solutions is not warranted. In some circumstances, this could give rise to bifurcation phenomena (Liu, 2002).

Rubbery materials, as dielectric polymer materials, also present a dipolar moment that deforms under the action of electric force fields. These rubbers are referred as electromechanically active elastomers (EMAE) (Eringen, 1990). More recent theoretical foundations of the electroelasticity are described elsewhere (Dorfmann and Ogden, 2005, 2006). It is worth noting that the field may cause some dielectrics to become thinner and other thicker (Xu et al., 2002; Liu et al., 2002). They can convert electrical into mechanical energy and vice-versa (Xu et al., 2001). In some cases, the mechanical and electrical force fields enter in competition between them, thus giving rise to interesting changes in the instability and bifurcation phenomena in these materials (Díaz-Calleja et al., 2009).

Potential applications of EMAE include biomedical prostheses, actuators, energy harvesters, and robotics. In particular, the electrostriction of elastomeric polymer dielectrics with compliant electrodes is potentially useful as a small-scale, solid-state actuator technology (Peltine et al., 1998). These materials combine an efficient fast response with relatively high strains (>30%), good actuation pressures (up to 1.9 MPa), and high specific energy densities (up to 0.1 J/g).

The design of active structures (robots) based on actuators follows an approach in which a passive skeletal structure composed of rods and joints is augmented by actuators, which apply force to the skeleton, such that it changes its shape (Kofod and Wirges, 2007). In this case, the proposed technology rests on the principle of minimal surfaces found in nature. The principle of the complex structure involved is substantiated with a model actuator consisting of a sheet of stiff plastic bent to a shell to which ends the elastomer is attached. Compliant electrodes are applied to both sides of the elastomer sheet, thus forming an elastomeric capacitor driven by Maxwell stress. The analytical model of this structure is based on a free energy function, which is the addition of the free energy of the elastomer (the simplest case corresponding to the Gaussian limit of a freely jointed chain), the elastic energy of the curved beam, and the voltage-controlled energy of the capacitor. As usual, the minimum value of the energy corresponds to the equilibrium

state of the system. This equilibrium state can be modified by changing the applied voltage. In this way, minimum-energy structures can be produced. The advantages of this type of dielectric elastomers are simplicity in manufacture, an inherent push–pull configuration, and the existence of a saturation voltage.

However, these actuators have experienced in some cases high rates of failure that have prevented their practical application. The large-scale failure modes of dielectric elastomer actuators have been studied by Plante and Dubowsly (2006). Using a model elastomer proposed by Ogden (1972), these authors developed a theory based on continuum mechanics (Holzapfel, 2000), and establish three large-scale failure criteria: material strength, dielectric strength and pull-in. These criteria depend on the material and on the stretch rate. In spite of the promising applications, the properties of dielectric actuators still need to be improved.

39.11 ELECTRICAL BREAKDOWN IN POLYMERS

Dielectrics are not an exception to the “first rule” of materials science that states that “everything can be broken.” In increasing the voltage applied to a capacitor, a voltage may be reached at which an electrical breakthrough across the dielectric inside the capacitor occurs, a phenomenon called “electrical breakdown”. This fact is made evident by an irreversible—and practically always destructive—sudden flow of current within very short times, of the order of 10^{-8} s. The voltage at which electrical breakdown occurs is not a well-defined property because depends on several parameters, the most important being the nature of the chemical and physical characteristics of the material itself, production process, thickness, temperature, internal structure of the material, boundary surfaces, age, field stress history, and environment, especially the humidity of the environment in which the material is used.

Polymer materials are characterized for displaying a wide range of mechanical strength and stiffness. These characteristics are coupled with high corrosion resistance, ease of processing and low cost. Moreover, the very high breakdown strengths ($\sim 5 \times 10^6$ up to $\sim 10^8$ V/m) most polymers present, together with the high DC resistivities (typically $> 10^{16}$ Ω m) and low dielectric losses (in many cases $\tan \delta < 0.001$) make these materials suitable for insulating purposes. Obviously, the voltage at the electrical breakdown depends on the electrical strength in such a way that the voltage necessary for this phenomenon to occur decreases with decreasing films thickness.

Electrical treeing degradation has been detected in inorganic as well polymeric materials and the mechanism of this process must be independent on the chemical nature of the insulation. The origin of the electrical tree could be traced to asperities on the conductor or metallic particles embedded in the polymer during the extrusion. If semiconductor layers are simultaneously laid down by means of a triple extrusion technique over the inner conductor and the outer insulation, then electrical trees initiated in this way are substantially reduced. However, treeing degradation could still persist caused by water trees. Water trees occur in a variety of polymers (Xu et al., 2001) including polyethylene, (e.g., ethylene-polypropylene rubber [EPR]), poly(vinyl chloride) (PVC), polycarbonate, aromatic derivatives such as polystyrene, all of them below and above the glass transition temperature, as well as in thermosets. The feature making the path of a water tree is the presence of a large density of spherical microvoids of radius 1–5 μ m (Shaw and Shaw, 1984).

FIGURE 39.39 Discharge in a block of poly(methyl methacrylate) previously charged with a 2 MeV electron beam and discharged through a point contact. Taken from *Fractals and Disordered Systems* (Figure 8.1) (Shaw and Shaw, 1984).

Dielectric breakdown is the fastest way to prepare a fractal structure. For example, it is possible to obtain a decorative “frozen lightning” by electron beam charging of an insulating material such as poly(methyl methacrylate) followed by a discharge through a point connector (Knizhnik et al., 1982). The tree-like patterns resulting from the experiment, shown in Figure 39.39, have a fractal structure similar to of clusters described by the diffusion limited aggregation model (Bunde, 1991). A more detailed information on fractals related with electrical treeing can be found elsewhere (Dissado and Fotherhill, 1992).

Electrical aging or deterioration of the electric strength properties of polymers, such as polyethylene and polypropylene, by the actions of electric fields decreases their electrical breakdown strengths. Up to date (Zakrevskii et al., 2003), the mechanism responsible for electrical breakdown in insulating polymers is a not well-understood issue yet. For example, the short free path length in insulating polymers makes highly improbable that electron avalanches occur in them. As a result, it is inapplicable the concept that electrical breakdown arises from an electron avalanche occurring at some critical electric field intensity E_{cr} when conditions for the impact ionization of molecular chains by fast electrons are created. The experimental evidence at hand suggests that the electrical breakdown is not a critical phenomenon, but a kinetic process that develops in time. The breakdown itself involves the formation of a conducting channel, and it is a final stage of polymer degradation in the electric field. This fact arises from the damage accumulation process whose rate depends on the electric field intensity. It is believed that after a cavity or a low density region in the material is formed, erosion of the polymer sample induced by discharges gives rise to a rapid propagation of a conducting channel through the sample, that is, to the sample breakdown. The mechanism of formation of pore-like or low density structures under the action of an electric field is a nonsolved major problem in the theory of electrical strengths of polymers. A thorough information concerning the physics involved in electrical breakdown can be found elsewhere (Dissado and Fotherhill, 1992).

40.1 INTRODUCTION

This chapter deals with the nondestructive inspection of materials, components, and structures. The term nondestructive inspection (NDI) or nondestructive evaluation (NDE) is defined as that class of physical and chemical tests that permit the detection and/or measurement of significant properties or the detection of defects in a material without impairing its usefulness. The inspection process is often complicated by the fact that many materials are anisotropic, and most NDI techniques were developed for isotropic materials such as metals. The added complication due to the anisotropy usually means that an inspection is more complicated than it would be with isotropic materials.

Inspection of complex materials and structures is frequently carried out by comparing the expected inspection data with a standard and noting any significant deviations. This means a well-defined standard must be available for calibration of the inspection instrumentation. Furthermore, standards also must contain implanted flaws that mimic those that naturally occur in the material or structure to be inspected. Without a well-defined standard to calibrate the inspection process, the analysis of NDI results can be significantly in error. For example, to estimate the amount of porosity in a cast component from ultrasonic measurements, standard calibration specimens with calibrated levels of porosity must be available to calibrate the instrumentation. Without such standards, estimation of porosity from ultrasonic data is a highly speculative process.

This chapter covers some important and some less well-known NDI tests. Since information on the less frequently used tests is not generally in standard texts, additional sources of information are listed in the references.

Inspection instrumentation must possess four qualities in order to receive widespread acceptance in the NDI community:

1. *Accuracy*: The instrument must accurately measure a property of the material or structure that can be used to infer either its properties or the presence of flaws.
2. *Reliability*: The instrument must be highly reliable, that is, it must consistently detect and quantify flaws or a property with a high degree of reliability. If an instrument is not reliable, then it may not detect flaws that can lead to failure of the component, or it may indicate the presence of a flaw where none exists. The detection of a phantom flaw can mean that an adequate component is rejected, which is a costly error.
3. *Simplicity*: The most frequently used instruments are those used by factory or repair technicians. The inspection community rarely uses highly skilled operators due to the cost constraints.

4. *Low Cost*: An instrument need not be low cost in an absolute sense. Instead, it must be an inexpensive relative either to the value of the component under test or to the cost of a failure or aborted mission. For example, in the aircraft industry as much as 12% of the value of the component may be spent on inspection of a flight-critical aircraft component.

40.1.1 Information on Inspection Methods

To the engineer confronted by a new inspection requirement, there may arise the question of where to find pertinent information regarding an inspection procedure and its interpretation. Fortunately, many potential sources of information about instrumentation and techniques are available for NDI, and a brief examination of this literature is presented here. Many of these references were generated because of the demands of materials used in flight-critical aerospace structures. In this chapter, we will refer only to scientific and engineering books and journals that one would reasonably expect to find in a well-provisioned library. With the rise of the Internet, now there are many electronic sources of information available on the World Wide Web. These include library catalogs, societal home pages, online journals devoted to inspection, home pages of instrument manufacturers with online demonstrations of their capabilities and inspection services, inspection software, and online forums devoted to solving inspection problems. The references provide many such sources. However, with new electronic sources appearing daily, it is only a brief snapshot of those available at the beginning of the twenty-first century. For those new to the technology, American Society for Testing and Materials (ASTM) standards are particularly valuable because they give very detailed directions on many NDE techniques. More importantly, they are widely accepted standards for inspections. The references also provide sources for those situations where standard inspection methods are not sufficient to detect the material condition of interest.

40.1.1.1 General NDE Reference Books General overviews to NDE techniques are provided in Refs. (ASM International, 1989; Mitchell and Buck, 1992; Shapuk, 1997; Green, 1998; Altergott and Henneke, 1990; Halmshaw, 1991; Kline, 1992; Mallick, 1997; McGonnagle, 1961; Ruud, 1986; Sharpe, 1984; Summerscales, 1994; Thompson and Chimenti, 1982; Boogaard and van Dijk, 1989; Bray and Stanley, 1989; Geier, 1994) (*British Journal of Nondestructive Testing*, no longer published; American Society for Nondestructive Testing, <http://www.asnt.org>; Center for Nondestructive Evaluation, <http://www.cnde.iastate.edu>; Center for Quality Engineering & Failure Prevention, Center for Quality Engineering & Failure Prevention, <http://www.cqe.nwu.edu>; *Nondestructive Evaluation System Reliability Assessment*, <http://www.ihserc.com>; Nondestructive Testing Information Analysis Center, <http://www.ntiac.com>). The reader will note that some of these citations are not recent, but they are included because of their value to the engineer who does not possess formal training in the latest inspection technologies. Additionally, some older works were included because of their clarity of presentation, completeness, or usefulness to the inspection of complex structures.

40.1.1.2 NDE Journals The periodical literature is often a source of the latest research results for new or modified inspection methodologies (*British Journal of Nondestructive Testing*, no longer published; Online Journal Publication Service, <http://ojps.aip.org>; *Journal of Composite Materials*, 2004; electronic journals, <http://lib-www.lanl.gov/>

cgi-bin/ejrnlsrch.cgi; Elsevier Science, <http://www.elsevier.com/homepage/elecserv.htm>; *Japanese Journal of Nondestructive Inspection*, http://sparc5.kid.ee.cit.nihon-u.ac.jp/homepage_Eng.html; *Journal of Nondestructive Evaluation*, Kluwer Academic, Norwell, MA, 2004). Some excellent journals are no longer available but are still a valuable source of information or may contain data available nowhere else. Whenever possible, World Wide Web addresses are provided to give the reader ready access to this material.

40.1.2 Electronic References

There are many useful electronic references for those working in NDE technology. Only a few of the many useful sites on the World Wide Web are included here. Many sites contain links to other sites that contain information on a special topic of interest to the reader. Because the Web is constantly being updated, the list in the References represents a very brief snapshot of the information available to the NDE community. Some useful sites associated with government agencies were not included due to space limitations. The Web addresses provided are associated with NDE societies (*British Journal of Non-destructive Testing*, no longer published; American Society for Nondestructive Testing, <http://www.asnt.org>; *Japanese Journal of Nondestructive Inspection*, http://sparc5.kid.ee.cit.nihon-u.ac.jp/homepage_Eng.html; IFANT, International Foundation for the Advancement of Nondestructive Testing, <http://www.ifant.org>; Japan JSNDI, <http://sparc5.kid.ee.cit.nihon-u.ac.jp/homepageEng.html>; SPIE, <http://spie.org/>; Institute of Electrical and Electronic Engineers, <http://www.ieee.org/>; *IEEE-ASME, Journal of Microelectromechanical Systems*, Vol. 2000, 2004; American Society of Mechanical Engineers, <http://www.asme.org/>) (British Institute of Non-Destructive Testing, 1999) institutes, (Center for Nondestructive Evaluation, <http://www.cnde.iastate.edu>; Center for Quality Engineering & Failure Prevention, <http://www.cqe.nwu.edu>; Nondestructive Testing Information Analysis Center, <http://www.ntiac.com>; Center for Nondestructive Evaluation, <http://www.cnde.com>; Airport and Aircraft Safety Research & Development, <http://www.asp.tc.faa.gov>; Fraunhofer IZFP, <http://www.fhg.de/english/profile/institute/izfp/index.html>; Stasuk Testing & Inspection, <http://www.nde.net>), government agencies (Electronic journals, <http://lib-www.lanl.gov/cgi-bin/ejrnlsrch.cgi>; Airport and Aircraft Safety Research & Development, <http://www.asp.tc.faa.gov>; AFRL electronic journals, <http://www.wrs.afrl.af.mil/infores/library/ejournals.htm>), and general-interest sites (Elsevier Science, <http://www.elsevier.com/homepage/elecserv.htm>; SPIE, <http://spie.org/>; *IEEE-ASME, Journal of Microelectromechanical Systems*, Vol. 2000, 2004; Link, Springer Verlag, <http://link.springer-ny.com/>; IBM Intellectual Property Network, <http://www.patents.ibm.com>; Lavender International NDT, in *Lavender International*, 2004). There are also many references for the reader interested in using or modifying existing NDE techniques (IFANT, International Foundation for the Advancement of Nondestructive Testing, <http://www.ifant.org>; *Journal of Intelligent Material Systems and Structures*, <http://www.techpub.com>) (Krishnadas Nair, 1997; Rose and Tseng, 1988).

40.1.3 Future NDE Capabilities

At this point, the reader might be tempted to ask if there are new technologies on the horizon that will enable more cost-effective, anticipatory inspection or monitoring of materials and structures. The answer to this is an emphatic yes. There are new developments in solid-state detectors that should significantly affect both inspection capability

and cost. For example, optical and X-ray detectors now give the inspector the ability to rapidly scan large areas of structures for defects. Many new developments in these areas are the outgrowth of advances in noninvasive medical imaging. By coupling this technology with computer algorithms that search an image, the inspection of large areas can be automated, providing more accurate inspections with much less operator fatigue. Hopefully, this technological advance will remove much of the drudgery of detecting the rather small number of flaws in an otherwise large population of satisfactory components.

The area of data fusion is just beginning to be explored in the NDE field. This means that data collected with one technique can be combined with another technique to detect a range of flaws not detected when either is used independently. Data from several techniques can then be coupled at the basic physics level to provide a more complete description of the microstructural details of a material than is now possible.

Finally, the development of new semiconductor-based devices microelectromechanical systems (MEMS) and radio-frequency identification (RFID) allows the implantation of monitoring devices into a material at the time of manufacture to enable real-time structural health monitoring. These devices will permit the inspector to detect and quantify material or structural degradation remotely. This should also enable management of the components and structures for optimum usage over their lifetimes. Remote inspection and tracking of material degradation should reduce the burden of inspection while giving the inspector the ability to examine areas of structure that are now called “hidden.” For more information about this rapidly evolving area, the reader is referred to the literature (*Journal of Micromechanics and Microengineering*, 2004; SPIE, <http://spie.org/>; Smart Structures, <http://www.adaptive-ss.com/>; Smart Materials and Structures, <http://www.adaptive-ss.com/>, 2001; Smart Structures–Harvard, <http://iti.acns.nwu.edu/clear/infr/imatsmart.html>).

A brief review of the commonly used NDI methods are listed in Table 40.1 along with types of flaws that each method detects and the advantages and disadvantages of each technique. For detailed information regarding the capabilities of any particular method, the reader is referred to the literature. A good place to start any search for the latest NDE technology is the home page of the American Society for Nondestructive Testing (American Society for Nondestructive Testing, <http://www.asnt.org>).

40.2 LIQUID PENETRANTS

Liquid penetrants are used to detect surface-connected discontinuities, such as cracks, porosity, and laps, in solid, nonporous materials (Tracy, 1999). The method uses a brightly colored visible or fluorescent penetrating liquid that is applied to the surface of a cleaned part. During a specified “dwell time,” the liquid enters the discontinuity and is then removed from the surface of the part in a separate step. The penetrant is drawn from the flaw to the surface by a developer to provide an indication of surface-connected defects. This process is depicted schematically in Figures 40.1–40.4. A penetrant indication of a flaw in a turbine blade is shown in Figure 40.5.

40.2.1 Penetrant Process

Both technical societies and military specifications require a classification system for penetrants. Society documents (typically ASTM E165) (Tracy, 1999) categorize penetrants

TABLE 40.1 Capabilities of the Common NDI Methods

Method	Typical Flaws Detected	Typical Application	Advantages	Disadvantages
Radiography	Voids, porosity, inclusions, and cracks	Castings, forging, weldments, and structural assemblies	Detects internal flaws; useful on a wide variety of geometric shapes; portable; provides a permanent record	High cost; insensitive to thin laminar flaws, such as tight fatigue cracks and delaminations; potential health hazard
Liquid penetrants technique	Cracks, gouges, porosity, laps, and seams open to a surface	Castings, forging, weldments, and components subject to fatigue or stress-corrosion cracking	Inexpensive; easy to apply; portable; easily interpreted	Flaw must be open to an accessible surface, level of detectability operator dependent
Eddy current inspection	Cracks and variations in alloy composition or heat treatment, wall thickness, dimensions	Tubing, local regions of sheet metal, alloy sorting, and coating thickness measurement	Moderate cost; readily automated; portable	Detects flaws that change conductivity of metals; shallow penetration; geometry sensitive
Magnetic particles method	Cracks, laps, voids, porosity, and inclusions	Castings, forging, and extrusions	Simple; inexpensive; detects shallow subsurface flaws as well as surface flaws	Useful on ferromagnetic materials only; surface preparation required; irrelevant indications often occur; operator dependent
Thermal testing	Voids or disbands in both metallic and nonmetallic materials, location of hot or cold spots in thermally active assemblies	Laminated structures, honeycomb, and electronic circuit boards	Produces a thermal image that is easily interpreted	Difficult to control surface emissivity and poor discrimination between flaw types
Ultrasonic methods	Cracks, voids, porosity, inclusions and delaminations, and lack of bonding between dissimilar materials	Composites, forgings, castings, and weldments and pipes	Excellent depth penetration; good sensitivity and resolution; can provide permanent record	Requires acoustic coupling to component; slow; interpretation of data is often difficult

FIGURE 40.1 Representation of part surface before cleaning for penetrant inspection.

into visible and fluorescent, depending on the type of dye used. In each category, there are three types, depending on how the excess penetrant is removed from the part. These are water washable, postemulsifiable, and solvent removable.

The first step in penetrant testing (PT) or inspection is to clean the part. This critical step is one of the most neglected phases of the PT procedure. Since PT only detects flaws that are open to the surface, the flaw and part surface must be free of dirt, grease, oil, water, chemicals, and other foreign materials that might block the penetrant's entrance into a defect. Typical cleaning procedures use vapor degreasers, ultrasonic cleaners, alkaline cleaners, or solvents.

FIGURE 40.2 Part surface after cleaning and before penetrant application.

FIGURE 40.3 Part after penetrant application.

FIGURE 40.4 Representation of part after excess penetrant has been removed and developer has been applied.

After the surface is clean, a liquid penetrant is applied to the part by dipping, spraying, or brushing. In this step, the penetrant on the surface is wicked into the flaw. In the case of tight or narrow surface openings, such as fatigue cracks, the penetrant must be allowed to remain on the part for a minimum of 30 min to completely fill the flaw. High-sensitivity fluorescent dye penetrants are used for this type of inspection.

After the dwell time, excess penetrant is removed by one of the processes mentioned previously. For water-based penetrants, an emulsifier is sprayed onto the part and again a dwell time is observed. Water is then used to remove the penetrant from the surface of the part. In some cases, the emulsifier is included in the penetrant, so one only needs to wash the part after the penetrant has had time to penetrate the flaw. These penetrants are therefore called “water washable.” Of course, the emulsifier reduces the brightness of any flaw indication because it dilutes the penetrant. Ideally, only the surface penetrant is removed with the penetrant in the flaw left undisturbed.

FIGURE 40.5 Penetrant indication of crack running along edge of jet engine turbine blade. UV illumination causes the extracted penetrant to fluoresce.

The final step in a basic penetrant inspection is the application of a fine powder developer. This may be applied either wet or dry. The developer aids in wicking the penetrant from the flaw and provides a suitable background for its detection. The part is then viewed under a suitable illumination—either an ultraviolet (UV) or a visible source. A typical fluorescent penetrant indication for a crack in a jet engine turbine blade is shown in Figure 40.5.

40.2.2 Reference Standards

Several reference standards are used to check the effectiveness of liquid penetrant systems. One of the oldest and most often used methods involves applying penetrant to hard chromium-plated brass panels. The panel is bent to place the chromium in tension, producing a series of cracks in the plating. These panels are available in sets containing fine, medium, and coarse cracks. The panels are used to classify penetrant materials by sensitivity and to detect degrading changes in the penetrant process.

40.2.3 Limitations of Penetrant Inspections

The major limitation of liquid penetrant inspection is that it can only detect flaws that are open to the surface. Other inspection methods must be used to detect subsurface defects. A factor that may inhibit the effectiveness of liquid penetrant inspection is surface roughness. Rough surfaces are likely to produce false indications by trapping penetrant, therefore, PT is not suited to the inspection of porous materials. Other penetrant-like methods are available for porous components—see the discussion of filtered particle inspection in Tracy (1999).

40.3 RADIOGRAPHY

In radiography used in NDE, the projected X-ray attenuations of a multitude of paths through a specimen are recorded as a two-dimensional image on a recording media, usually film. One might ask if the newer solid-state X-ray imaging technologies used in medicine also apply to NDE. The answer is yes, as will be discussed in the latter part of this section. The most used recording medium is still film because it is the simplest to apply and provides a resolution of subtle details not currently available with solid-state detectors. However, this situation may not be the case much longer as rapid progress is being made in the development of solid-state detectors with significantly enhanced resolution capabilities. Therefore, since this chapter is written at the beginning of the twenty-first century, when film usage for inspection is still commonplace, this portion of the chapter approaches radiography from the standpoint of film-based recording. Since most quantitative relationships for film also apply to solid-state detectors, the material presented should be applicable for the near future.

The radiography testing (RT) process is shown schematically in Figure 40.6. RT records any feature that changes the attenuation of the X-ray beam as it traverses the component. This local change in attenuation produces a change in the intensity of the X-ray beam, which translates into a change in the density, or darkness, on a film. This change in brightness may appear as a distinct shadow or in some cases a delicate shadow on the radiograph. The inspector is greatly aided in detecting a flaw or discrepancy in a part by

FIGURE 40.6 Schematic radiograph with typical flaws.

his or her knowledge of part shape and its influence on the radiographic image. Flaws, which do not change the attenuation of the X-ray beam on passage through the part, are not recorded. For example, a delamination in a laminated specimen is not visible because there is no local change in attenuation of the X-ray beam as it transverse the part. Conversely, flaws that are oriented parallel to the X-ray path do not attenuate the beam as much, allowing more radiation to expose the film and appearing darker than the surrounding image. An example of a crack in the correct orientation to be visible on a radiograph of a piece of tubing is shown in Figure 40.7.

40.3.1 Generation and Absorption of X Radiation

X radiation can be produced from a number of processes. The most common method of generating X rays is with an electron tube in which a beam of energetic electrons impacts a metal target. As the electrons are rapidly decelerated by this collision, a wide band of X radiation is produced, analogous to white light. This band of radiation is referred to as *Bremsstrahlung* or breaking radiation. These high-energy electrons produce short-wavelength energetic X rays. The relationship between the shortest wavelength radiation and the highest voltage applied to the tube is given by

$$\lambda = \frac{12,336}{\text{voltage}},$$

FIGURE 40.7 Radiograph of crack in end of aluminum tubing.

FIGURE 40.8 Plot of X-ray tube voltage versus thickness of several industrial materials.

where λ is the wavelength in angstroms and is the shortest wavelength of the X radiation produced. The more energetic the radiation, the more penetrating powers it possesses, and very high energy radiation is used on dense materials such as metals. While it is possible to analytically predict what X-ray energy would provide the best image for a specific material and geometry, a simpler method of determining the optimum X-ray energy is shown in Figure 40.8. Note that high-energy X-ray beams are used for dense materials, for example, steels, or for thick low-density materials, for example, large plastic parts. An alternate method to using this figure is to use the radiographic equivalence factors given in Table 40.2 (Quinn, 1980). Aluminum is the standard material for X-ray tube voltages below 100 keV, while steel is the standard above this voltage. When radiographing another material, its thickness is multiplied by the factor in this table to obtain the equivalent thickness of the standard material. The radiographic parameters are set up for this thickness of aluminum or steel. When used in this manner, good radiographs can be obtained for most parts. For example, assume that one must radiograph a 0.75-in.-thick piece of brass with a 400-keV X-ray source. The inspector should multiply the 0.75 in. of brass by the factor of 1.3 to obtain 0.98. This means that an acceptable radiograph of the brass plates would be obtained with the same exposure parameters as would be used for 0.98 in. (~ 1 in.) of steel.

Radiation for RT can also be obtained from the decay of radioactive sources. In this case, the process is usually referred to as gamma radiography. These radiation sources have several characteristics that differ from X-ray tubes. First, gamma radiation is very nearly monochromatic; that is, the spectrum of radiation contains only one or two dominant energies. Second, the energies of most sources are on the order of millions-of-volts range, making this source ideal for inspecting highly attenuating materials or very large structures. Third, the small size of these sources permits them to be used in tight locations where an X-ray tube could not fit. Fourth, since the gamma-ray source is continually decaying, adjustments to the exposure time must be made to achieve consistent results over time. Finally, the operator must always remember that the source is continually on and is therefore a persistent safety hazard! Aside from these differences, gamma radiography differs little from standard practice, so no further distinction between the two will be given.

TABLE 40.2 Approximate Radiographic Equivalence Factors

Energy Level	150kV	150kV	250 kV	400kV	400 kV	1 MeV	2 MeV	4–25 MeV	¹⁹² Ir	⁶⁰ Co
Metal

FIGURE 40.9 Plot of mass absorption coefficient for neutron radiography versus atomic number.

40.3.2 Neutron Radiography

Neutron radiography (Burger, 1965) may be useful to inspect some materials and structures. Because the attenuation of neutrons is not related to the elemental composition of the part, some elements can be more easily detected than others. While X rays are most heavily absorbed by high-atomic-number elements, this is not true of neutrons, as shown in Figure 40.9. In Figure 40.10 two aluminum panels are bonded with an epoxy adhesive. The reader can discern that hydrogen adsorbs neutrons more than aluminum does, and thus the missing adhesive is easily detectable.

Neutron radiography, however, does have several constraints. First, neutrons do not expose radiographic film and therefore a fluorescing medium is often used to produce light, which exposes the film. The image produced in this manner is not as sharp and well defined as that from X rays. Second, at present, there is no portable high-flux source of neutrons. This means that a nuclear reactor is most often used to

FIGURE 40.10 Representation of neutron radiograph showing flaws in adhesive bond.

supply the neutron radiation. Although neutron radiography has these severe restrictions, at times there is no alternate, and the utility of this method outweighs its expense and complexity.

40.3.3 Attenuation of X Radiation

An appreciation of how radiographs are interpreted requires a fundamental understanding of X-ray absorption. The relationship governing this phenomenon is de Beer's law:

$$I = I_0 e^{-\mu x},$$

where I , I_0 = transmitted and incident X-ray beam intensities, respectively; μ = attenuation coefficient of material, cm^{-1} ; x = thickness of specimen, cm.

Since the attenuation coefficient is a function of both the composition of the specimen and the wavelength of the X rays, it would be necessary to calculate or measure it for each wavelength used in RT. However, it is possible to calculate the attenuation coefficient of a material for a specific X-ray energy using the mass absorption coefficient μ_m as defined below. The mass absorption coefficients for most elements are readily available for a variety of X-ray energies (Bossi et al., 2002),

$$\mu_m = \frac{\mu}{\rho},$$

where μ = attenuation coefficient of an element, cm^{-1} ; ρ = density, g/cm^3 .

The mass absorption coefficient for the material is obtained, at a specific X-ray energy, by multiplying the μ_m of each element by its weight fraction in a material and summing these quantities. Multiplying this sum by the density of the material yields its attenuation coefficient for the material. This procedure is often not used in practice because the results are valid only for a narrow band of wavelengths. Radiographic equivalency factors are used instead. This process points out that each element in a material contributes to the attenuation coefficient by an amount proportional to its amount in the material.

40.3.4 Film-Based Radiography

The classical method of recording an X-ray image is with film. Because of the continued importance of this medium of recording and the fact that much of the technology associated with it is applicable to newer solid-state recording methods, this section explores film radiography in some detail.

The relationship between the darkness produced on an X-ray film and the quantity of radiation impinging on it is shown by log-log plots of darkness, or film density, and relative exposure (Figures 40.11 and 40.12). Varying the time of exposure, intensity of the beam, or specimen thickness changes the density, or darkness, of the image. The slope of the curve along its linear portion is referred to as the film gamma, γ . Film has characteristics that are analogous to electronic devices: The greater the gamma or amplification capability of the film, the smaller its dynamic range—the range of exposures over which density is linearly related to thickness. If it is necessary to use a high-gamma film to detect very subtle flaws in a part with a wide range of thicknesses, then it is necessary to

FIGURE 40.11 Density or darkness of X-ray film versus relative exposure for three common films.

use several different film types in the same cassette or package. In this way, each film will be optimized for flaw detection in a narrow thickness range of the part.

Using this information, one may calculate the minimum detectable flaw size for a specific RT inspection. A simple method is available to check the radiographic procedure to determine if this detectability has been achieved on the film. This method does not ensure that the radiograph was taken with the specimen in the proper orientation; it merely provides a method of checking for proper execution of a radiographic procedure (see Section 40.3.5).

FIGURE 40.12 Density versus relative exposure for films that could be used in multiple film exposure to obtain optimum flaw detectability in complex part.

TABLE 40.3 Radiographic Sensitivity with Thinnest Penetrameter and Smallest Hole Visible on Radiograph

Sensitivity, S (%)	Quality Level (% T – Hole Diameter)
0.7	1 – 1 T
1.0	1 – 2 T
1.4	2 – 1 T
2.0	2 – 2 T
2.8	2 – 4 T
4.0	4 – 2 T

Using a knowledge of the minimum density difference that is detectable by the average radiographic inspector, the following equation relates the radiographic sensitivity, S , to radiographic parameters:

$$S = \frac{2.3}{\gamma \mu x},$$

where S is the radiographic sensitivity in percent, γ is the film gamma, μ is the attenuation coefficient of the specimen material, and x is the maximum thickness of the part associated with a particular radiographic film. The radiographer uses a penetrameter to determine if this sensitivity was achieved. Table 40.3 give the sensitivity S in percent and the expected RT performance in penetrameter values (see Section 40.3.5).

40.3.5 Penetrameter

An example of a penetrameter is shown schematically in Figure 40.13, while its image on a radiograph is shown in Figure 40.14. While there are many types of penetrameters, this one was chosen because it is easily related to radiographic sensitivity. The penetrameter is simply a thin strip of metal or polymeric material (Fassbender and Hagemaiier, 1983) in which three holes of varying sizes are drilled or punched. It is composed of the same material as the specimen and has a thickness 1, 2, or 4% of maximum part thickness. The holes in the penetrameter have diameters that are 1 T , 2 T , and 4 T . The sensitivity achieved for each radiographic is determined by noting the smallest hole just visible in the thinnest penetrameter on a film and using Table 40.3 to determine the sensitivity achieved. By calculating the radiographic sensitivity and then noting the level achieved in practice, the radiographic process can be quantitatively evaluated. While this procedure does not offer any guarantee of flaw detection, it is useful in evaluating the effectiveness of the RT process.

**FIGURE 40.13** Schematic of typical film penetrameter.

FIGURE 40.14 Radiograph of penetrameter shown in Figure 40.13. The 1T hole is just visible, indicating the resolution obtained in the radiograph.

Almost all variables of the radiographic process may be easily and rapidly changed with the aid of tables, graphs, and nomograms, which are usually provided by film manufacturers free of charge. For more information, the reader is referred to the commercial literature.

40.3.6 Real-Time Radiography

While film radiography represents the bulk of radiographic NDE performed at this time (the beginning of the twenty-first century), new methods of both recording the data and analyzing it are coming into widespread usage. For example, filmless radiography (FR) and real-time radiography (RTR) use solid-state detectors and digital signal processing (DSP) software instead of film to record and enhance the radiographic image. These methods have many advantages, along with some disadvantages. For example, FR permits viewing a radiographic image while the specimen is being moved. This often permits the detection of flaws that would normally be missed in conventional film radiography because of the limited number of views or exposures taken—remember that the X-ray beam must pass along a crack or void for it to be detectable. Additionally, the motion of some flaws enhances their detectability because they present the inspector with a different image as a function of time. Additionally, image enhancement techniques can now be economically and rapidly applied to these images because of the availability of inexpensive, fast computing hardware. The disadvantage of RTR is its lower resolution compared to film. Typical resolution capabilities of RTR or FR systems are in the range of 4 to perhaps 20 line pairs/mm, whereas film resolution capabilities are in the range of 10–100 line pairs/mm. This means some very fine flaws may not be detectable with FR and the inspector must resort to film. However, in cases where resolution is not the limiting factor, the benefits of software image enhancement can be significant. While the images on film may also be enhanced using the image processing schemes, they cannot be performed in real or near real time, as can be done with an electronic system.

40.3.7 Computed Tomography

Another advance in industrial radiography has been the incorporation of computed tomography (CT) into the repertoire of the radiographer. Unfortunately, CT has not been exploited to its fullest extent principally due to the high cost of instrumentation. The capability of CT to link NDE measurements with engineering design and analysis gives this inspection a unique ability to provide quantitative estimates of performance not associated with NDE.

The principal advantage of this method is that it produces an image of a thin slice of the specimen under examination. This slice is parallel to the path of the X-ray beam that passes through the specimen, in contrast to the shadowgraph image produced by traditional radiography shown in Figure 40.7. Whereas the shadowgraph image can be difficult to interpret, the computed CT image does not contain information from planes outside the thin slice.

A comparison between CT and traditional film radiography is best made with images from these two modalities. Figure 40.7 shows a typical radiograph where one can easily see the image of the top and bottom surfaces of the tube under inspection. The reader can contrast this with the image in Figure 40.15, a CT image of a flashlight. The individual components of the flashlight are easily visible and any misplacement of its components or defects in its assembly can be easily detected. An image with a finer scale that reveals the microstructural details of a pencil is shown in Figure 40.16. Clearly visible are not only the key features and even the growth rings of the wood. In fact, the details of the growth during each season are visible as rings within rings. The information in the CT image contrasted with conventional radiographs is striking. First, the detectability of a defect is independent of its position in the image. This is not the case with the classical radiograph, where the defect detectability decreases significantly with depth in the specimen because the defect represents a smaller change in the attenuation of the X-ray beam as the depth increases. Second, the defect detectability is very nearly independent of its orientation. This again is clearly not the case with classical radiography. New applications for CT are constantly being discovered. For example, with a digital CT image, it is possible to search for various flaw conditions using computer analysis and relieve the inspector of much of the tedium of examining structures for the odd flaw. In addition, it is possible to link the digital CT image with finite-element analysis software to examine precisely how the flaws present will affect such parameters as stress distribution, heat flow, and the like. With little effort, one could analyze the full three-dimensional performance of many engineering structures.

FIGURE 40.15 Computed tomography image of flashlight showing details of internal structure.

FIGURE 40.16 Computed tomography of pencil. The reader will note the yearly growth rings and even the growth variations within a single growing season.

40.4 ULTRASONIC METHODS

Ultrasonic inspection methods utilize high-frequency sound waves to inspect the interior of solid parts. Sound waves are mechanical or elastic disturbances or waves that propagate in fluid and solid media. Ultrasonic testing (UT) or inspection is similar to the angler who uses sonar to detect fish (Birks and Green, 1991). The government and various technical societies have developed standard practice specifications for UT. These include ASTM specifications 214-68, 428-71, and 494-75 and military specification MIL-1-8950H. Acoustic and ultrasonic testing can take many forms, from simple coin tapping to the transmission and reception of very high frequency or ultrasonic waves into a part to analyze its internal structure.

UT instruments operating in the frequency range between 20 and 500 kHz are referred to as *sonic* instruments, while those that operate above 500 kHz are called *ultrasonic*. To generate and receive ultrasonic waves, a piezoelectric transducer is employed to convert electrical signals to sound waves and back again. The usual form of a transducer is a piezoelectric crystal mounted in a waterproof housing that is electrically connected to a pulsar (transmitter) and a receiver. In the transmit mode a high-voltage, short-duration electrical spike is applied to the crystal, causing it to rapidly change shape and emit an acoustic pulse. In the receive mode, sound waves or returning echoes compress the piezoelectric crystal, producing an electrical signal that is amplified and processed by the receiver. This process is shown schematically in Figure 40.17.

40.4.1 Sound Waves

Ultrasonic waves have physical characteristics such as wavelength (λ), frequency (f), velocity (v), pressure (p), and amplitude (a). The following relationship between

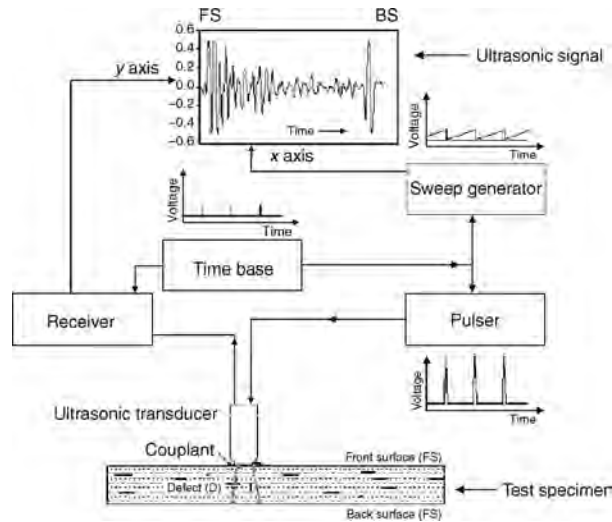

FIGURE 40.17 Schematic of ultrasonic data collection and display in A-scan mode.

wavelength, frequency, and sound velocity is valid for all sound waves:

$$f\lambda = v.$$

For example, the wavelength of longitudinal ultrasonic waves of frequency 2 MHz propagating in steel is 3 mm and the wavelength of shear waves is about half this value, 1.6 mm. The relation between the sound pressure and the particle amplitude is

$$p = 2\pi f \rho v a,$$

where p is density, f is the frequency of the sound wave, v is its velocity, and a the amplitude.

Ultrasonic waves are reflected from boundaries between different materials or media. Each medium has characteristic acoustic impedance and reflections occur in a manner similar to those observed with electrical signals. The acoustic impedance Z of any media capable of supporting sound waves is defined by

$$Z = \rho v$$

where ρ = density of medium, g/cm^3 ; v = velocity of sound along direction of propagation.

Materials with high acoustic impedance are often referred to as sonically hard, in contrast to sonically soft materials with low impedances. For example, steel ($Z = 7.7 \text{ g/cm}^3 \times 5.9 \text{ km/s} = 45.4 \times 10^6 \text{ kg/m}^2\cdot\text{s}$) is sonically harder than aluminum ($Z = 2.7 \text{ g/cm}^3 \times 6.3 \text{ km/s} = 17 \times 10^6 \text{ kg/m}^2\cdot\text{s}$). The Appendix at the end of this chapter lists the acoustic properties of many common materials.

40.4.2 Reflection and Transmission of Sound

Almost all acoustic energy incident on air–solid interfaces is reflected because of the large impedance mismatch between air and most solids. For this reason, a medium with impedance close to that of the part is used to couple the sonic energy from the transducer into the part. A liquid couplant has obvious advantages for parts with a complex geometry, and water is the couplant of choice for most inspection situations. The receiver, in addition to amplifying the returning echoes, also time gates the returning echoes between the front surface and rear surfaces of the component. Thus, any unusually occurring echo is displayed separately or used to set off an alarm, as shown in Figure 40.17. This method of displaying the voltage amplitude of the returning pulse versus time or depth (if acoustic velocity is known) at a single point in the specimen is known as an A scan. In this figure, the first signal corresponds to a reflection from the front surface (FS) of the part and the last signal corresponds to the reflection from its back surface (BS). The signal or echo between the FS and BS is from the defect in the middle of the part.

The portion of sound energy that is either reflected from or transmitted through each interface is a function of the impedances of the medium on each side of that interface. The reflection coefficient R (ratio of the sound pressures or intensities of the reflected and incident waves) and the power reflection coefficient R_{pwr} (ratio of the power in the reflected and incident sound waves) for normally incident waves onto an interface are given as

$$R = \frac{p_r}{p_i} = \frac{Z_1 - Z_2}{Z_1 + Z_2} \quad R_{\text{pwr}} = \frac{I_r}{I_i} = \left(\frac{Z_1 - Z_2}{Z_1 + Z_2} \right)^2.$$

Likewise, the transmission coefficients T and T_{pwr} defined as

$$T = \frac{p_t}{p_i} = \frac{2Z_2}{Z_1 + Z_2} \quad T_{\text{pwr}} = \frac{I_t}{I_i} = \frac{4(Z_2/Z_1)}{[1 + (Z_2/Z_1)]^2},$$

where I_i , I_r , and I_t are the incident, reflected, and transmitted acoustic field intensities, respectively; Z_1 is the acoustic impedance of the medium from which the sound wave is incident; and Z_2 is impedance of the medium into which the wave is transmitted. From these equations, one can calculate the reflection and transmission coefficients for a planar flaw containing air, $Z_1 = 450 \text{ kg/cm}^2\cdot\text{s}$, located in a steel part, $Z_2 = 45.4 \times 10^6 \text{ kg/m}^2\cdot\text{s}$. In this case, the reflection coefficient for the flaw is virtually -1.0 . The minus sign indicates a phase change of 180° for the reflected pulse (note that the defect signal in Figure 40.17 is inverted or phase shifted by 180° from the FS signal). Effectively, no acoustic energy is transmitted across an air gap, necessitating the use of water as a coupling media in ultrasonic testing. Using the acoustic properties of common materials given in the Appendix the reader can make a number of simple, yet informative, calculations.

Thus far, our discussion has involved only longitudinal waves. This is the only wave that travels through fluids such as air and water. The particle motion in this wave, if one could see it, is similar to the motion of a spring, or a Slinky toy, where the displacement and wave motion are collinear (the oscillations occur along the direction of propagation). The wave is called compressional or dilatational as both compressional and dilatational forces are active in it. Audible sound waves are compressional waves. This wave propagates in liquids and gases as well as in solids. However, a solid medium can also support additional types of waves such as shear and Rayleigh or surface waves. Shear or

FIGURE 40.18 Generation and propagation of surface waves in a material.

transverse waves have a particle motion that is analogous to what one sees in an oscillating rope. That is, the displacement of the rope is perpendicular to the direction of wave propagation. The velocity of this wave is about half that of compressional waves and is only found in solid media, as indicated in the Appendix. Shear waves are often generated when a longitudinal wave is incident on a fluid-solid interface at angles of incidence other than 90° . Rayleigh or surface waves have elliptical wave motion, as shown in Figure 40.18, and penetrate the surface for about one wavelength; therefore, they can be used to detect surface and very near surface flaws. The velocity of Rayleigh waves is about 90% of the shear wave velocity. Their generation requires a special device, or wedge as shown in Figure 40.18, which enables an incident ultrasonic wave on the sample at a specific angle that is characteristic of the material (Rayleigh angle). The reader can find more details in the scientific literature (Ash and Paige, 1985; Viktorov, 1967; Krautkramer and Krautkramer, 1983).

40.4.3 Refraction of Sound

The direction of propagation of acoustic waves is governed by the acoustic equivalent of Snell's law. Referring to Figure 40.19, the direction of propagation is determined with the equation

$$\frac{\sin\theta_i}{c_I} = \frac{\sin\theta_r}{c_I} = \frac{\sin\gamma_r}{b_I} = \frac{\sin\theta_t}{c_{II}} = \frac{\sin\gamma_t}{b_{II}},$$

where c_I is the velocity of the incident longitudinal wave, c_I and b_I are the velocities of the longitudinal and shear reflected waves, and c_{II} and b_{II} are the velocities of the longitudinal and shear transmitted waves in solid II. In the water-steel interface, there is no reflected shear wave because these waves do not propagate in fluids such as water. In this case, the above relationship is simplified. Since the water has a lower longitudinal wave speed than either the longitudinal or shear wave speeds of the steel, the transmitted acoustic waves are refracted away from the normal. If the incident wave approaches the interface at increasing angles, there will be an angle above which there will be no transmitted acoustic wave in the higher wave speed material. This angle is referred to as a critical angle. At this angle, the refracted wave travels along the interface and does not enter the solid. A computer-generated curve is shown in Figure 40.20 in which the normalized acoustic energy that is reflected and refracted at a water-steel interface is plotted as a function of

FIGURE 40.19 Representation of Snell's law and mode conversion of longitudinal wave incident on solid–solid interface.

the angle of the incident longitudinal wave. Note that a longitudinal or first critical angle for steel occurs at 14.5° . Likewise, the shear or second critical angle occurs at about 30° . If the angle of incidence is increased above the first critical angle but less than the second critical angle, only the shear wave is generated in the metal and travels at an angle of refraction described by Snell's law. Angles of incidence above the second critical angle produce a complete reflection of the incident acoustic wave; that is, no acoustic energy enters the solid. At a specific angle of incidence (Rayleigh angle) surface, acoustic waves are generating on the material. The Rayleigh angle can be easily calculated from Snell's law by assuming that the refracted angle is 90° . The Rayleigh angle for steel occurs at

FIGURE 40.20 Amplitude (energy flux) and phase of reflected coefficient and transmitted amplitude versus angle of incidence for longitudinal wave incident on water–steel interface. The arrows indicate the critical angles for the interface.

29.5°. In the region between the two critical angles, only the shear wave is generated and is referred to as *shear wave testing*. There are two distinct advantages to inspecting parts with this type of shear wave. First, with only one type of wave present, the ambiguity that would exist concerning which type of wave is reflected from a defect does not occur. Second, the lower wave speed of the shear wave means that it is easier to resolve distances within the part. For these reasons, shear wave inspection is often chosen for inspection of thin metallic structures such as those in aircraft.

Using the relationships for the reflection and transmission coefficients, a great deal of information can be deduced about any ultrasonic inspection situation when the acoustic wave is incident at 90° to the surface. For other angles of incidence, computer software is often used to analyze the acoustic interactions. Analytic predictions of ultrasonic performance in complex materials such as fiber-reinforced composites require the use of more complex algorithms because more complicated modes of wave propagation can occur. Examples of these include Lamb waves (plate waves), Stoneley waves (interface waves), Love waves (guided in layers of a solid material coated onto another one), and others.

40.4.4 Inspection Process

Once the type of ultrasonic inspection has been chosen and the optimum experimental parameters determined, one must choose the mode of presentation of the data. If the principal dimension of the flaw is less than the diameter of the transducer, then the A-scan method may be chosen, as shown in Figure 40.17. The acquisition of a series of A-scans obtained by scanning the transducer in one direction across the specimen and displaying the data as distance versus depth is referred to as a B scan. This is the mode most often used by medical ultrasound instrumentation. In the A-scan mode, the size of the flaw may be inferred by comparing the amplitude of the defect signal to a set of standard calibration blocks. Each block has a flat bottom hole (FBH) drilled from one end. Calibration blocks have FBH diameters that vary in 1/64-in. increments, for example, a number 5 block has a 5/64-in. FBH. By comparing the amplitude of the signal from a calibration block with one from a defect, the inspector may specify a defect size as equivalent to a certain size FBH. The equivalent size is meaningful only for smooth flaws that are nearly perpendicular to the path of the ultrasonic beam and is used in many industrial situations where a reference size is required by a UT procedure.

If the flaw size is larger than the transducer diameter, then the C-scan mode is usually selected. In this mode, shown in Figure 40.21, the transducer is rastered back and forth across the part. In normal operation, a line is traced on a computer monitor or a piece of paper. When a flaw signal is detected between the front and back surfaces, the line drawing ceases and a blank place appears on the paper or monitor. Using this mode of presentation, a planar projection of each flaw is presented to the viewer and its positional relationship to other flaws and to the component boundaries is easily ascertained. Unfortunately, the C-scan mode does not show depth information, unless an electronic gate is set to capture only information from within a specified time window or time gate in the part. With current computer capability, it is a rather simple matter to store all of the returning A-scan data and display only the data in a C-scan mode for a specific depth.

Depending on the structural complexity and the attenuation of the signal, cracklike flaws as small as 0.015 in. in diameter may be reliably detected and quantified with this method. An example of a typical C-scan printout of an adhesively bonded test panel is shown in Figure 40.22. This panel was fabricated with a void-simulating Teflon implant

FIGURE 40.21 Representation of ultrasonic data collection. The data are displayed using the C-scan mode. The image shows a defect located at a certain depth in the material.

and the numerous additional white areas indicate the presence of a great deal of porosity in the part.

40.4.4.1 Through Transmission Versus Pulse–Echo Thus far, the discussion of ultrasonic inspection methods has been concerned with the setup that uses a single transducer to send a signal into the part and to receive any returning echoes. This method is variously referred to as pulse–echo or pitch–catch inspection and is shown schematically in Figure 40.23. The other frequently used inspection setup for many structures is called through transmission. With this setup, two transducers are used, one to send ultrasonic pulses and the other placed on the opposite side of the part to receive the transmitted signals, as shown schematically in Figure 40.24. In Figures 40.23 and 40.24 a large number of reflections occur for the many individual layers in a composite part that can obscure subtle reflections from inclusions whose reflectivity is similar to that of the layered materials. An inclusion with an acoustic impedance very close to that of the part, for example, paper or peel-plys in polymer-based composites, is very difficult to detect with the through–transmission mode of inspection. In this case, the pulse–echo inspection mode is often used to detect these flaws. On the other hand, reflections from distributed flaws such as porosity, as shown on the right-hand side of Figures 40.23 and 40.24, can be obscured by the general background noise present in an acoustic signal. Therefore, it is the loss in signal strength

FIGURE 40.22 Typical C-scan image of composite specimen showing delaminations and porosity.

FIGURE 40.23 Representation of pulse-echo mode of ultrasonic inspection.

of the transmitted signal of the through-transmission method that is most often used to detect this type of flaw. While porosity is detectable in this manner, its location may not be determined. In this situation, the pulse-echo mode is required because the distance from the front or back surface to the flaw can be determined by the relative position of the reflections of the scattered porosity with respect to the surface reflection. Because each method supplies important information about potential flaws and its location, modern ultrasonic instrumentation is frequently equipped to perform both types of inspection nearly simultaneously (Jones and Stone, 1976; Jones, 1985). In such a setup, two transducers are used to conduct a through-transmission test and then each is used separately to conduct pulse-echo tests from opposite sides of the part. This method also helps ensure that a large flaw does not shadow a smaller one, as shown in Figures 40.23 and 40.24.

40.4.4.2 Portable Ultrasonic Systems This ability to image defects on specific levels within a layered component, for example, a composite, is so important that C-scan instrumentation has been miniaturized for usage in the field. An example of one such system developed for aircraft inspection is shown in Figure 40.25. The heart of this system is a computer that records the position of a hand-held transducer and the complete A-scan wave train at each point of the scan. Since the equipment tracks the motion of the

FIGURE 40.24 Representation of through-transmission mode of inspection.

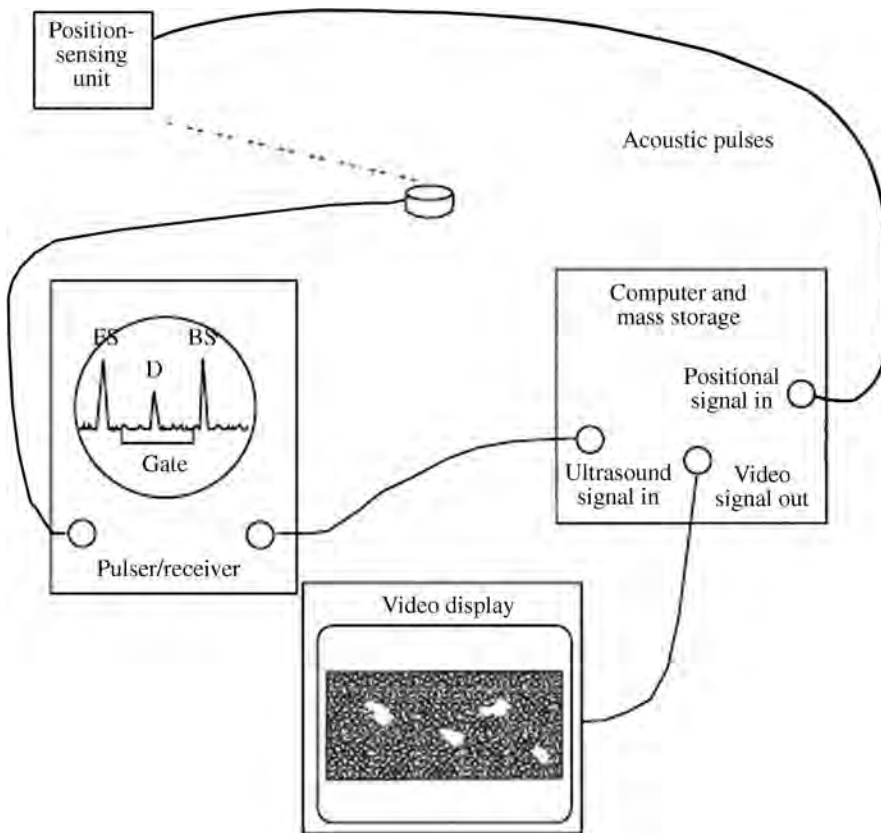

FIGURE 40.25 Field level C-scan instrumentation that is capable of simultaneously tracking the motion of a handheld transducer and recording the ultrasonic information.

transducer as it is scanned manually across a structure, the inspector can see which areas have been scanned. If areas are missed, he or she can return to “color them in,” as shown in the image on the monitor. Additionally, computer manipulation of ultrasonic image data allows the inspector to select either one or a small number of layers for evaluation. In this way, an orderly assessment of the flaws in critical structures can be accomplished. This process of selecting flaws on a layer-by-layer basis for evaluation is shown schematically in Figure 40.26 for the instrument depicted in Figure 40.25.

40.4.5 Bond Testers

A great deal of the ultrasonic inspection literature is devoted to instruments that test adhesive bonds. There has been a recent resurgence of interest in the inspection of adhesive bonds due to concerns about the viability of bonded patches on our aging aircraft (Hsu and Patton, 1993). For an extensive treatment of most of the currently used instruments, the reader is referred to review articles (Swamy and Ali, 1984; Papadakis and Chapman, 1993; Hagemier, 1971, 1972a, 1972b). However, while there may seem to be a large number of instruments, some with exaggerated claims of performance, most operate on the same physical principles.

FIGURE 40.26 Three different displays of delaminations in 16-ply composite obtained from field-level C-scan system. (a) Projection of all flaws through specimen. (b, c) Images from selected depths within specimen.

Bond-testing instruments use a variety of means to excite sonic or low-frequency sound waves into the part. In these methods, a low-frequency acoustic transducer is attached to the structure through a couplant.

As the driving frequency of the transducer is varied, the amplitude and phase of the transducer oscillations change dramatically as it passes through a resonance. The phase and amplitude of these vibrations change very rapidly and reach a maximum as the driving frequency passes through the resonance frequency of the transducer. The effect of the structure is to dampen the resonant response of the transducer–block combination because of the transfer of acoustic energy into it. Defects such as delaminations and porosity in the adhesive bond layer increase the stiffness of the structure and lower the resonant frequency of the combination. The amplitude of the resonance is increased since there is less material to adsorb the sound energy. These changes in the sharpness of the resonant response are easily detectable electronically.

An alternate method of detecting flaws in bonded components is with a low-frequency or sonic instrument that senses the change in the time of flight for sound waves in the layered structure due to the presence of planar delamination. In such instruments, the increased time of traveling from a transmitting to a receiving transducer is detected electronically. Several commercially available bond-testing instruments successfully exploit this principle. A clever adaptation of a commercial version of this instrument has recently been used to successfully test the joints of structures made from sheet molding compounds (Papadakis and Chapman, 1993).

Probably, the most often used method of detecting delaminations in laminated structures is with a coin or tap hammer. This simple instrument is surprisingly effective in trained hands at detecting flaws since an exceedingly complex computer interprets the output signal, that is, the human brain. Consider, for a moment, that most parents can easily hear their child playing a musical instrument at a school concert. They can perform this task even though their child may have a minor part to play and all the other instruments are much louder than the one that their child is playing. With this powerful real-time signal-processing capability, inspectors can often detect flaws that cannot be detectable with current instrumentation and computers.

40.5 MAGNETIC PARTICLE METHOD

The magnetic particle method of nondestructive testing is used to locate surface and subsurface discontinuities in ferromagnetic materials (Schmidt and Skeie, 2001). An

FIGURE 40.27 Representation of magnetic lines of flux in ferromagnetic metal near a flaw. Small magnetic particles are attracted to the leakage field associated with the flaw.

excellent reference for this NDE method is Bray and Stanley (1989), especially Chapters 10–16. Magnetic particle inspection is based on the principle that magnetic lines of force, when present in a ferromagnetic material, are distorted by changes in material continuity, such as cracks or inclusions, as shown schematically in Figure 40.27. If the flaw is open to the surface or close to it, the flux lines escape the surface at the site of the discontinuity. Near-surface flaws, such as nonmagnetic inclusions, cause the same bulging of the lines of force above the surface. These distorted fields, usually referred to as a leakage fields, reveals the presence of the discontinuity when fine magnetic particles are attracted to them during magnetic particle inspection. If these particles are fluorescent, their presence at a flaw will be visible under UV light, much like penetrant indications. Magnetic particle inspection is used for steel components because it is fast and easily implemented and has rather simple flaw indications. The part is usually magnetized with an electric current and then a solution containing fluorescent particles is applied by flowing it over the part. The particles stick to the part, forming the indication of the flaw.

40.5.1 Magnetizing Field

The magnetizing field may be applied to a component by a number of methods. Its function is to generate a residual magnetic field at the surface of the part. The application of a magnetizing force (H) generates a magnetic flux (B) in the component, as shown schematically in Figure 40.28. In this figure, the magnetic flux density B has units of newtons per

FIGURE 40.28 Magnetic flux intensity H versus magnetic flux density B hysteresis curve for typical steel. Initial magnetization starts at the origin and progresses as shown by the arrows. Demagnetization follows the arrows of the smaller hysteresis loops.

ampere or webers per square meter, and the strength of the magnetic field or magnetic flux intensity H has units of oersteds or amperes per meter. Starting at the origin, a magnetizing force is applied and the magnetic field internal to the part increases in a nonlinear fashion along the path shown by the arrows. If the force is reversed, the magnetic field does not return to zero but follows the arrows around the curve as shown. The reader will note that once the magnetizing force is removed, the flux density does not return to zero but remains at an elevated value called the material's remanence. This is the point at which most magnetic particle inspections are performed. The reader will also note that an appreciable reverse magnetic force H must be applied before the internal field density is again zero. This point is referred to as the coercivity of the material. If the magnetizing force is applied and reversed, the material will respond by continually moving around this hysteresis loop.

Selection of the type of magnetizing current depends primarily on whether the defects are open to the surface or are wholly below it. Alternating-current (ac) magnetization is best for the detection of surface discontinuities because the current is concentrated in the near-surface region of the part. Direct-current (dc) magnetization is best suited for subsurface discontinuities because of its deeper penetration of the part. While dc can be obtained from batteries or dc generators, it is usually produced by half-wave or full-wave rectification of commercial power. Rectified current is classified as half-wave direct current (HWDC) or full-wave direct current (FWDC). The ac fields are usually obtained from conventional power mains, but it is supplied to the part at reduced voltage for reasons of safety and the high-current requirements of the magnetizing process.

Two general types of magnetic particles are available to highlight flaws. One type is low-carbon steel with high-permeability and low-retentivity particles, which are used dry and consist of different sizes and shapes to respond to leakage fields. The other type of is very fine particles of magnetic iron oxide that are suspended in a liquid (either a petroleum distillate or water). These particles are smaller and have a lower permeability than the dry particles. Their small mass permits them to be held by the weak leakage fields at very fine surface cracks. Magnetic particles are available in several colors to increase their contrast against different surfaces or backgrounds. Dry powders are typically gray, red, yellow, and black, while wet particles are usually red, black, or fluorescent.

40.5.2 Continuous Versus Noncontinuous Fields

Because the field is always stronger while the magnetizing current is on, the continuous magnetizing method is generally preferred. Additionally, for specimens with low retentivity, this continuous method is often preferred. In the continuous method, the current can be applied in short pulses, typically 0.5 s. The magnetic particles are applied to the surface during this interval and are free to move to the site of the leakage fields. Liquid suspended fluorescent particles produces the most sensitive indications. For field inspections, the magnetizing current is often continuously applied during the test to give time for the powder to migrate to the defect site. In the residual method, the particles are applied after the magnetizing current is removed. This method is particularly well suited for production inspection of multiple parts.

The choice of direction of the magnetizing field within the part involves the nature of the flaw and its direction with respect to the surface and the major axis of the part. In circular magnetization, the field runs circumferentially around the part. It is induced into

the part by passing current through it between two contacting electrodes. Since flaws perpendicular to the magnetizing lines are readily detectable, circular magnetization is used to detect flaws that are parallel or less than 45° to the surface of the long, circular specimens. Placing the specimen inside a coil to create a field running lengthwise through the part produces longitudinal magnetization. This induction method is used to detect transverse discontinuities to the axis of the part.

40.5.3 Inspection Process

The surface of the part to be examined should be clean, dry, and free of contaminants such as oil, grease, loose rust, loose sand, loose scale, lint, thick paint, welding flux, and weld splatter. Cleaning of the specimen may be accomplished with detergents, organic solvents, or mechanical means, such as scrubbing or grit blasting.

Portable and stationary equipment are available for this inspection process. Selection of the specific type of equipment depends on the nature and location of testing. Portable equipment is available in lightweight units (35–90 lb) that can be readily taken to the inspection site. Generally, these units operate at 115, 230, or 460 V ac and supply current outputs of 750–1500 A in half-wave ac.

40.5.4 Demagnetizing the Part

Once the inspection process is complete, the part must be demagnetized. This is done by one of several ways depending on the subsequent usage of the component. A simple method of demagnetizing to remove residual magnetism from small tools is to draw it through the loop-shaped coil tip of a soldering iron. This has the effect of retracing the hysteresis loop a large number of times, each time with a smaller magnetizing force. When completely withdrawn, the tool will then have a very small remnant magnetic field, which for all practical purposes is zero. This same process is accomplished with an industrial part by slowly reducing and reversing the magnetizing current until it is essentially zero, as shown schematically by the arrows in Figure 40.28. Another method of demagnetizing a part is to heat it above its Curie temperature (about 550°C for iron), at which point all residual magnetism disappears. This last process is the best means of removing all residual magnetism, but it requires the expense and time of an elevated heat treatment.

40.6 THERMAL METHODS

Thermal nondestructive inspection methods involve the detection of infrared (IR) energy emitted from the surface of a test object (Maldague, 2001). This technique is used to detect the flow of thermal energy either into or out of a specimen and the effect of anomalies have on the surface temperature distribution. The material properties that influence this method are heat capacity, density, thermal conductivity, and emissivity. Defects that are usually detected include porosity, cracks, and delaminations that are parallel to the surface. The sensitivity of any thermal method is greatest for near-surface flaws that impede heat flow and degrades rapidly for deeply buried flaws in high-conductivity materials. Materials with lower thermal conductivity yield better resolution because they allow larger thermal gradients.

40.6.1 IR Cameras

All objects emit IR radiation with a temperature above absolute zero. At room temperature, the thermal radiation is predominately IR with a wavelength of approximately 10 μm . IR cameras are available that can produce images from this radiation and are capable of viewing large areas by scanning. Since the IR images are usually captured and stored in digital form, image processing is easily performed and the enhanced images are stored on magnetic or optical media. For many applications, an uncalibrated thermal image of a specimen is sufficient to detect flaws. However, if absolute temperatures are required, the IR instrumentation must be calibrated to account for the surface emissivity of the test subject.

The ability of thermography to detect flaws is often affected by the type of flaw and its orientation with respect to the surface of the object. To have a maximum effect on the surface temperature, the flaw must interrupt heat flow to the surface. Since a flaw can occur at any angle to the surface, the important parameter is its projected area to the camera. Subsurface flaws such as cracks parallel to the surface of the object, porosity, and debonding of a surface layer are easily detected. Cracks that are perpendicular to the surface can be very difficult or impossible to detect using thermography.

Most thermal NDE methods do not have good spatial resolution due to spreading of thermal energy as it diffuses to the surface. The greatest advantage of thermography is that it can be a noncontact, remote-viewing technique requiring only line-of-sight access to one side of a test specimen. Large areas can be viewed rapidly, since scan rates for IR cameras run between 16 and 30 frames per second. Temperature differences of 0.02 $^{\circ}\text{C}$ or less can be detected in a controlled environment.

40.6.2 Thermal Paints

A number of contact thermal methods are available for inspection purposes. These usually involve applying a coating to the sample and observing a color change as the specimen is thermally cycled. Several different types of coatings are available that cover a wide temperature ranges. Temperature-sensitive pigments in the form of paints have been made to cover a temperature range 40–1600 $^{\circ}\text{C}$. Thermal phosphors emit visible light when exposed to UV radiation. (The amount of visible light is inversely proportional to temperature.) Thermochromic compounds and cholesteric liquid crystals change color over large temperature ranges. The advantages of these approaches are the simplicity of application and relatively low cost if only small areas are scanned.

40.6.3 Thermal Testing

Excellent results may be achieved for thermographic inspections performed in dynamic environments where the transient effects of heat flow in the test object can be monitored. This enhances detection of areas where different heat transfer rates are present. Applications involving steady-state conditions are more limited. Thermography has been successfully used in several different areas of testing. In medicine, it is used to detect subsurface tumors. In aircraft manufacturing and maintenance, it may be used to detect debonding in layered materials and structures. In the electronics industry, it is used to detect poor thermal performance of circuit board components. Recently thermography has been used to detect stress-induced thermal gradients around defects in dynamically loaded test samples. For more information on thermal NDE methods, the reader is referred to Refs. Maldague, (2001); Stanley, (1995); Zorc, (1989).

40.7 EDDY CURRENT METHODS

40.7.1 Eddy Current Inspection

Eddy current (EC) methods are used to inspect electrically conducting components for flaws. Flaws that cause a change in electrical conductivity or magnetic permeability such as surface-breaking cracks, subsurface cracks, voids, and errors in heat treatment are detectable using EC methods. Thickness measurements and the thickness of non-conducting coatings on metal substrates can also be determined with EC methods (Udpa, 2004). Quite often, several of these conditions can be monitored simultaneously if instrumentation capable of measuring the phase of the EC signal is used.

This inspection method is based on the principle that ECs are induced in a conducting material when a coil (probe) is excited with an alternating or transient electric current that is placed in close proximity to the surface of a conductor. The induced currents create an electromagnetic field that opposes the field of the inducing coil in accordance with Lenz's law. The ECs circulate in the part in closed, continuous paths, and their magnitude depends on many variables. These include the magnitude and frequency of the current in the inducing coil, the coil's shape and position relative to the surface of the part, electrical conductivity, magnetic permeability, shape of the part, and presence of discontinuities or inhomogeneities within the material. Therefore, EC inspection is useful for measuring the electrical properties of materials and detecting discontinuities or variations in the geometry of components.

40.7.1.1 Skin Effect EC inspections are limited to the near-surface region of the conductor by the skin effect. Within the material, the EC density decreases with the depth. The density of the EC field falls off exponentially with depth and diminishes to a value of about 37% of the surface value at a depth referred to as the standard depth of penetration (SDP). The SDP in meters is calculated with the formula

$$SDP = \frac{1}{\sqrt{\pi f \sigma \mu}},$$

where f = test frequency, Hz; σ = test material's electrical conductivity, mho/m; μ = permeability, H/m.

The latter quantity is the product of the relative permeability of the specimen, 1.0 for nonmagnetic materials, and the permeability of free space, $4\pi \times 10^{-7}$ H/m.

40.7.1.2 Impedance Plane While the SDP is used to give an indication of the depth from which useful information can be obtained, the choice of the independent variables in most test situations is usually made using the impedance plane diagram suggested by Förster (1952). It is theoretically possible to calculate the optimum inspection parameters from numerical codes based on Maxwell's equations, but this is a laborious task that is justified in special situations.

The ECs induced at the surface of a material are time varying and have amplitude and phase. The complex impedance of the coil used in the inspection of a specimen is a function of a number of variables. The effect of changes in these variables can be conveniently displayed with the impedance diagram, which shows the variations in amplitude and phase of the coil impedance as functions of the dependent variables specimen

FIGURE 40.29 Representations of EC inspection of solid cylinder. Also shown are the EC paths within the cross section of the cylinder near the crack.

conductivity, thickness, and distance between the coil and specimen, or lift-off. For the case of an encircling coil on a solid cylinder, shown schematically in Figure 40.29, the complex impedance plane is displayed in Figure 40.30. The reader will note that the ordinate and abscissa are normalized by the inductive reactance of the empty coil. This eliminates the effect of the geometry of the coil and specimen. The numerical values shown on the large curve, which are called reference numbers, are used to combine the effects of the conductivity, size of the test specimen, and frequency of the measurement into a single parameter. This yields a diagram that is useful for most test conditions. The reference numbers shown on the outermost curve are obtained with the following relationship for nonmagnetic materials:

$$\text{References number} = r\sqrt{2\pi f\mu\sigma},$$

where r = radius of bar, m; f = frequency of test, Hz; m = magnetic permeability of free space, $4\pi \times 10^{-7}$ H/m; σ = conductivity of specimen, mho/m.

The outer curve in Figures 40.30 and 40.31 is useful only for the case where the coil is the same size as the solid cylinder, which can never happen. For those cases where the coil is larger than the test specimen, which is usually the case, a coil-filling factor is calculated. This is quite easily accomplished with the formula

$$N = \frac{\text{diameter}_{\text{specimen}}}{\text{diameter}_{\text{coil}}}.$$

Figure 40.30 shows the impedance plane with a curve for specimen/coil inspection geometry with a fill factor of 0.75. Note that the reference numbers on the curves representing the different fill factors can be determined by projecting a straight line from point 1.0 on the ordinate to the reference number of interest, as is shown for the reference

FIGURE 40.30 Normalized impedance diagram for long encircling coil on solid, nonferromagnetic cylinder. For $N=1$, the coil and cylinder have the same diameter, while for $N=0.75$ the coil is approximately 1.155 times larger than the cylinder.

number 5.0. Both the fill factor and the reference number change when the size of either the specimen or coil changes. Assume that a reference number of 5.0 is appropriate to a specific test with $N=1.0$; if the coil diameter is changed so that the fill factor becomes 0.75, then the new reference number will be equal to approximately 7. While the actual change in reference number for this case follows the path indicated by the dashed line in Figure 40.30, we have estimated the change along a straight line. This yields a small error in optimizing the test setup but is sufficient for most purposes. For a more detailed treatment of the impedance plane, the reader is referred to Udpa, (2004). The inspection geometry discussed thus far has been for a solid cylinder. The other geometry of general interest is the thin-walled tube. In this case, the skin effect limits the thickness of the metal that may be effectively inspected.

For an infinitely thin-walled tube, the impedance plane is shown in Figure 40.31, which includes the curve for a solid cylinder. The dashed lines that connect these two cases are for thin-walled cylinders of varying thicknesses. The semicircular curve for the thin cylinder is used in the same manner as described above for the solid cylinder.

40.7.1.3 Lift-off of Inspection Coil from Specimen In most inspection situations, the only independent variables are frequency and lift-off. High-frequency excitations are frequently used for detecting defects such as surface-connected cracks or corrosion, while low frequencies are used to detect subsurface flaws. It is also possible to change the coil shape and measurement configuration to enhance detectability, but the discussion of

FIGURE 40.31 Normalized impedance diagram for long encircling coil on both solid and thin-walled conductive but nonferromagnetic cylinders. The dashed lines represent the effects of varying wall thicknesses.

FIGURE 40.32 Effects of various changes in inspection conditions on local signal changes in impedance plane of Figure 40.31. Phase differentiation is relatively easily accomplished with current instrumentation.

these more complex parameters is beyond the scope of this chapter and the reader is referred to the literature. The relationships discussed so far may be applied by examining Figure 40.32, where changes in thickness, lift-off, and conductivity are represented by vectors. These vectors all point in different directions representing the phases of the different possible signals. Instrumentation with phase discrimination circuitry can differentiate between these signals and therefore is often capable of detecting two changes in specimen condition at once. Changes in conductivity can arise from several different conditions. For example, aluminum alloys can have different conductivities depending on their heat treatment. Changes in apparent conductivity are also due to the presence of cracks or voids. A crack decreases the apparent conductivity of the specimen because the ECs must travel a longer distance to complete their circuit within the material. Lift-off and wall thinning are also shown in Figure 40.32. Thus, two different flaw conditions can be rapidly detected. There are situations where changes in wall thickness and lift-off result in signals that are very nearly out of phase and therefore the net change is not detectable. If this situation is suspected, then inspection at two different frequencies is warranted. There are other inspection situations that cannot be covered in this brief description. These include the inspection of ferromagnetic alloys, plate, and sheet stock and the measurement of film thicknesses on metal substrates. For a treatment of these and other special applications of EC inspection, the reader is referred to Udpa (2004).

40.7.2 Probes and Sensors

In some situations, it may be advantageous to have a core with a high magnetic permeability inside the coil. Magnetic fields will pass through the medium with the highest permeability if possible. Therefore, materials with high permeability can be placed in different geometric configurations to enhance the sensitivity of a probe. One example of this is the cup-core probe where the coil has a ferrite core, shield, and cap (Vernon, 1989).

For low frequency or transient tests, using the inductive coil as a sensor is not sufficient since it responds to the time change in magnetic field and not the direct

FIGURE 40.33 Representation of (a) absolute versus (b) differential coil configurations used in EC testing.

magnetic field. It is necessary to induce a magnetic field sensor that responds well at the lower frequencies. Sensors such as the Hall effect sensor and giant magneto-resistive (GMR) sensors have been used to accomplish this (Wincheski, 2002).

There are numerous methods of making EC NDE measurements. Two of the more common methods are shown schematically in Figure 40.33. In the absolute coil arrangement, very accurate measurements can be made of the differences between the two samples. In the differential coil method, it is the differences between the two variables at two slightly different locations that may be detected. For this arrangement, slightly varying changes in dimensions and conductivity are not sensed, while singularities such as cracks or voids are highlighted, even in the presence of other slowly changing variables. Since the specific electronic circuitry used to accomplish this task can vary dramatically, depending on the specific inspection situation, the reader is referred to the current NDE and instrumentation Förster, (1952); Blitz, (1997); Libby, (1971).

One of the daunting challenges that a designer faces when making a material selection is knowing what properties are the most critical for a given application. Assuming that the appropriate properties can be chosen, the designer next needs to be able to find the properties for each metallic material of interest (a challenge in itself) and then interpret the values relative to the design requirements. This requires that the designer has rudimentary knowledge of both the properties and test methods as well as an understanding of how to interpret the properties in the design context.

The purpose of this chapter is to provide some of the basic background for how metallic materials are mechanically tested. The goal is not to provide enormous detail for each different type of property; other sources, for instance Kuhn (2000), can provide this. Rather, the intent is to provide sufficient basic information so that the reader understands what the purpose of the mechanical test is, what mechanical property typically results, and what the corresponding design implication is.

The complexity of metallic materials testing and the specific technical language required can be confounding, especially to engineers not intimately familiar with the field. Those of us in the field also can confuse each other as new methods, terminologies, and approaches develop and are adopted. Luckily, there exists an organization whose mission in part is to minimize this type of misunderstanding.

The American Society for Testing and Materials (ASTM) is one of the world's largest standards development organizations with over 34,000 members responsible for more than 10,000 standards. The breadth of these standards is enormous (74 volumes), covering not only test/evaluation procedures but also standardization approaches for designating metals, paints, plastics, and the like. Originally developed in 1898, this independent, not-for-profit organization serves as a forum for producers, users, consumers, and others in developing voluntary, consensus standards. In practice, a hierarchical committee organization develops the standards initially with a group of experts providing a draft standard. This draft is subsequently balloted by ASTM and does not become a standard until all concerns raised during the voting process that have been fully addressed.

The test-related standards that ASTM publishes help to ensure that mechanical properties generated in one laboratory are consistent with those generated in another laboratory. This consistency is critical from a design point of view as specific property values are typically extracted from numerous sources, and knowing that consistent methods were used in generating these properties is subsequently crucial. The majority of the ASTM standards related to metals test methods and discussed in this chapter are contained within ASTM (2000).

Knowing where to look for the standard does not necessarily imply that it is easy to know which property is the most germane for a given design. For instance, under the classification "fracture testing," there are 16 separate standards in ASTM (2000), all very different and evaluating disparate quantities such as crack-tip opening displacement (CTOD), plane-strain fracture toughness, surface crack toughness, dynamic tear properties, and the like. The fundamental characteristics of the design scenario involved and the candidate metallic materials considered will dictate which fracture property is suitable. In a case such as this where many different test methods are available, selection of the appropriate test standard is complex and beyond the scope of this elementary treatise.

Finally, ASTM also provides other resources to ensure that the properties required are available. In particular, the Directory of Testing Labs (ASTM, 2001) provides a state-by-state listing of laboratories that are available to perform materials testing. The laboratories are identified by the type of test performed, with an index cross-referenced to specific test methods. Moreover, a brief synopsis of the laboratory, including scope of testing, facilities, and staff, is also provided to allow differentiating between the different available choices.

41.1 MECHANICAL TEST LABORATORY

During mechanical testing, a component or material is loaded with either displacement or force, causing a deformation and associated mechanical response to occur. The loading occurs at a design relevant rate (impact, static, or cyclic), and the test is typically performed in the most suitable environment for the end use of the component. The two key components in this process that make up the primary constituents in a mechanical test laboratory (Figure 41.1) are the test machine required to apply the specified loading as well as the sensors and instrumentation used to measure the behavior of the test article.

FIGURE 41.1 Typical material test laboratory containing numerous servohydraulic test frames (Courtesy of Fracture Technology Associates).

41.1.1 Test Machines

The test machine, or loading frame, is used to apply stress (or strain) resulting in axial tension or compression, bending, shear, torsion, or pressure. Although a variety of different loading systems are available, the most common is the universal testing machine, which allows all of these different types of loading types by use of different test fixtures and load train components. Load is applied through a hydraulic piston and cylinder (servohydraulic machine) or with precision machine screws (screw machine) driven by an electric motor and a gear box system. Although screw machines have lower load capacities than servohydraulic systems (generally 125 kips or less), their displacement stability, accuracy, and precision is better than typically observed with servohydraulic systems. Nevertheless, the advantage of the more common servohydraulic systems is the rapid rate of response necessary for many types of tests (e.g., any type of cyclic testing, including fatigue and fracture applications).

For the case of servohydraulic machines, the actuators are typically double-ended allowing tension and compression of the load train. The displacement rate of these machines range from nearly static to approximately 350–1000 in./s. The actual highest rate possible for a given machine/specimen combination is difficult to assess as it depends upon the actuator size, flow rating of the servovalve, as well as the supply pump, plumbing configuration, and control system parameters. Servohydraulic test machines range in size but are typically available from 1–1000 kips or more.

The control of screw and servohydraulic machines is accomplished through dedicated microprocessor-based electronics. Controllers generally fall into two categories: the older generation (but stable and cost effective) analog controller and the newer digital controller (Figure 41.2). In the strictest sense, an analog controller needs a signal source to drive it, typically either a built-in function generator or an external computer for complex waveforms or more stringent control requirements. Whereas machine control in this case is with analog electronics, in the fully digital system closed-loop control is achieved with a computer running software designed to perform the test of interest. The digital systems are typically provided with a suite of programs designed to perform a wide variety of standard test protocols.

FIGURE 41.2 Servohydraulic test frame and digital controller (Courtesy of MTS Corporation).

A test machine is incomplete without a range of grips and fixtures suitable for inserting a test specimen into the load train of the frame. Although the majority of the ASTM test standards address fixtures and grips in some manner, inevitably the hardware available in a given laboratory is diverse and varied, consisting of both standard and hybrid fixtures whose functionality has been proven through repeated use. Versatile pneumatically or hydraulically actuated mechanical clamp grips constitute one of the more popular types available.

41.1.2 Sensors and Instrumentation

The sensors and instrumentation in a laboratory are designed to measure mechanical behavior. Perhaps, the most commonly used sensor is the load-measuring device, also called a load cell. Load cells are placed in series with the specimen in the loading train and can come in a wide variety of sizes and configurations. Normally, threaded couplings are available on either side of the load cell to attach fixtures. Inside the load cell is an instrumented transducer, typically using strain gauge technology to relate applied load to a resistance change suitable for sensing.

Although numerous nontraditional methods and systems exist for measuring displacement or strain, (Lucas, 1997, 2001) the most common method is based on a sensor that provides output based upon strain gauge technology. An example of this is the highly reliable modern material test extensometer (Figure 41.3). This device, fastened to the specimen by mechanical clamping, is used to accurately measure displacement between a

FIGURE 41.3 Extensometer (displacement measurement device) mounted on a tensile specimen.

pair of short knife edges affixed to the gauge length of the specimen. Another type of displacement gauge is the clip gauge, which is basically a spring-loaded extensometer with longer arms. These devices are extremely accurate and robust, but they do have environmental limitations to some extent due to their reliance on strain gauge technology.

Sometimes, it is also useful to mount strain gauges directly on the surface of the test specimen to infer localized behavior. Furthermore, linear variable differential transformers (LVDTs) and capacitive coupling-based displacement devices are commercially available for use in the most aggressive environments. In addition, noncontact optical systems (laser or charge coupled device, CCD, camera based) can also be used to obtain displacement measurements. Recent improvements in computer processor speed, CCD camera size, as well as more affordable random-access memory (RAM), and disk storage make these vision-based technology methods more desirable now more than ever before. The preponderance of optical systems and lack of any standardization in the core technology has resulted in recent ASTM standards activity and a draft standard that defines the relevant terminology.

Data acquisition tools have also benefited greatly from the recent advances in personal computers. Newer data acquisition systems tend to be more flexible than the older, device-dependent applications. The most popular platform for application building currently appears to be the LabVIEW (National Instruments, Austin, TX) programming environment. The LabVIEW platform provides a graphical, icon-based environment to build and modify applications that are more device/board independent and well suited to typical complex process and data acquisition requirements.

Some of the most complex tests performed in a mechanical test laboratory are fatigue and fracture evaluations of metallic components and materials. These tests usually require highly specialized, custom software to control the test machine, take the data, and analyze the results. It is always difficult to know *a priori*, without extensive experience performing these tests, what data acquisition parameters are the most critical. For this reason, a recent guide, ASTM E1942, has been developed that assists a user to understand the limitations of instrumentation and data acquisition systems, especially as related to cyclic fatigue and fracture mechanics testing. Furthermore, this standard is also useful for the segment of the test community not familiar with fatigue and fracture tests, as it provides a practical guide for understanding data acquisition performance.

41.2 TENSILE AND COMPRESSIVE PROPERTY TESTING

The tension test, defined for metallic materials in ASTM E8, is perhaps one of the simplest and most common tests of mechanical behavior. The test is conducted by gripping each end of a reduced section specimen and slowly pulling it until catastrophic failure occurs. Several sample specimen geometries (round and flat, threaded and smooth shank), conventionally described as “dogbone” specimens by virtue of their reduced section geometry, are shown in Figure 41.4. Moreover, tension test specimens are sometimes notched in the center of the gauge length as described in ASTM E338 and E602. These tests are useful for determining how the given metallic material behaves in the presence of a stress concentration. Furthermore, results from these tests have also been related to fracture mechanics parameters for a given material.

In a tensile (or compressive) test, the applied load and displacement (or strain) in the gauge section is used to develop a plot of the stress–strain behavior using the specimen geometry and calibration constants of the transducers used during the test. One challenge during tensile testing is measuring elongation to high strain levels while still having sufficient sensitivity in the elastic region. It is therefore not uncommon to utilize two strain

FIGURE 41.4 Several sample specimen geometries for tensile testing in accordance with ASTM E8 (Courtesy of the Instron Corporation).

FIGURE 41.5 Example stress–strain data from a tensile test from a pipe material tested at 325°F.

transducers as shown in Figure 41.5. Special high-gain strain gauges or transducers are typically required to provide sufficient sensitivity and resolution in the elastic region to derive a Young's modulus value. This is contrasted with conventional extensometry, which is usually used to measure higher levels of strain, even 20% or higher. Alternately, two extensometers, one measuring behavior over a small range while the other configured for a large range, can be mounted on a single specimen. One advantage with this approach is that strain differences as a consequence of different gauge lengths, due to issues such as strain localization, is greatly reduced since each extensometer can have the same basic gauge length but be calibrated to different ranges.

During tensile testing, the ultimate strength is the largest applied stress measured in the specimen section. The proportional limit, often called the yield strength, indicates the onset of plasticity where the assumption of linear stress–strain behavior is violated. As there are many definitions of proportional limit (e.g., the conventional 0.2% strain offset method or the American Petroleum Institute (API) approach (API, 1998) using the stress corresponding to a specific strain level), it is imperative that the physical meaning of the limit be clearly defined when presenting the results. Moreover, post-test measurements made on the gauge length and fracture surface of the specimen are used to quantify the ductility of the specimen. Ductility is the ability of a material to deform plastically without failure occurring. Ductility parameters include percent elongation and percent reduction of area.

The mode of failure can also sometimes influence the strain results obtained. For instance, if the metallic material tested tends to exhibit highly localized plastic deformation, the region of confined necking results in either higher or lower effective strain if the gauge length is short or long, respectively. On the other hand, if deformation is equally distributed along the gauge section, the strain data exhibits no gauge length dependence. Obviously, the potential exists for misinterpretation when comparing stress–strain behavior from one sized specimen to another. Therefore, it is important to ensure that specimen

size is constant when performing a relative comparison of properties from one condition to another or between metallic materials.

Compression testing is typically performed on short cylindrical specimens (ASTM E9). Care must be taken during testing to minimize the influence of both buckling and barreling, two modes of behavior that can corrupt compression test results. Buckling is prevented by minimizing the ratio of specimen length to diameter (typically in the range of 1–2). Load train alignment is also a critical feature of these tests. Alignment is often practically achieved by loading the specimen through a spherical joint so that slight, nearly unmeasurable misalignment will not cause buckling. Barreling results from the friction between the end faces of the specimen and the loading platens. Friction is minimized by using lubricant and machining concentric rings on the end of the specimen to trap the lubricant and keep it from squeezing out.

41.3 CREEP AND STRESS RELAXATION TESTING

Creep and stress relaxation properties are critically important for high-temperature applications. Without knowledge of these properties, both air- and land-based jet turbines, internal combustion engines, and even some electronic equipment could not be adequately designed. Furthermore, there is always increasing pressure to develop new metallic materials with better performance at high temperature so that operating temperature in these applications can be increased to yield higher efficiencies.

Creep deformation is examined by applying either a constant load or a constant true stress to a material held at a specified temperature. When the material is first loaded, a small permanent loading strain occurs and the creep strain rate gradually decreases. This portion of the creep strain versus time plot is called primary creep (stage I). This is subsequently followed by secondary (or also steady-state or stage II) creep with the highest rates observed in the final tertiary creep (stage III) immediately before failure. These three regions of the creep curve are shown schematically in Figure 41.6. Whereas the test methods are described in detail in ASTM E139, the primary components of the test include a static load frame, furnace, and high-temperature extensometry.

The test specimens are similar to those used in a quasi-static tensile test, although the actual geometry used is often controlled by the metallic material form available. Static

FIGURE 41.6 Schematic of the different regions of a classic creep curve.

FIGURE 41.7 Loading frame to apply static (or extremely slow cyclic) load conditions (Courtesy of the Instron Corporation).

deadweight machines are typically used for this type of test, as shown in Figure 41.7. The frames usually have a balance beam to magnify the load applied to the specimen by a factor of between 2 and 25. All of the pull-rod and coupling fixtures used are manufactured from high-temperature alloys impervious to the environment used during the test. Tubular, electric resistance furnaces are usually used with the number of zones typically dependent upon the size of the specimen. Special attention must be made to ensure minimal thermal gradients and uniform temperatures applied to the specimen.

The measurement of gauge length deformation is typically critical during a creep experiment. If temperatures are sufficiently low ($<400^{\circ}\text{F}$), conventional extensometry as used in tensile tests can be used on the specimen. However, higher temperatures are usually involved for most metals, which necessitates using LVDT, capacitive, or other types of displacement measurement transducers. The most common transducer is the LVDT coupled with linkages that reach up through the furnace to attach to the specimen. Special care must subsequently be taken to ensure that the displacements measured actually correspond to gauge length deformation and are not biased by linkage or transducer effects.

Stress relaxation testing (ASTM E328) is similar in many ways to creep testing except that the applied boundary condition is a constant displacement (as opposed to a constant load). This type of test is more suitable for metallic materials that have significant constraint and hence exhibit little strain increase as a function of time. One example of this is

a high-temperature bolted joint where a displacement boundary condition is first applied and then the stress relaxes with time. Testing times include both long term (months or more) at the service temperature and accelerated tests (days) at more aggressive thermal conditions.

Creep and stress relaxation testing can also be performed on specimens with a more complex stress state than simple tension. Examples include compression testing (typically using a carefully machined cylindrical specimen similar to that described earlier for quasi-static compression testing), bend testing (e.g., with a cantilever beam specimen), or even torsion testing. Testing has also been performed on tubular specimens that are subject to complex, multiaxial stress states.

41.4 HARDNESS AND IMPACT TESTING

This section addresses two mechanical test methods that are used to indirectly determine the tensile and toughness properties of a metallic material. As with any indirect test method, there are well-known limitations to these techniques, but they are clearly offset by the reduced cost and increased efficiency of the indirect methods. The test methods, as well as their limitations, will be explained in more detail in this section.

Hardness refers to a material's ability to resist deformation when loaded by an indenter. The indenter can differ in geometry; for instance, it can be conical (the Rockwell test), spherical (Brinell), or pyramidal (Vickers and Knoop). For metallic materials, hardness is directly proportional to the yield stress of the material. Nevertheless, conversions are readily available to relate hardness to ultimate tensile strength (most commonly for steel although other conversions for different metallic materials do exist). Hardness testing (ASTM E6, E10, E18, E92, E1842, and others) is industrially attractive since the testing is rapid (<20 s), low cost, nondestructive, and generally does not require a machined specimen. As a consequence of these issues, hardness is often used as an industrial screening tool to ensure metallic material processing control. An ASTM standard (E140) exists to convert between the different superficial hardness and conventional hardness scales.

The majority of hardness testers (e.g., those shown in Figure 41.8) utilize deadweight, springs, or (infrequently) closed-loop computerized systems. Although many testers provide output on an analog meter, bench-top units with digital readouts (sometimes with an interface for a PC) are generally more popular today. When the component being hardness tested is too large to practically position onto the anvil of the tester, portable test units are available to locally measure hardness. A typical portable hardness measurer is shown in Figure 41.8b. Regardless of the type of hardness tester used, care must be taken to ensure that the system is in proper working order by using commercially available calibration blocks.

Although hardness testing is relatively simple, accurate measurements depend greatly on careful attention to detail. The anvil should minimize the contact area with the component. Surface finish can sometimes be of paramount concern; for 100–150 kgf, a finish ground surface is sufficient whereas for a 15-kgf load, a polished or lapped surface usually is required. Surfaces that are ridged due to machining or that exhibit loose, flaking scale can yield incorrect hardness results. The test surface should be perpendicular to the indenter since even slight ($<5^\circ$) angular deviation can cause hardness to shift by several points. Indenter size should be chosen with the underlying grain structure of the metallic material in mind. In general, the indenter should be larger than the grain size if a

FIGURE 41.8 Hardness testers including (a) a benchtop and (b) portable unit (Courtesy of the Instron Corporation).

macroscopic measurement of hardness is desired. Finally, metallic material homogeneity is also important since the indenter effectively samples a region approximately 10 times deeper than the depth of the indenter penetration.

Instrumented indentation testing is a more recent method developed to derive more extensive data from effectively a hardness test. During this type of testing, the instantaneous load–displacement data is recorded continuously. The measured data can be related to such things as elastic modulus, yield strength, and strain hardening exponent. Highly empirical punch test methods are also continually evolving to relate local deformation behavior to properties such as fracture toughness.

Since some percentage of loading is inevitably dynamic and components often have to be designed to survive high loading rates typical during an accident, dynamic fracture testing can ensure structural integrity under this type of loading. During impact testing, a pendulum machine (example shown in Figure 41.9) with a striker is typically used to impart high energy to a notched sample. The notch toughness of the specimen, typically a flat bar with a carefully machined notch of various geometries, is measured in terms of the absorbed impact energy that causes fracture in the specimen. Some other parameters that are commonly examined include fracture appearance and the deformation noted on the surface of the specimen. The independent variable controlled during testing is most often temperature. A typical energy–temperature curve for A36 steel is shown in Figure 41.10 contrasting the typical difference between slow bend tests and rapid impact results.

The Charpy and Izod impact tests both utilize pendulum loading albeit with specimens of slightly different geometry, especially as related to the specimen notch dimensions. The primary difference between the two tests though is that the Charpy V-notch (CVN

FIGURE 41.9 Example of a pendulum impact machine (Courtesy of the Instron Corporation).

FIGURE 41.10 Impact test results illustrating CVN energy versus temperature curves for A36 steel.

test as defined in ASTM E23) specimen is three-point loaded whereas the Izod specimen is cantilever loaded.¹ Of the two methods, the CVN test remains the most popular method available, and manufacturing lot release requirements using CVN data are actually written into many metallic material specifications. The CVN test is rapid and low cost; the most expensive part is machining specimens although commercial machining templates to ease fabrication are readily available.

Two other impact tests include the drop-weight (ASTM E208) and the drop-weight tear test (DWTT as per E436). During drop-weight tests, a series of experiments are performed where different specimens at a range of temperatures are impacted with a guided, free-falling weight dropped from a fixed height. The key finding is the nil-ductility transition temperature (NDTT), which is the maximum temperature where fracture was observed. The DWTT test is similar to the drop-weight test although the specimen used is slightly larger and the test fixturing is very different. The fracture surfaces are evaluated and the percentage of shear quantified. The temperature at which 50% shear occurs is loosely defined as the ductile-to-brittle transition temperature.

CVN testing can also be performed with a fatigue precracked specimen to eliminate the notch acuity and depth restrictions inherent to the standard CVN specimen geometry. Considerable effort has also been recently expended developing instrumented impact testers to record more data. Nevertheless, the primary shortfall with most of the impact test methods is (a) the relatively small specimen size (relative to component size) and (b) the high degree of empiricism used to relate the results to metallic material properties. These disadvantages are offset by the simplicity and low cost of the test, particularly for production environments where the test can be used effectively as a quality control tool.

41.5 FRACTURE TOUGHNESS TESTING

The foregoing discussion introduced the concept of notch toughness, defined loosely as the energy required to initiate a running fracture from a machined notch. This is an important design parameter as nearly all structures contain notchlike stress concentrations. However, in the strictest sense according to the science of fracture mechanics (the study of cracks), fracture is broadly classified as either brittle [governed by linear elastic fracture mechanics concepts (LEFM)] or ductile [elastic plastic fracture mechanics (EPFM)]. Fracture toughness is the ability of a material to withstand unstable crack propagation (e.g., fracture) assuming of course the presence of a crack. Fracture mechanics provides the theoretical underpinning that relates the following quantities:

- magnitude and range of the remote applied stress,
- geometry of the component,
- morphology (size and shape) of the crack

to what is loosely termed the “crack driving force,” or stress–intensity factor K . Detailed stress analyses of cracks have shown that the magnitude of the local crack-tip stress field

¹ Both machines were developed in the beginning of the twentieth century although Charpy was a Frenchman and Izod was an Englishman.

is proportional to this K parameter. Although K applies for LEFM, in the case of EPFM, there exists another similitude parameter that is termed J .

Fracture toughness testing requires closed-loop, computer-controlled servohydraulic test equipment, and a suite of accurate displacement extensometers. Virtually, all tests are computer controlled due to the complexity of the test and the requirements for recorded data. As a minimum, most fracture tests require measuring the applied load and some displacement measurement across the crack. Most tests are analyzed by custom software developed specifically for the particular test. The most common fracture toughness test is the plane-strain fracture toughness measurement, which yields the K_{Ic} parameter as described in detail in ASTM E399. For an ASTM valid K_{Ic} value, the loading must be such that there is no significant plastic deformation (specifically, the plastic zone at the tip of the crack is less than 2% of the thickness and total crack length). The plane-strain requirement implies that the fracture toughness specimens tend to be quite thick, most are commonly greater than 0.5 in.

Although E399 allows a variety of specimens, the most commonly used is the compact-tension specimen, a pin-loaded, edge-notched geometry. The specimen is first pre-cracked under fatigue loading to ensure that the crack tip is sufficiently sharp for the fracture test. The specimen is then loaded to failure by a constant displacement ramp applied between the pins. During the test, the load and crack mouth opening displacement (CMOD) is measured. Two sample load-displacement plots are shown in Figure 41.11. In Figure 41.11a, the behavior is more brittle with catastrophic failure at peak load. Conversely, in Figure 41.11b, the trend is more suggestive of a ductile and somewhat more stable material with slow crack advance gradually relieving load as the test progresses past the point of maximum load.

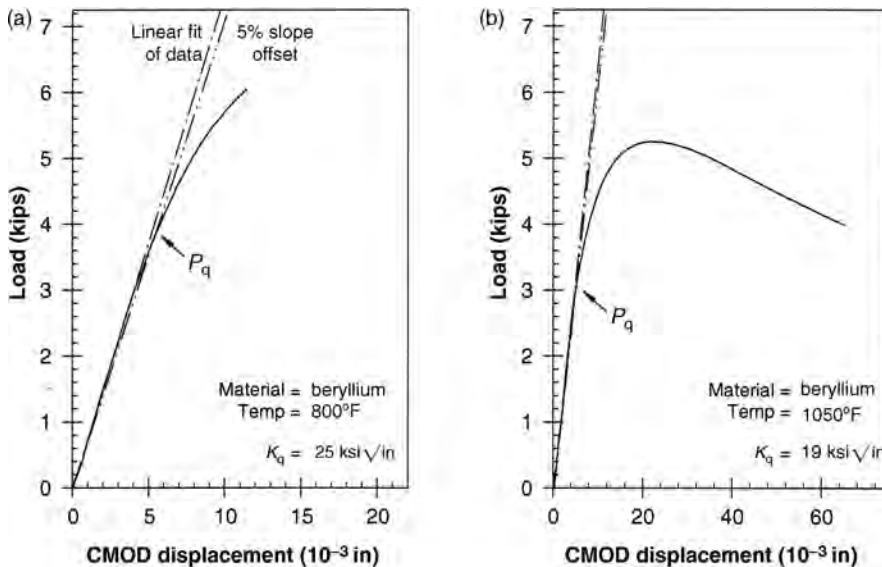

FIGURE 41.11 Two load-displacement plots from K_{Ic} fracture toughness tests conducted on beryllium at elevated temperature.

Determining a K_{Ic} toughness from the load–CMOD data requires fitting the initial linear portion of the data and plotting a 5% secant offset to that linear region. The intersection between the measured load–CMOD data and this secant line defines the critical load. This graphical construction is evident in Figure 41.11a. However, there are stringent limits for qualifying the conditional K_q toughness as an ASTM-valid K_{Ic} . Most importantly, the crack length and thickness are required to be sufficiently long to satisfy the small-scale yielding criteria described earlier. Furthermore, nonlinearity is minimized by requiring that the critical load (corresponding to K_q and denoted by P_q) must be no less than 90% of the maximum measured load. The two sets (Kuhn, 2000) of data indicated in Figure 41.11 are clearly invalid since the conditional P_q load is too low relative to the maximum measured load.

Whereas K_{Ic} applies for thicker, more constrained sections where catastrophic fracture occurs rapidly, a different K_C fracture test (ASTM E561, also termed a K – R curve) applies for thinner structure where slow stable crack extension precedes unstable fracture. The test specimen geometry typically used is a wide, center cracked panel precracked at low loads to generate a sharp fatigue crack suitable for fracture. The specimen is monotonically displaced similar to a K_{Ic} specimen while recording load, CMOD, and often some parameter such as electric potential drop that can be used to instantaneously provide crack length measurement.

The resistance curve, also called an R curve, is then generated by plotting crack driving force K against crack extension, termed Δa . Crack extension is defined as the sum of the physical crack length change, usually derived from either compliance (stiffness) or some other nonvisual crack length indicator, plus the half plastic zone size. Because the stress state is typically something more like plane stress, the plastic zones as observed on the surface of the specimen tend to be quite large. An example R curve is shown in Figure 41.12. The K_C value is defined as the K magnitude at the tangent intersection between the R curve and lines of constant load plotted in K versus crack length (or crack length extension) space. This load represents the maximum level that can be achieved before the crack extends (often unstably) and structural integrity is lost. A careful examination of the data in Figure 41.12 clearly illustrates that some crack growth was apparent in this metallic material since catastrophic failure did not occur at the point of instability.

Fracture toughness testing in the elastic–plastic regime is time consuming, not trivial, and requires advanced instrumentation to yield excellent results (Joyce, 1996). After conducting and analyzing the test, the goal is to generate an R curve, similar to that described earlier for the K_C testing, as shown in Figure 41.13. However, instead of K on the abscissa, the J parameter is included. The J parameter is calculated by including an elastic portion related to K combined with a nonlinear portion related to the area under the load–displacement curve (with respect to load-line displacement). The plane-strain, elastic plastic J_{Ic} parameter measures the onset of instability, in this case corresponding to the point where the crack has advanced a certain amount (after blunting) on the R curve (note this instability criteria is very different than that described for K_C). It is often the case in this type of test that slow, stable cracking will continue as the specimen is displaced and the load gradually drops to a small fraction of the peak obtained.

The J_{Ic} test procedure is usually performed using compact-tension specimens, although three-point bend specimens are also possible provided care is taken to ensure that accurate instrumentation is available to measure load-line displacement. The primary challenge with J_{Ic} testing is the high accuracy required from measurements of the load-line displacement. High-resolution measurement is required so as to infer the extremely small

FIGURE 41.12 Example R curve from a K_{Ic} fracture toughness test performed on stainless steel.

amount of crack tearing necessary for the J_{Ic} fracture toughness definition. This high accuracy is practically achieved through higher accuracy (minimum of 16 bit), low noise data acquisition boards combined with extreme care and control over the critical test details, especially as related to loading pin interfaces and clip gauge attachment.

In editions of the ASTM test standards before 1998, the test method for the elastic-plastic J_{Ic} parameter has always been described in ASTM E813. However, the E08 committee of ASTM has recently published a combined approach under the designation E1820. This combined approach outlines a procedure to follow that can result in any one of the primary toughness parameters, namely K_{Ic} , K -, and J -resistance curves. Although these three parameters constitute the most common fracture test standards, other ASTM methods are also available:

- CTOD fracture toughness (E1290),
- plane-strain crack arrest fracture toughness (E1221),
- fracture testing with surface-crack tension specimens (E740),
- Chevron notch fracture toughness of metallic materials (E1304).

However, these methods are typically neither as wide-ranging nor as commonly encountered in design as the previously noted fracture toughness test methods.

FIGURE 41.13 Example of an R curve from a J_{Ic} fracture toughness test performed on a high-strength weld.

41.6 FATIGUE TESTING

The previous section described basic fracture mechanics concepts as well as the test methods used to quantify fracture behavior given a pre-existing crack. In this section, the process of crack nucleation (e.g., crack initiation) and stable propagation (e.g., crack growth) under cyclic loading is addressed. Understanding crack propagation behavior is critically important since some structures, most notably the current fleet of commercial airliners, adopt a damage tolerance design philosophy whereby cracks are assumed in the structure, and a safe structural life requires detecting and managing these cracks. Quantifying crack nucleation is also important as much of a crack's cyclic life is spent initiating or growing when it is small in size.

The test specimens used for fatigue crack initiation testing are similar geometrically to tensile specimens. The two basic test methods for initiation testing are ASTM E606 and E466 for strain- and stress-controlled testing, respectively. With both of these methods, the goal is to cycle a specimen until failure occurs. Strain control is typically used if (a) the loading is with a constant displacement or (b) the focus is on the short life regime (estimated to be less than 10^3 to 10^5 cycles although this is fairly controversial) where applied stress levels often approach the yield strength of the metallic material. Conversely, load control testing is performed for the mid- to high-cycle life regime. Stress (effectively load) control testing is relatively straightforward since no displacement monitoring or measurement is required. The specimen can be gripped, cycling can commence, and continue unmonitored (provided the servocontrol loop does not require any attention) until failure occurs.

One of the most critical details when performing this type of fatigue testing is controlling bending in the specimen. Poor control of bending typically increases the apparent scatter in the fatigue data generated. Commercial alignment fixtures are available to

mitigate bending. These fixtures utilize a strain gauged specimen and a fixture that allows minute adjustments of the loading train. However, these fixtures are not always available, which means less high tech and pragmatic methods are often required to minimize the effect.

Although guidelines on how to measure and verify specimen alignment are provided in ASTM E1012, minimizing bending practically requires control of three issues. First, the specimen must be carefully machined with excellent dimensional control, parallelism, and axisymmetry. Second, the fixtures used to connect the specimen to the loading train must not introduce any asymmetry. Threaded specimen ends, although commonly used during fatigue testing, should be avoided as the tolerances required to engage the thread make accurate alignment problematic (however, it must be stated that it is not always practical or possible to avoid threaded ends). If the loading cycle is tensile only (e.g., a positive R ratio where R is the ratio of minimum to maximum load), a spherical joint, or more commonly known as a U-joint, in the loading train can minimize bending. Third, the fixtures in the load train should be designed well enough to grip repeatably in the same manner so that once a load train has been carefully aligned with an instrumented specimen it does not vary.

Some typical stress-life ($S-N$) data are shown in Figure 41.14 for two materials, an aluminum and titanium alloy. $S-N$ data are usually generated at a fixed R ratio with the results represented as a plot with stress amplitude or maximum stress on the abscissa and cyclic life on the ordinate. Data are sometimes generated on specimens that have a groove or hole to simulate stress concentrations typically found in structure. Furthermore, it is often of practical interest to know the endurance limit of a metallic material; in theory the endurance limit is defined as the applied stress level that corresponds to infinite life, in practical terms infinite life is approximated in the laboratory as a million cycles. The

FIGURE 41.14 Conventional $S-N$ fatigue test data presented for example titanium and aluminum alloy materials.

usual approach (ASTM, 1963) is to test 30 specimens using an iterative, staircase method to converge on the stress level corresponding to the endurance limit. The nominal stress step chosen is approximately 2% of the ultimate tensile strength of the metallic material. Although this is a test-intensive methodology, the technique is able to clearly define the endurance limit to the accuracy given by the stress step.

The specimens used for fatigue crack propagation testing are similar to that described previously when discussing fracture. The most common geometries are the compact tension, C(T), and the middle cracked tension, M(T), specimens. However, the pin-loaded C(T) is most suitable for positive R ratio (e.g., tension) as the cracked geometry is unstable in compression. Fatigue crack growth (FCG) testing is described in detail in one of the longest and most complex ASTM test standards, ASTM E647. The standard has grown in length as the understanding of the FCG process has deepened. During FCG testing, the goal is to determine crack growth rate as a function of stress intensity factor range, ΔK . A typical series of FCG curves are shown in Figure 41.15 for an aluminum alloy subject to a number of different stress ratios. The central regions of the crack growth curves can be observed to be relatively linear as expected in the moderate growth rate Paris regime.

One of the most critical aspects of FCG testing is measurement of the crack length. The most common method is to use a traveling telemicroscope mounted on a vernier scale for accurate measurement. Recent advances in both crack length measurement and test automation (Braun, 2002; Ruschau, 1995) use elastic compliance and electric potential

FIGURE 41.15 Series of FCG curves for aluminum at various R ratios.

drop methods to measure crack length. However, it is critical to note that these indirect, nonabsolute measurement techniques both require periodic visual crack length measurement for each test to ensure proper calibration. The quality of a laboratory's nonvisual crack length measurement technique and equipment is critical and often directly related to the quality of the FCG data generated.

The conventional method for performing crack growth testing is to record growth rate data with a fixed loading cycle as the crack grows. More efficiently, newer methods are now available that critically depend upon nonvisual crack length measurement methods to control the applied loading. For instance, K gradient techniques can be used where the quantity $C = dK/K da$ is fixed at different levels for different portions of the test. This increases efficiency since (a) it allows the generation of multiple crack growth data sets from the same specimen and (b) data can be generated in short growth intervals resulting in much faster data generation than with constant amplitude loading. However, these advanced FCG test techniques must be carefully applied by experienced testing professionals who fully understand the limitations of this accelerated approach and have the instrumentation available to accurately measure crack length nonvisually.

Most FCG rate testing is performed at a fixed load ratio as this variable does not change for many structures. However, another method gaining wide popularity is generating FCG data from the highest rates down to near threshold (e.g., crack growth rate at a very low magnitude, a quantity especially useful for design purposes) using a constant K_{\max} , increasing K_{\min} loading condition. Consequently, when the test starts, the R ratio is low (0.1 or so) and as the test progresses R increases until approximately 0.9 or more in the near-threshold regime. Whereas conventional FCG threshold testing may take weeks or months to complete, this method results in a highly accelerated test and can be performed in a matter of days. Again, care must be taken to ensure that the choice of the variable test control parameters does not affect the magnitudes or trends of the FCG rate data obtained.

For design purposes, it is sometimes necessary to understand the potential impact of external variables on FCG behavior. For this case, constant ΔK testing can be used to determine effects difficult and time consuming to detect if a complete crack growth curve were generated. As observed in the data in Figure 41.16, several regions of nominally constant ΔK are sequentially applied with the external environmental variable perturbed for each segment. This allows a better assessment of the effect of the variable since a statistically relevant number of crack growth rates are available for each segment. Although this is a highly efficient method to determine effects, the disadvantage is that the measurement strictly applies to only one constant ΔK level. Nevertheless, a similar approach can be used to indirectly determine, for instance, the magnitude of internal residual stresses in a component by examining small changes in FCG rate.

The challenge in applying FCG rate data is accounting for the variable amplitude loading environment typically applied to a component in service. Most of the analytical tools available are empirically based and require some testing under the variable amplitude, spectrum load condition. In these cases, it is not uncommon to perform a crack growth test using a repeated variable amplitude spectrum derived from either service recorded or design loading. The test specimens in these cases are typically more complex, reflecting some design detail such as a fastener hole or weld. Rather than generating crack growth rate data with these tests, the goal is typically to provide crack length as a function of spectrum passes (or cycle count). Although this type of test is widely performed in the aerospace and ground vehicle industries, (McKeighan, 2003) the myriad of approaches

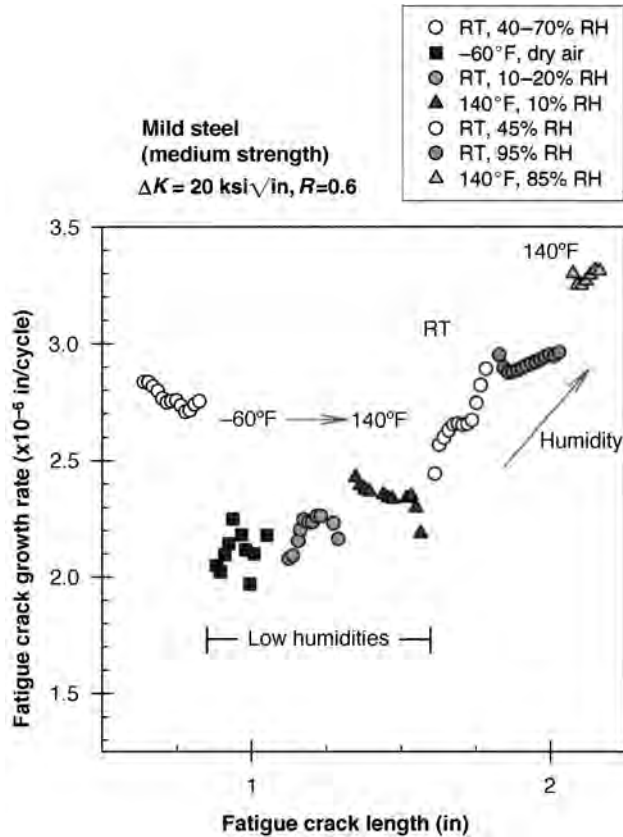

FIGURE 41.16 Influence of environment on FCG rate behavior using a constant ΔK testing approach.

used has stifled standardization, and it is only now underway within ASTM to develop a standard practice applicable to this highly complex test.

41.7 OTHER MECHANICAL TESTING

There are a number of test methods and procedures that are related to the areas described earlier but, in the spirit of brevity, have been omitted. Nevertheless, several are sufficiently popular and warrant some mention, albeit brief.

Some highly specialized assessments other than tensile tests exist for determining the strength and ductility of a metallic material. One common application for the bending strength test is the use of flat metallic materials for spring applications (ASTM E855). The two primary properties that this test provides are the modulus of elasticity in bending and the bending yield strength (proportional limit). Moreover, bend tests used to assess ductility (ASTM E190 and E290) do not provide quantitative results, but rather provide a deformed sample suitable for close visual inspection to determine basic metallic material behavior. The region of highest strain is typically inspected for possible cracking, rumples, or orange peeling as a quality control assessment suitable for the shop floor.

High strain rate testing is another area where significant effort has been expended to generate the constituent properties applicable in the high rate regime. For instance, the split Hopkinson pressure bar deforms a sample at a high strain rate ($>100\%$) while applying uniaxial stress to the sample. Similar methods have been developed that also allow high rate torsional loading. These methods have been successfully applied to a wide range of metallic materials.

Finally, numerous test techniques are also available for testing adhesion, friction, and wear of surfaces. These are critical issues from a design viewpoint with new standardized methods being developed fairly regularly.

41.8 ENVIRONMENTAL CONSIDERATIONS

It is often necessary to perform mechanical testing under environmental conditions other than ambient air. For instance, FCG testing is often performed in either dry, high humidity, or aqueous conditions. For aqueous conditions, a setup as shown in Figure 41.17 can be constructed to perform crack growth rate measurements. Sealing against a flat surface is relatively straightforward provided the materials used in the chamber are impervious to the environment contained.

Other strategies such as that shown in Figure 41.18 can be used to seal the loading pins in a compact tension specimen. This technique has proven very suitable in the past for containing aqueous environments. Clear Teflon (PTFE) bags are commercially available that allow the setup to also be subjected to temperatures in the range of -400 to 300°F . Simpler methods using supermarket polypropylene bags can also be used to contain conditioned air by introducing either desiccant or a hydrated sponge for the dry and humid conditions, respectively. Although the engineer's inclination might be to build a more elaborate environmental chamber, a simple plastic bag with duct tape seals works sufficiently well to contain dry [$<5\%$ relative humidity (RH)] and humid [$>95\%$ RH] environments.

FIGURE 41.17 Chamber around a flat panel M(T) specimen for suspending jet fuel or other aqueous environments while measuring FCG rate behavior.

FIGURE 41.18 Schematic of a compact tension specimen sealed with a plastic bag.

Finally, it is sometimes not simple to superimpose two rate-dependent processes without special attention. For instance, care must be taken to ensure that the time-dependent effects that often occur in an environment are properly applied in the materials test. As an example, the deleterious effect of seawater is gradually lost during a FCG test as the frequency exceeds 1 Hz.

If a geometry is somewhat unusual and a setup does not fit into existing furnaces, it is sometimes necessary to construct a custom furnace from insulating fiberboard so long as the temperature required is not too high. In this case, a circulating fan is included along with a heater element and an inexpensive temperature controller. However, an inexpensive approach such as the one just described will not perform well given an aggressive environment, higher pressure applications or more highly elevated temperatures. For these cases, more expensive and custom containments are typically required as shown in Figure 41.19.

Thermomechanical fatigue (TMF) differs from the fatigue testing described earlier as the temperature of the specimen is programmed to vary in a precise manner relative to the mechanical loading. The challenge with this type of testing includes (a) achieving and (b) controlling the thermal environment required. The limiting factor is not usually with

FIGURE 41.19 Several examples of enclosures for both high- and low-temperature materials testing (Photos courtesy of the Instron Corporation and MTS Corporation).

heating as induction furnaces, for instance, can heat a sample very rapidly in a uniform manner. The cycling rate is typically controlled by cooling and concerns regarding large thermal gradients exist if cooling occurs too quickly. Recent work within ASTM has generated a draft standard for TMF testing that is currently undergoing balloting.

ACKNOWLEDGMENTS

The author would like to graciously acknowledge the wisdom and lessons gained from working closely with two highly experienced colleagues and mentors at Southwest Research Institute. Jack FitzGerald taught me that often the simplest approach, the one that seemed too elementary and often at odds with engineering education, was always the best approach when faced with something unusual or unknown in the laboratory. Furthermore, Andy Nagy exhibited incredible creativity by taking half-baked, malformed ideas and transforming them into real devices that functioned flawlessly in the test laboratory. Both of these consummate professionals, now deceased, provided excellent role models and mentors for the development of an inexperienced test engineer. Finally, gratitude is extended to FTA Inc, Instron, and MTS for supplying some of the photographs used herein.

42.1 INTRODUCTION

Ceramics are being used in an ever-increasing capacity in numerous industrial and scientific applications. Advanced ceramics, in particular, have great future possibilities for use in a wide variety of applications where their unique combination of properties can achieve better results than other materials such as metals and polymers. Advanced ceramics

are typically wear and corrosion resistant, lightweight, and thermodynamically stable. In addition, many advanced ceramics have electrical properties that make them advantageous for use in electronic applications such as electronic packaging. Ceramics are finding increasing use in such areas as biomaterials, electronics, microelectromechanical systems (MEMS), and heat transfer applications such as gas turbines in the aerospace industry. The market value of advanced ceramics in the United States is estimated to increase to \$11 billion by the year 2003 from a value of \$7.5 billion in 1998 (Richerson and Associates and Energetics, Inc., 2000). Similarly, the world demand for advanced ceramics has increased from an estimated \$16.7 billion in 1994 to \$25.3 billion in the year 2000 (ISO/TC, 2000).

With the steadily increasing use of ceramics in industry, there exists an increasing demand to characterize and quantify the properties of ceramics. This leads to higher demand for improved testing techniques to yield more exact data used for endeavors such as design, safety analysis, quality control, and scientific understanding. In particular, the brittle nature of ceramics makes their fracture characteristics especially important for the engineer that needs to design ceramic components with life-cycle and safety considerations. In addition to the predominant mechanical testing being performed, there is demand for improved testing of thermal, electrical, and environmental properties as well as others.

Of equal importance to the driving forces behind ceramic testing is the value of the data being obtained from these tests. Do the potential benefits of the data outweigh the cost of performing the tests? What are the predictive abilities of the quantified test results?

To aid an engineer or a scientist who is starting their research into potential ceramic test methods, this chapter gives a brief overview of the major test methods currently being used, relative advantages and disadvantages to each other, and some common sources of error. In addition, a listing of standards that are both relevant and directly applicable to ceramics is given for various testing methods. These standards can be further investigated by the reader who wants a more in-depth look into the exact setup and requirements of a given test. Standardization is an important process in the evolution of ceramic testing to improve accuracy and precision of measured results. New standards are continuously being developed and while not all the standards listed for each test are specifically targeted for ceramics, they still have relevance in terms of improving the exactness of the test setup and results.

42.2 MECHANICAL TESTING

With the increasing role of ceramics in technology, further understanding of mechanical properties has become increasingly more important. This has resulted in the use and standardization of various test methods to better understand and quantify mechanical properties. Test methods reveal such properties as strength, fatigue, fracture resistance, creep, and slow crack growth, which contribute to design, scientific understanding, and estimations of service life among others.

42.2.1 Strength

One of the most important properties for characterizing a material is strength. Strength (yield, ultimate, etc.) is often used as a measure of success in materials development (Jenkins et al., 1998). The characterization of the fracture strength (approximately equal to

FIGURE 42.1 Schematic of tensile, flexure, and compressive setups (from Jenkins et al. (1998) by courtesy of Marcel Dekker Inc.).

ultimate strength for brittle materials) distribution is needed when ceramic design for structural applications involves failure probability as a criteria (Khandelwhal and Vaccari, 1992). Various test methods are used to determine the fracture strength of a given ceramic material. Usually, the fracture strength is equated to the maximum stress at the point of fracture, which requires that the stress distribution in the test specimen be known. A common source of error in tests measuring fracture strength is that the strength of ceramic materials is strongly influenced by the test specimen's size, geometry, and surface finish. The more common methods for measuring fracture strength include uniform uniaxial stress loading, nonuniform uniaxial stress loading, and biaxial stress loading.

Uniform uniaxial stress load testing is performed by putting a given test specimen into a state of tension or compression (Figure 42.1). Testing in a uniform, uniaxial stress field controls the stress-state variable that allows determination of the mechanical behavior at given loads. Tension and compression tests are not as common as the nonuniform flexure test because the brittle nature of many ceramics results in the need for specialized testing equipment, extensive preparation of test specimen, and an adequately uniform stress state, which can be difficult to achieve (Jenkins et al., 1998).

42.2.1.1 Tension The tensile test equipment consists of two main parts, the test specimen grip holding the actual test specimen and the interface attachment that connects the test specimen grip to the test machine. The grip should be designed to reduce any eccentricity to maintain a uniaxial stress state. Ceramics, in particular, are not able to use a threaded head as an interface because of the difficult nature of machining such a brittle material. The tapered head test specimen is also difficult to machine to proper tolerances. The button head test specimen has emerged as the most reliable interface method (Richerson and Associates and Energetics, Inc., 2000). The attachment interfacing between the test specimen grip and the test machine is usually one of two designs: flexible, self-aligning and fixed, alignable (Jenkins et al., 1998).

Ideally, the stress state will be characterized by the simple equation:

$$\sigma = \frac{P}{A}$$

where σ is the normal stress, P is the applied force, and A is the cross sectional area.

However, the actual stress state in the gauge section, σ_{gs} , will include error from eccentricity in the testing equipment and/or the test specimen and can be characterized as:

$$\sigma_{gs} = \sigma_a + \sigma_b$$

where

$$\text{axial stress, } \sigma_a = \frac{P}{A} \quad \text{and} \quad \text{bending stress, } \sigma_b = \frac{Per}{I}$$

with e being the eccentricity distance, r being the distance from the point in the gauge section at which the stress is being measured to the centroid, and I being the moment of inertia in the gauge section cross section.

Some of the tensile testing standards that apply directly to ceramics are:

Japanese Industrial Standards Committee (JISC),¹ “Testing Methods for Tensile Strength of Monolithic Advanced Ceramics at Room and Elevated Temperature,” JIS R1606-1995;

American Society for Testing and Materials (ASTM),² “Standard Test Method for Tensile Strength of Monolithic Advanced Ceramics at Ambient Temperatures,” C1273-95;

ASTM, “Standard Test Method for Tensile Strength of Monolithic Advanced Ceramics at Elevated Temperatures.” C1366-97.

The following standards are directly applicable to metals but can have applicability to ceramics:

ASTM, “Standard Test Methods for Tension Testing of Metallic Materials,” E8-96a;

ASTM, “Standard Test Methods for Elevated Temperature Tension Testing of Metallic Materials.” E21-92;

ASTM, “Standard Practice for Verification of Specimen Alignment under Tensile Loading,” E1012-93A.

42.2.1.2 Compression The compression strength of ceramic materials is usually much greater than that in tension. Consequently, tensile strength is usually the critical factor in terms of design. The compression test usually consists of two load blocks exerting a compressive force on a cylindrical test specimen. The test specimen should be uniform to avoid buckling of individual layers aligned with the applied load.

Common sources of error are size mismatches between the load block and specimen, surface irregularities, and eccentric loading as explained in the tensile testing section (Jenkins et al., 1998). The first three errors bring about excessive stresses in the ends of the test specimen, which can cause failures in the nongauge section of the test specimen. Eccentricity, as in tensile testing, reduces uniformity in the gauge section stress state.

The following standards are directly applicable to compressive testing of ceramics:

JISC, “Testing Method for Compressive Strength of High Performance Ceramics.” R1608-1990;

¹ Japan Standards Association, Tokyo, Japan.

² ASTM International, West Conshohocken, Pennsylvania, USA.

FIGURE 42.2 Three- and four-point flexure testing and resulting stress state (from Jenkins et al. (1998) by courtesy of Marcel Dekker Inc.).

ASTM, “Standard Test Method for Compressive (Crushing) Strength of Fired White-ware Materials,” C773-88.

42.2.1.3 Flexure Testing in flexure typically involves a three- or four-point loading of a test specimen as shown in Figure 42.2. Compared to tension and compression tests, flexure tests are less expensive, simpler in setup, and easier to adapt to elevated temperature testing (Jenkins et al., 1998). The applied moment, M , yields the equation for uniaxial normal stress, σ :

$$\sigma = \frac{MC}{I}$$

where the moment of inertia I is $(bh^3)/12$ (b = width and h = height) and C is the distance from the neutral axis to the outer surface of the test specimen. Given that the moment $M = P(L_o - L_i)/4$ (L_o = outer span, L_i = inner span) and $y = h/2$ we can substitute into the equation to find the fracture strength, S_f , which is the maximum tensile stress obtained at the fracture force, P_f :

$$S_f = \frac{1.5P_f(L_o - L_i)}{bh^2}$$

Various sources of internal and external errors in the testing process can affect the measured results of flexure tests. Errors classified as “internal” involve deviations from simple beam theory and involve test specimen geometry and properties (Quinn and Baratta, 1985). A test specimen with an initial curvature resulting from residual stresses generated

during machining would cause an internal error. Another example of an internal error would be excessive specimen deflection during testing. Support point frictional forces at large deflections will have a component aligned with the applied force that will increase the applied moment. "External" errors are those classified as being caused by incorrect test fixture geometry. Improper location of the inner load points is an example that causes external error. Another example is the generation of torque on the test specimen. This can be caused by an initially twisted test specimen, unparallel line loads, or nonuniform line loads at the contact points (Quinn and Baratta, 1985; Baratta, 1984). External error can also occur from compressive contact stresses at the support pins, which can result in localized crushing. This error can be reduced by using support pins above a critical radius r_c (Jenkins et al., 1998).

To minimize the errors associated with flexure testing, the test specimen and test fixtures must adhere to certain restraints and standards. Test specimen geometry has been standardized based on error considerations. A common geometry in the United States is 3 by 4 by 50 mm for the test specimen and inner and outer spans of 20 and 40 mm, respectively, for the fixtures (Quinn, 1990). The test specimen must be isotropic and homogeneous to apply the maximum tensile stress equation previously given. In addition, the specimen should be as free as possible of surface defects as the maximum tensile stress occurs on the surface.

In comparing the three- and four-point flexure test methods, it is found that the four-point method is more appropriate for determining fracture strength because no shear stresses are generated as in the three-point test method. The three-point test method with its simpler geometry, however, may be more attractive for tests in which stable crack growth must be induced into the test specimen (Jenkins et al., 1998).

Some of the flexure test standards that are applicable to advanced ceramics are listed here:

JTSC, "Testing Method for Flexural Strength (Modulus or Rupture) of Fine Ceramics," R1601-1995;

JISC, "Testing Method for Flexural Strength of Fin Ceramics at Elevated Temperature," R1604-1995;

ASTM, "Standard Test Method for Flexural Strength of Advanced Ceramics at Ambient Temperatures," C1 161-94;

ASTM, "Standard Test Method for Flexural Strength of Advanced Ceramics at Elevated Temperatures," C1211-92;

Comité Européen de Normalisation (CEN),³ "Advanced Technical Ceramics—Monolithic Ceramics—Mechanical Properties at Room Temperature—Part 1: Determination of Flexural Strength," EN843—1:1995;

CEN, "Advanced Technical Ceramics—Monolithic Ceramics—Thermomechanical Properties—Part 1: Determination of Flexural Strength at Elevated Temperature," ENV820—1:1993.

42.2.2 Creep

Similar to the fracture testing methods previously discussed, the three test methods used to determine creep characteristics in ceramics are the tensile, compressive, and flexural

³ Comité Européen de Normalisation, Brussels, Belgium.

FIGURE 42.3 Schematic of typical test setup for creep testing in flexure (from Jenkins et al. (1998) by courtesy of Marcel Dekker Inc.).

tests. The primary differences in the test fixtures are that the gauge section must be heated to the desired elevated temperature and an alternate method of measuring deflection such as extensometers must be employed because of the increased temperature. Figure 42.3 shows a typical test setup for a flexure test that utilizes extensometers.

42.2.2.1 Flexure Creep Flexure testing using four-point loading yields the maximum tensile stress of a beam in bending given in the fracture strength section:

$$S_f = \frac{1.5P_f(L_o - L_i)}{bh^2}$$

In addition, the maximum tensile strain equation is given as:

$$\varepsilon_{\max} = \frac{4h\delta_{\text{center}}}{(L_i)^2}$$

Compared to the tensile and compressive creep tests, flexure testing is less expensive, easier to design, and requires less test specimen preparation. However, the nonuniform stress state induced in the flexure testing results in difficulty in determining the creep characteristics of a material if it deforms differently in tension than in compression. This difference in tensile and compressive creep behavior is a result of cavitation among other factors. Conducting an additional test in either compression or tension allows for the determination of uniform stress-state creep characteristics from the nonuniform flexure test results. Additional errors from twisting, friction between test specimen and load points, and excessive contact stress at support points are also considerations.

42.2.2.2 Tensile Creep Tensile testing to determine creep characteristics yields a uniform stress state characterized by the equation:

$$\sigma_{\text{gs}} = \frac{P}{A}$$

The uniform stress state eliminates the problem of different deformations in tension and compression. This results in the much simpler calculation of stress and strain than with flexure testing. The test setup, however, is more expensive and difficult to implement. The test specimens required for creep tensile testing are also more difficult and time intensive to design and manufacture. In addition to stress gradients from the test specimen geometry, temperature differences induce an unwanted temperature gradient in the specimen from the grip contact portion of the specimen to the heated gauge section (Jenkins et al., 1998). This temperature gradient becomes larger and poses more of a problem when cold grips are used. Unwanted failure in the grip interface portion of the specimen can also be a problem. Various test standards are applicable to tensile testing of advanced ceramics. ASTM C1291-95 directly applies to tensile testing for creep behaviors:

ASTM, "Standard Test Method for Elevated Temperature Tensile Creep Strain, Creep Strain Rate, and Creep Time to Failure for Advanced Monolithic Ceramics," C1291-95;

ASTM, "Standard Test Method for Tensile Strength of Monolithic Advanced Ceramics at Elevated Temperatures," C1366-95;

ASTM, "Standard Test Method for Monotonic Tensile Strength Testing of Continuous Fibre-Reinforced Advanced Ceramics with Solid Rectangular Cross-Sections at Elevated Temperatures," C1359-96.

42.2.2.3 Compressive Creep Compressive testing to determine creep behavior, like tensile testing, results in a uniform stress state that allows for easy determination of creep characteristics. It has been shown that creep in compression can vary significantly from creep in tension so it is of value to conduct both tests to "get the best picture" of a material's creep properties. Some advantages to the compressive test are the low cost in preparing the material as well as the small geometry of the specimen, which allows for more testing per sample material size.

There are some drawbacks to the compressive test as well. The test specimen must be aligned to a greater accuracy than tension or flexure tests to prevent unwanted bending and buckling. End constraints on the test specimen can result in shear stresses if the specimen ends are constrained, which results in a nonuniform stress state. In addition, temperature gradients can have an adverse effect on test result accuracy.

42.2.3 Hardness

Hardness is an important property to quantify in ceramics. Measured hardness indicates the ability of the ceramic to resist deformation by a hard object. Usually, Knoop or Vickers diamond indenters are used in conjunction with a microindentation hardness machine (Quinn, 2000). Rarely are the popular Rockwell and Brinell indenters used for ceramics research. Vickers indenters are used to characterize roughly 60% of the ceramic hardness values that are published (Quinn, 2000).

The indentation force should always be included with the hardness value. For the most accurate results, the entire force versus hardness curve should be measured as shown in Figure 42.4.

FIGURE 42.4 Typical hardness versus load (force) plot (from Quinn (2000), Figure 3, p. 245).

Discrepancies can arise at different indentation forces. At higher forces, cracking can complicate the measuring process or make measuring impossible (Quinn, 2000). Measuring the hardness from the indentation, especially at small forces, is also a significant source of error in hardness testing. The hardness value can change based on the force value applied to the test specimen at small forces. Volume 8 of the *ASM Handbook* (Quinn, 2000) recommends forces greater than or equal to 9.8 N for Vickers and Knoop indentations. Errors in the measurement of the indentation diagonal length essentially double the hardness error as the hardness value is proportional to the square of the diagonal length. A Versailles Advanced Materials and Standards (VAMS) round-robin test project conducted on alumina ceramic samples resulted in uncertainty in the hardness values given by the laboratories involved (Butterfield et al., 1989). Although using numerous indentations can reduce some of this uncertainty, engineers and scientists conducting hardness tests should nevertheless keep this uncertainty in mind when considering their data.

Standards for measuring hardness for ceramics are listed below:

Vickers hardness;

ASTM, “Standard Test Method for Vickers Indentation Hardness of Advanced Ceramics,” C1427-97;

CEN, “Advanced Technical Ceramics—Monolithic Ceramics—Mechanical Properties at Room Temperature—Part 4: Determination of Vickers, Knoop and Rockwell Superficial Hardness Tests,” prEN834-4;

JISC, “Testing Method for Vickers Hardness of High Performance Ceramics,” R1610:1991.

ISO, “Fine Ceramics (Advanced Ceramics, Advanced Technical Ceramics)—Test Method for Hardness of Monolithic Ceramics at Room Temperature,” ISO 14705:2000

Knoop hardness;

ASTM, "Standard Test Method for Knoop Indentation Hardness of Advanced Ceramics," C1426-99;

CEN, "Advanced Technical Ceramics—Monolithic Ceramics—Mechanical Properties at Room Temperature—Part 4: Determination of Vickers, Knoop and Rockwell Superficial Hardness Tests," prEN834-4;

ISO, "Fine Ceramics (Advanced Ceramics, Advanced Technical Ceramics)—Test Method for Hardness of Monolithic Ceramics at Room Temperature," ISO 14705:2000;

ISO, "Glass and Glass-Ceramics—Knoop Hardness Test," ISO 9385-1990.

42.2.4 Fracture Toughness

The brittle nature of ceramics results in low resistance to fracture, quantified as fracture toughness, which is an important factor in many applications of ceramics. Fracture toughness is a measure of a specimen's ability to resist further growth of a crack. Low fracture toughness values increase the risk of catastrophic failure of a ceramic component. Ceramic matrix composites (CMCs) have better fracture toughness compared to monolithic ceramics as the additional reinforcing elements help to deter crack growth. The concepts of the linear-elastic fracture mechanics (LEFM) method commonly used for other materials can be applied to monolithic ceramics for the purpose of analysis. For ceramic matrix composites, ongoing research is being conducted regarding the application of the concepts of elastic-plastic fracture mechanics (EPFM) methods (Miller and Liaw, 2000).

There are various testing methods and setups for fracture toughness testing. Some methods included in the testing standard, ASTM C1421, are the single-edge precracked beam (SEPB) method, the surface crack in flexure (SCF) method, and the chevron notched beam (CNB) method.

The SEPB, SCF, and CNB methods all consist of a flexural test of a beam in which a short straight crack is induced into the tensile side. The primary differences are the methods by which the beam is deformed to introduce the preliminary short crack. All three methods have good calibration characteristics but have some drawbacks as well. With the SEPB method, it can be difficult to obtain straight-fronted cracks. Crack initiation in CNB testing can be difficult as a result of residual stresses from machining. SCF testing can only be performed on materials that produce high-quality cracks from the indentation (Miller and Liaw, 2000).

Standards organizations have introduced fracture toughness testing standards utilizing various testing methods. For example, ASTM C1421 generally uses a flexure test of a cracked bend bar while JIS R1607 utilizes only two test methods, SEPB and IF (indentation fracture). Standards that apply directly to fracture toughness testing of ceramics are given below.

Japanese Industrial Standards Committee, "Testing Methods for the Fracture Toughness of High Performance Ceramics," JIS R1607-1990;

American Society for Testing Materials, "Standard Test Methods for the Determination of Fracture Toughness of Advanced Ceramics at Ambient Temperature" ASTM C1421-99;

FIGURE 42.5 Test setup schematic for traditional split Hopkinson pressure bar testing (from Subhash and Ravichandran (2000), Figure 1, p. 497).

International Organization for Standardization, “Fine Ceramics (Advanced Ceramics, Advanced Technical Ceramics)—Test Method for Fracture Toughness of Monolithic Ceramics at Room Temperature by Single Edge Pre-Cracked Beam (SEPB) Method,” ISO DIS15732 (in 1999).

42.2.5 High Strain Rate

Split Hopkinson pressure bar (SHPB) testing has primarily been used in the past to measure the plastic properties of metals. The fact that ceramics are brittle and many ceramic compounds and alloys show only elastic strains before fracture makes accurate testing and measurement more difficult than with more ductile materials such as metals.

A traditional SHPB test configuration is shown in Figure 42.5 (Subhash and Ravichandran, 2000). The test setup consists of an incident bar, a transmission bar, and a striker bar. The ceramic test specimen is placed in between the incident and transmission bars as shown. The striker bar strikes the incident bar at a predetermined velocity by being launched from a gas gun. When it impacts the incident bar, it generates a compressive pulse that continues to travel to the test specimen. Part of the incident pulse travels through the test specimen, and the remaining part is reflected back into the incident bar. The stress pulses are measured by strain gauges placed at midpoints on the transmission and incident bars. An oscilloscope displays the measured pulses. The stress, strain, and strain rate equations are given as (Kolsky, 1949):

$$\sigma_s(t) = \frac{A_o E_o}{A_s} \varepsilon_T(t)$$

$$\dot{\varepsilon}_s = -\frac{2C_o}{l_s} \varepsilon_R(t)$$

$$\varepsilon_s(t) = \int_0^t \dot{\varepsilon}_s(t) dt$$

where E is Young's modulus, l is length, A is cross-sectional area, σ is stress, ε is strain, $\dot{\varepsilon}$ is strain rate, and t is time. Subscripts T , s , o , and R refer to the transmitted pulse, specimen, bar, and reflected pulse.

Some of the inherent properties of ceramics such as brittleness and high strength, conflict with assumptions that are made in deriving the stress, strain, and strain rate equations

FIGURE 42.6 Incident bar and transmission bar protection using tungsten-carbide inserts (from Subhash and Ravichandran (2000), Figure 3, p. 499).

(Subhash and Ravichandran, 2000). An example is the assumption that the bar end surfaces remain flat and parallel during the deformation of the test specimen. The hard nature of ceramics can cause the test specimen to indent into the steel bar ends, resulting in stress concentration around the test specimen end faces. These stress concentrations result in nonuniform, nonuniaxial stress state in the test specimen, which violates another assumption in using the equations, which is that the stress state is uniform and uniaxial. The stress concentrations can consequently lead to chipping and failure of the ceramic test specimen through microcrack initiation.

One way to minimize the problem of test specimen damage is to place tungsten-carbide inserts in between the test specimen and bar ends as shown in Figure 42.6 (Subhash and Ravichandran, 2000). The high strength of the inserts prevents the ceramic test specimen from indenting into the incident and transmission bars, thereby reducing stress concentrations. However, the tungsten-carbide inserts can have the adverse effect of altering the incident, transmitted, and reflected stress-wave properties that can result in inaccurate strain gauge measurements. This can be prevented by selecting tungsten-carbide inserts with the same impedance as the bar material. Selection of the diameter of the inserts can also help solve this problem. Typically, the insert lengths are one fourth of the test specimen length (Subhash and Ravichandran, 2000).

42.2.6 Fatigue

Fatigue testing is an important design tool for the designer of ceramic components where reliability and lifetime estimates need to be made. Fatigue tests for ceramics generally cover the three situations of cyclic fatigue, static fatigue, and dynamic fatigue (Breder and Wereszczak, 1998). Cyclic fatigue is the periodic loading of a component under various load ratios usually denoted as R :

$$R = \frac{\sigma_{\min}}{\sigma_{\max}}$$

Common scenarios for the stress ratio include $R > 0$ (both minimum and maximum stresses in tension or compression) and $R < 0$ (minimum stress in compression and

maximum stress in tension). The simple loading scenario would involve a sinusoidal loading that varied continuously with a minimum and maximum stress. In real-world examples, however, the loading can be much more complicated.

Static fatigue testing involves slow crack growth of a test specimen with a constant tensile force under the desired conditions. The length of time for the test specimen to fail and the applied stress are measured and used to obtain the fatigue characteristics by using various fatigue equations. Dynamic fatigue testing involves applying a constant, increasing stress (i.e., constant nonzero stress rate) to a test specimen under desired conditions. The stress rate and maximum applied stress at failure are measured and used in conjunction with various fatigue equations to determine the fatigue characteristics.

Fatigue testing can further be divided into the two categories of “direct” and “indirect.” Direct methods, also known as fracture mechanics methods, involve running tests with test specimens with previously induced cracks and directly observing crack growth. Indirect methods, also known as strength measurement techniques, involve measuring the strength of the test specimen over time intervals and using the data to estimate fatigue properties.

42.2.6.1 Indirect Methods Static loading utilizing the indirect method involves subjecting a tensile or flexure test specimen to a constant load under the desired environment conditions. The applied force stress and the amount of time for specimen failure are measured and used to estimate the fatigue properties of the ceramic material. A typical plot of failure stress versus time to failure is shown in Figure 42.7.

Uniaxial flexural tests in three- or four-point loading situations are performed under the directions given in JIS R1601, “Test Method for Flexural Strength (modulus of rupture) of Fine Ceramics.” At least three levels of stress are recommended. The fatigue strength can be related to the failure time with the following equation (Salem and Jenkins, 2000):

$$t_f = \frac{B}{\sigma_f^2} \left[\left(\frac{\sigma_i}{\sigma_f} \right)^{n-2} - 1 \right]$$

FIGURE 42.7 Failure stress versus time to failure (from Salem and Jenkins (2000)).

FIGURE 42.8 Failure stress versus stress rate (from Salem and Jenkins (2000)).

where B is a variable determined from crack geometry, fracture toughness, loading situation, and K and n , which are material and environment constants; σ_i is the inert strength at which no crack extension occurs for noncorrosive conditions.

Indirect dynamic loading usually involves tensile or flexure test specimens subjected to a constant stress rate. The applied stress rate and the failure stress are measured and used to estimate fatigue properties. Figure 42.8 shows a typical plot of failure stress versus the stress rate.

The standard, ASTM C1368, gives guidelines for fatigue strength estimating via dynamic loading. It involves four-point flexure testing of a ceramic specimen in accordance with ASTM C1161 “Standard Test Method for Flexural Strength of Advanced Ceramics at Ambient Temperature.” The fatigue strength and applied stress rate are related by the equation (Salem and Jenkins, 2000):

$$\sigma_f = [B(n+1)\sigma_i^{n-2}\dot{\sigma}]^{1/n+1}$$

where the same variable definitions apply as in the static loading equation.

There are various methods for applying periodic loads to ceramics. With bending fatigue tests, a periodic force with a specified frequency and stress ratio is applied to three- or four-point flexure test setups. Cyclic tensile fatigue tests involve cyclically loading a test specimen with a testing apparatus with specified load ratio and frequency. Various test specimen shapes can be used and tension-compression cyclic fatigue (stress ratio < 0) has been performed utilizing a button-head specimen and clamping fixture. Rotary bending is also used for fatigue testing ceramics and is especially useful for analyzing components such as shafts that undergo similar stress states while in use.

42.2.6.2 Direct Methods Direct methods, also known as fracture mechanics methods, use fatigue tests that use test specimens with an induced crack (Salem and Jenkins, 2000). Crack growth is observed directly or via strain gauges or other measuring devices.

FIGURE 42.9 Double-cantilever beam test method (from Salem and Jenkins (2000)).

One testing technique is the double-cantilever beam method, shown schematically in Figure 42.9. For the configuration shown, the stress-intensity factor and fracture toughness can be found utilizing the equation (Salem and Jenkins, 2000)

$$K_I = \frac{Pa}{h^{3/2}\sqrt{Bb}} \left(3.47 + 2.32 \frac{h}{a} \right)$$

where B is the thickness of the test specimen, b is the web thickness, a is the crack length, h is half the specimen height, and P is the applied force. Some standards that directly apply to fatigue testing of ceramics are given below.

- Japanese Industrial Standards Committee, “Test Methods for Static Bending Fatigue of Fine Ceramics,” JIS R1632—1998;
- Japanese Industrial Standards Committee, “Test Method for Flexural Strength,” JIS R1601—1995;
- American Society for Testing Materials, “Standard Test Method for Determination of Slow Crack Growth Parameters of Advanced Ceramics by Constant Stress-Rate Flexural Testing at Ambient Temperature,” ASTM C1368-99;
- American Society for Testing Materials, “Standard Test Method for Flexural Strength of Advanced Ceramics at Ambient Temperature,” ASTM C1161-99;
- Japanese Industrial Standards Committee, “Test Method for Bending Fatigue of Fine Ceramics,” JIS R1621—1996;
- American Society for Testing Materials, “Standard Test Method for Flexural Strength of Advanced Ceramics at Elevated Temperatures,” ASTM C1211-95.

42.3 THERMAL TESTING

42.3.1 Thermal Expansion

Thermal expansion is an important property that quantifies the volume change a material undergoes when it is subjected to temperature changes. Typically, materials expand when heated and contract when cooled. This characteristic is valuable to the engineer or scientist involved in ceramic design or research. The coefficient of thermal expansion (COTE),

α , is strongly related to the strength of the atomic bonds. Energy must be put into the material for the atoms to move from their equilibrium positions. Typically, ceramics, which have strong ionic or covalent bonds, have lower thermal expansion coefficients than metals. The average COTE is simply the change in the length of the material per unit length per unit temperature:

$$\alpha = \frac{\Delta L}{L_0 \Delta T}$$

The volume COTE, α_v , is the change in volume of the material for a given temperature. Consequently, for an isotropic material the volume COT is given as:

$$\alpha_v = 3\alpha$$

Thermal expansion is a tensor property that is different along individual crystallographic axes (Hammetter, 1991). This varying expansion can cause residual stresses in some test specimens that can actually cause cracks between the crystal faces in some rare situations. This thermal cycling cracking will manifest itself in the form of a hysteresis curve from expansion data during thermal cycling tests.

Typically, the COTE is lower for materials having a high melting point. The linear COTE is a more exact definition and continuously changes with regard to temperature. The COTE for materials is usually listed in handbooks as a complicated temperature-dependent function or is shown as a constant that is valid only for a specified temperature range. Taking into account, the temperature dependence of the linear COTE, experimental measuring gives the more exact equation (Hammetter, 1991)

$$\alpha(T_i) = \left(\frac{\partial L(T)}{\partial T} \right)_{T=T_i} \frac{1}{L(T)}$$

where $L(T_i)$ is the experimentally measured length of the specimen at a given temperature T_i . The difference in the linear COTE and the average COTE is shown graphically in Figure 42.10.

Understanding the thermal expansion of a given ceramic is especially important in design applications such as composites that combine structurally distinct constituents (fiber, matrix, etc.) of different materials (ceramic, metal, etc.) with different COTE. For example, a ceramic with a low COTE combined with a metal possessing a high COTE can result in critical stresses for a given temperature change.

42.3.1.1 Dilatometry The most popular method for measuring thermal expansion is dilatometry (Hammetter, 1991). The test setup is simple, consisting of a cylindrical test specimen placed between a fixed base and a movable push rod. The ceramic test specimen is heated at a fixed rate, which displaces the push rod a given distance that is recorded by a sensing device. Software is readily available to record the data and determine the temperature-dependent COTE and the average COTE record.

Dilatometers can be of the single or double push rod variety. The single push rod method involves first calibrating the test apparatus in terms of the change in length versus temperature-sensing device with a test specimen possessing a known COTE. Next, the ceramic test specimen is tested compared to the previously measured standard to determine its COTE. Calibrating the test apparatus with a standard reference specimen first in

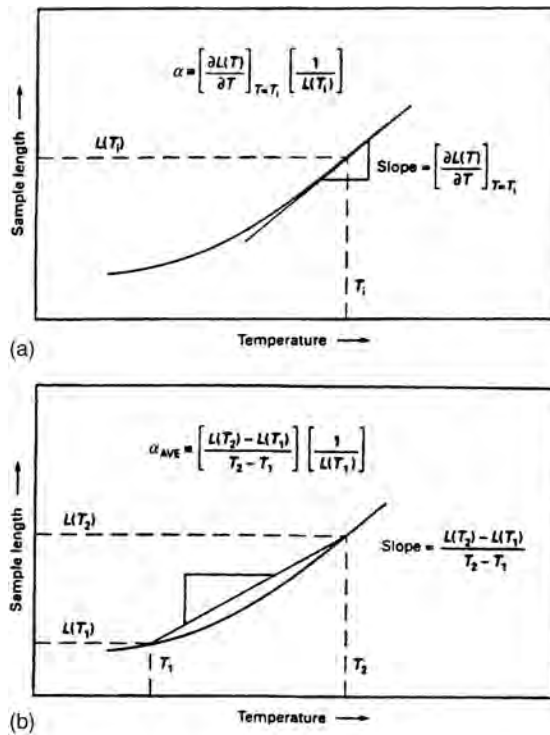

FIGURE 42.10 Difference in linear COTE and average COTE (from Hammett (1991), Figure 1, p. 612).

this manner can correct for problems such as dilatometer material expansion, thermal gradients, and nonlinearity in the heating rate (Hammett, 1991). The double push rod design tests the ceramic test specimen and the standard reference material side by side. The thermal expansion data is then calibrated by comparing it with the standard reference material with a known COTE.

42.3.1.2 Other Techniques X-ray diffraction can give insight into the structure of ceramics. The tensor components of thermal expansion can be determined with X-ray diffraction through the measuring of changes of the interplanar spacing with relation to the temperature. One distinct advantage with this method is that only a very small sample of the ceramic is required. Another advantage is that measuring the tensor components of thermal expansion of a specimen is possible with X-ray diffraction. This can be important when trying to estimate residual stresses that will occur during thermal cycling.

Interferometry is a technique that involves placing the test specimen between two reflecting surfaces and measuring the displacement through the movement of the surfaces. The basis for this being that parallel reflective surfaces a short distance apart will show interference fringes when illuminated by monochromatic light. As the reflective surfaces move apart from the specimen expansion. The interference fringes move past a reference point on one of the reflecting planes. The expansion of the sample in terms of length can

be expressed as (Hammetter, 1991):

$$\frac{\Delta L}{L} = \frac{\lambda N}{2L} + \frac{A}{L}$$

where N is the number of interference fringes that pass the reference point, L is the specimen length, ΔL is the change in the specimen length, λ is the wavelength of the light source, and A is the correction for the light source based on the atmosphere in the measuring environment. Restrictions on the test specimen geometry make this technique less popular than dilatometry methods. One advantage to this technique, however, is that ceramics with volatile components can be tested by interferometry inside a closed, heated test chamber where the volatile component's vapor pressure can be controlled.

42.3.2 Thermal Conductivity

Thermal conductivity is a measure of the rate of heat transfer in a given material by conduction. The heat flowrate through a material is proportional to the heated area of the material and the temperature gradient across the specimen. This proportionality yields the coefficient of thermal conductivity, κ , which is shown in the following equation (Hammetter, 1991):

$$\frac{dQ}{dt} = -\kappa A \frac{dT}{dx}$$

The negative sign on the right side indicates that heat flows from a higher to a lower temperature. The rate of heat flow is dQ/dt , A is the cross-sectional area of the material, and dT/dx is the temperature gradient.

Two important mechanisms involved in transferring thermal energy are lattice vibrations (or phonons) and transfer of free electrons. Valence electrons travel from hot to cold areas with the energy gained, and then transfer their energy to other atoms. Many electrons in ceramics cannot be excited into the conduction band except at quite high temperatures because the energy gap is typically too large (Hammetter, 1991). Consequently, heat transfer in ceramics is primarily a result of lattice vibrations. This results in ceramics typically having a much lower thermal conductivity than metals. However, not all ceramics have low thermal conductivity. Advanced ceramics such as AlN and SiC have good thermal conductivity and low electrical conductivity. Consequently, they are good for electronic applications where dissipating heat is a requirement. Thermal conductivity is an important aspect of materials for microelectronic substrates and electronic packaging materials. The development of higher density circuits makes heat dissipation an increasingly difficult problem to overcome.

42.3.2.1 Guarded Hot Plate The guarded hot plate technique is a comparative method that measures thermal conductivity through the application of thermocouples to a cylindrical ceramic test specimen sandwiched between two cylindrical sections of a reference material with the same diameter and with a known thermal conductivity. The test setup is shown in Figure 42.11. Thermally conductive paste is applied to the mating surfaces to ensure adequate heat transfer between materials. Using a reference material with a thermal conductivity similar to that of the ceramic test specimen will

FIGURE 42.11 Guarded hot plate test setup (from Hammett (1991), Figure 2, p. 613).

yield the best results. Stack heaters at the top and bottom of the cylinder stack introduce heat into the materials. The thermocouples are positioned near the mating surfaces on the reference and test cylinders. The thermocouples determine the temperature gradient and then the steady-state heat flux is established between the stack heaters. Using the thermal conductivity of the reference material and the measured temperature gradients in the two test specimen cylinders sandwiching the reference cylinder, the heat flux through the entire stack can be calculated using the thermal expansion equation previously given. These two independent calculations of heat flux through the stack are then averaged, and the average is used as the heat flux value for the ceramic test specimen. In addition, the difference in the two calculated values give the heat loss value for the stack. The coefficient of thermal conductivity, κ , can then be determined because the average heat flux through the stack, the area of the test specimen cylinder, and the measured temperature gradient along the ceramic test specimen's length are all already known. To eliminate convective heat losses, measurements can be made in a vacuum or reduced atmosphere environment.

42.3.2.2 Laser Flash Method Another method for determining thermal conductivity is the laser flash method, which involves quickly heating a thin ceramic specimen on one side via a quick “thermal pulse” from a laser and then using the measured temperature values over time of the back face of the specimen to calculate thermal diffusivity and conductivity. Thermal diffusivity, α , is a different means of expressing a material's heat conduction properties. Thermal diffusivity takes into account that heat can diffuse through a material subject to different boundary conditions, causing both spatial

FIGURE 42.12 Schematic of laser flash method test setup (from Hammetter (1991), Figure 3, p. 614).

and temporal variations of temperature (Hammetter, 1991). Thermal diffusivity is a temperature-dependent material tensor property that is defined by the equation

$$\frac{dT}{dt} = \alpha_{ij}(T) \nabla^2 T$$

The relationship between thermal diffusivity and thermal conductivity is given by the equation

$$\alpha_{ij}(T) = \frac{k_{ij}(T)}{\rho(T)c_p(T)}$$

where $\rho(T)$ is the temperature-dependent density and $c_p(T)$ is the specific heat capacity of the test specimen.

The ceramic test specimen is in the shape of a thin disk and is at a constant temperature T , when the laser flash exerts a thermal pulse on the front face. Figure 42.12 shows a schematic of the test setup.

The assumptions here are that the thermal energy is deposited uniformly over the front face of the test specimen, that the heat travels along the thickness of the specimen only to the back face, and that the pulse heats the sample only (Hammetter, 1991). Then, knowing the temperature of the back face at times after the pulse is introduced into the test specimen, the thermal diffusivity of the test specimen can be calculated using various algorithms. Different available algorithms use various temperatures of the back face to calculate thermal diffusivity.

An advantage of the laser flash method is that, in addition to having a simple test setup, it can be used over a large range of thermal conductivities and ceramic specimen temperatures. Also, it is quite popular for measuring thermal conductivities at high temperatures as maintaining a steady-state condition is difficult at higher temperatures.

Other thermal pulse methods using different sources such as electron beams or quartz flash lamps are also possible utilizing very similar test procedures.

42.3.3 Heat Capacity

Heat capacity is a property that refers to the amount of energy that must be added or subtracted from a material to raise or lower its temperature. The amount of energy required to raise the temperature of a material by a degree varies from material to material based on its properties. Specific heat at a constant pressure, c_p , is the most common

expression of a material's heat capacity and is defined as the amount of heat needed to raise the temperature of one gram of a substance by one kelvin at a constant pressure. The specific heat is derived from the enthalpy, H , and this relation is shown in the following equation:

$$c_p \left(\frac{\partial H}{\partial T} \right)_p$$

where T is the temperature and the subscript p indicates constant pressure. From this equation, we can see that the specific heat is the slope of the enthalpy versus temperature change. The specific heat value can be considered a constant for a short range of temperature, but the actual measured specific heat term is expressed as a polynomial to express the nonlinearity of the specific heat with the temperature. This more defined specific heat capacity and its form are given in the equation

$$C_p(T) = a + bT + cT^2 - dT^{-2} + eT^{-1/2}$$

However, the form of equation above does not provide a specific heat for all temperature ranges of many materials. Various equations of this form must be determined for various temperature ranges. There are various methods for determining the heat capacity of ceramics.

42.3.3.1 Calorimetry Calorimetry can be used to determine the heat capacity of a ceramic material. A specific amount of a material test specimen is heated to an initial temperature with an external furnace and then deposited into a calorimeter of a lower temperature. The calorimeter measures the heat energy that the test specimen gives off while cooling to the equilibrium temperature that is between the specimen and calorimeter temperature. Measurements of the enthalpy, H , at various temperatures gives a plot of $H(T)$ versus T . Consequently, the specific heat, c_p , can be calculated from this data.

An advantage of calorimetry is that it can calculate specific heats over a wide temperature range. A drawback, however, is that the method is insensitive to transitions with minor changes in enthalpy (Hammetter, 1991).

42.3.3.2 Differential Scanning Calorimetry Differential scanning calorimetry is the most popular method for measuring the specific heat of a ceramic. This type of calorimeter measures the heat flowrate to a ceramic test specimen while it is heated at a given constant rate. A computer monitors the temperature of the test specimen and makes adjustments to keep the temperature of the ceramic test specimen increasing at a constant rate. Consequently, the specific heat, c_p , of a ceramic test specimen of known mass m can be calculated from the following equation (Hammetter, 1991):

$$\frac{dH(T)}{dt} = mc_p(T) \frac{dT}{dt}$$

This method is commonly used and there are various commercial differential scanning calorimeters available. One of the major drawbacks to this technique is that commercial setups can only be used up to a temperature of about 800°C (Hammetter, 1991). In addition, testing errors resulting from thermal resistance between the test specimen and heat

flow sensing device and other sources requires the use of a comparative process when testing. A different material with a known heat capacity is tested under the same conditions and any difference is noted and incorporated into the error evaluation of the ceramic test specimen being investigated.

42.4 NONDESTRUCTIVE EVALUATION TESTING

Many nondestructive evaluation (NDE) testing techniques are commonly used for evaluating metals and other materials. Applying these techniques, however, to ceramics does not always provide adequate results because of the unique nature of ceramics that impede many of the typical testing techniques. The increasing use of advanced ceramic materials in critical applications along with properties that make them sensitive to quite small defects increases the need to define NDE testing methods directly applicable to ceramics.

Advanced ceramics are typically brittle in nature. Defects as small as 10 μm can be critically detrimental and must be avoided. They can be prevented with careful process control of the fabrication of the ceramic materials from fine powders or with careful inspection of the finished ceramic parts. Both strategies can be applied with NDE testing as a major component.

42.4.1 Ultrasonography

Ultrasonic testing is a common NDE testing technique that can detect and describe flaws and material conditions that other methods are unable to do. Ultrasonic waves are propagated through the material and the waves are disrupted at the discontinuities in the material such as defects, voids, or cracks. The waves are scattered or partially reflected at these discontinuities and from this action, a measure of the discontinuity characteristics such as location, size, and shape are revealed. The ultrasonic method does not always reveal everything about the discontinuity to the degree desired but is still an invaluable tool.

The distinguishing characteristic of ceramics that make typical ultrasonic testing techniques less successful are the high ultrasonic velocities and the smaller critical defect size that must be detected. To detect and characterize small defects, the equipment must be modified so that the ultrasonic wave frequency is increased. An ultrasonic wave with a wavelength of similar size to the defect is required to detect the defect. Consequently, with a ceramic material where a critical defect can be a very small value such as 10 μm , a wavelength of approximately the same size is needed (Lott and Kunerth, 1991). This indicates a very high frequency, f , is required based on the frequency equation

$$f = \frac{v}{\lambda}$$

where λ is the wavelength and v is the longitudinal wave velocity.

An important property to be discerned in a ceramic material is its bulk porosity. Ultrasonic testing can reveal the material's bulk porosity even though the individual pore size is much smaller than the investigating wavelength. The porosity can be characterized by measuring the ultrasonic velocity and attenuation. Measuring the ultrasonic velocity typically entails using a transducer to a face of a ceramic specimen with parallel faces and a known thickness. The round-trip travel time of the acoustic pulse is measured with the

transducer in a pulse-echo mode. The ultrasonic velocity v is given by the equation

$$v = \frac{2d}{t}$$

where d is the thickness of the test specimen and t is the time for round-trip travel. It has been found that there is a linear relationship between ultrasonic velocity and porosity. Once the ultrasonic velocity has been measured, the variations in porosity in a specimen can be shown with the aid of ultrasonic C-scans.

Ultrasonic attenuation is the process by which the ultrasonic beam, when propagating through the test specimen, loses energy. Grain boundaries, pores, voids, and other internal defects cause scattering of the waves, resulting in a lower energy beam. This attenuation in the ultrasonic beam is expressed by the equation

$$I = I_0 \exp(-\alpha x)$$

where I is the beam intensity, x is the distance into the test specimen ($x = 0$ at surface), and α is the ultrasonic attenuation coefficient of the material. Once the attenuation of a material is characterized, various imaging equipment can map the amplitude image of a specimen, which visually describes the porosity of a test specimen.

A standard that applies directly to ultrasonic testing is ASTM E494, "Standard Practice for Measuring Ultrasonic Velocity in Materials."

42.4.2 Radiography

Radiography uses radiation to characterize a material's structure by examining the interaction between the electromagnetic wave and the material itself. The detection of voids, cracks, pores, and other defects is the primary goal of this technique. The detection of these defects is a result of the attenuation and scatter of the radiation as it passes through the material. Various radiation sources can be used in the application of radiography but the most versatile has been found to be X-ray sources. There are two common methods for using X-ray sources to discover discontinuities and defects in a material's structure. One method is to create a two-dimensional image of the test specimen or component where the variation of the image intensity indicates the degree of attenuation. Another approach is to use many attenuation image "slices" and an algorithm to develop a three-dimensional image.

X-ray microradiography techniques use a divergent X-ray beam to produce a two-dimensional image of the test specimen or component being investigated. High contrast and clarity are required when trying to detect the inherently small defects in most ceramics. One common method of applying X-ray microradiography is using a contact method where the test specimen or component being studied contacts an imaging medium, which results in a high-resolution image. Another method uses X-ray sources that are typically less than 100 μm , which allows direct magnification of the component or test specimen image (Lott and Kunerth, 1991). The ability of these methods to detect defects is dependent on the degree of contrast and resolution that is obtained in the image. One disadvantage to this two-dimensional technique is that cracks and other linear defects orientated transverse to the beam direction will be much more difficult to detect.

X-ray computed tomography utilizes many two-dimensional "slice" images of the X-ray attenuation to form a three-dimensional representation of the object being

investigated. This is especially useful when trying to discover defects and discontinuities in a complex three-dimensional component. It is used primarily as a research tool and a few of the main drawbacks to the technique are its high cost and complexity.

42.5 ELECTRICAL TESTING

Ceramic materials have important functions in various electrical and electronic applications. Ceramics, with their unique properties, provide capacitive, insulative, conductive, resistive, and other functions in electronic circuitry. An example of the important role ceramics have in electronics is the use of advanced ceramics such as alumina oxide (Al_2O_3) as the substrate material in electronic packaging. Increases in circuit density have consequently resulted in more stringent requirements being placed on substrate materials. A substrate is desired that has thermal expansion characteristics that closely match with silicon to prevent critical thermal stresses. A low dielectric constant is also needed to improve signal processing. In addition, thermal conductivity is a high priority to dissipate heat from the high-density circuit. Based on stringent requirements such as these, the development of new advanced ceramics and subsequent testing to quantify the development and selection of ceramic materials for important electrical/electronic applications is of increasing importance. Directly adapting current electrical testing techniques to ceramics serves to improve the process of ceramic integration into electronics and other electrical applications.

42.5.1 Electrical Resistance at Elevated Temperatures

An important aspect of ceramic use in electronic applications is the variation of electrical resistance as the temperature rises. With the trend toward higher and higher density circuits, characterizing substrate and other chip component properties at elevated temperatures is quite important.

Measuring electrical resistance at high temperature involves applying a voltage across a test specimen contained in a heating furnace. A ceramic test specimen is mounted between the electrodes in the furnace that has heated the test specimen to the desired temperature. A voltage of 500 V DC is applied across the test specimen for one minute and the volume resistance is measured. The process is repeated for various temperatures until maximum test temperature is reached. The volume resistivity, ρ , is then calculated from the following equation:

$$\rho = \frac{A}{h} R_v$$

where R_v is the measure volume resistance, A is the area of the electrode, and h is the average thickness of the ceramic specimen in the area covered by the electrode. Further specifics are given in ASTM D1829-90, "Electrical Resistance of Ceramic Materials at Elevated Temperatures."

42.5.2 Flexural Strength of Electronic-Grade Ceramics

Another important test for characterizing electronic ceramic components is the flexural strength test. Flexural strength testing is already standardized, but application to

electronic-grade ceramics requires slight modification. The testing sample sizes are much smaller and commonly referred to as “microbars.” Changes in the size of the bending test fixtures, load application, and material preparation are also required. The specifics are outlined in ASTM F417-78, “Standard Test Method for Flexural Strength of Electronic-Grade Ceramics.” The flexural strength is still calculated using the standard equation:

$$S = \frac{3PL}{2bd^2}$$

where S is the flexural strength, P is the force at fracture, L is the distance between supports, and b and d are the width and thickness, respectively, of the specimen.

42.6 SUMMARY

Testing of ceramics has been standardized or formalized for mechanical, thermal, NAE, and electrical aspects of these brittle materials. Although testing for many properties and performance related to these aspects is accepted, methodologies for material selection and design with brittle materials are still being developed. As these methodologies mature and become widely accepted, additional test methods related to the required properties and performance will be proposed, developed, and approved.

43.1 INTRODUCTION

First commercial plastic material known as Bakelite was developed by Dr. Baekeland in 1909. To commercialize this new product it was necessary to test and develop property data. This was the beginning of the plastics testing technology. Initially the methods developed for testing metals and other traditional materials were employed for testing plastic materials. In very short time the scientist realized that the fundamental differences between the polymeric materials and other traditional materials would necessitate developing slightly different and unique test methodology for plastics. For example, metals usually display unchanged mechanical behavior up to their recrystallization temperature of greater than 300°C. For most applications designers can disregard the effect of temperature, environmental, and long term effects of load. They can rely on instantaneous stress strain properties. Such is not the case with plastics. Plastics are viscoelastic. Viscoelasticity is defined as the tendency of plastics to respond to stress as if they are combination of elastic solids and viscous fluids. This property possessed by all plastics to some degree, dictates that while plastics have solid-like characteristics such as elasticity, strength, and form stability, they also have liquid-like characteristics such as flow depending on time, temperature, rate, and amount of loading. This also means that unlike metals, ceramics and other traditional materials, plastics do not exhibit a linear stress–strain relationship. Plastics are sensitive to change in temperature rate of loading environment etc. Over the years ASTM (American Society for Testing and Materials) has done an excellent job in developing and providing the plastics industry with standard testing procedures. ASTM Committee D20 on Plastics was formed in 1937. The committee oversees the development of test methods, specifications, recommended practices, nomenclature, definitions, and the stimulation of research relating to plastics, their raw materials, components, and compounding ingredients, and to finished products made from plastics. These standards have and continue to play a preeminent role in all aspects important to the effective utilization of plastics, including specimen preparation, material specifications, and methodologies for mechanical, thermal, optical, and analytical testing.

43.2 MECHANICAL PROPERTIES

The mechanical properties, among all the properties of plastic materials, are often the most important properties because virtually all service conditions and the majority of end-use applications involve some degree of mechanical loading. Nevertheless, these properties are the least understood by most design engineers. The material selection for a variety of applications is quite often based on mechanical properties such as tensile strength, modulus, elongation, and impact strength. These values are normally derived from the technical literature provided by material suppliers. More often than not, much emphasis is placed on comparing the published values of different types and grades of plastics and not enough on determining the true meaning of the mechanical properties and their relation to end-use requirements. In practical applications, plastics are seldom, if ever, subjected to a single, steady deformation without the presence of other adverse factors such as environment and temperature. Since the published values of the mechanical properties of plastics are generated from tests conducted in a laboratory under standard test conditions, the danger of selecting and specifying a material from these values is obvious. A thorough understanding of mechanical properties, tests employed to determine such properties, and the effect of adverse conditions on mechanical properties over a long period is extremely important.

43.2.1 Tensile Tests (ASTM D 638, ISO 527-1)

Tensile elongation and tensile modulus measurements are among the most important indications of strength in a material and are the most widely specified properties of plastic materials. Tensile test, in a broad sense, is a measurement of the ability of a material to withstand forces that tend to pull it apart, and to determine to what extent the material stretches before breaking. Tensile modulus, an indication of the relative stiffness of a material, can be determined from a stress–strain diagram. Different types of plastic materials are often compared on the basis of tensile strength, elongation, and tensile modulus data. Many plastics are very sensitive to the rate of straining and environmental conditions. Therefore, the data obtained by this method cannot be considered valid for applications involving load-time scales or environments widely different from this method. The tensile property data are more useful in preferential selection of a particular type of plastic from a large group of plastic materials and such data are of limited use in actual design of the product. This is because the test does not take into account the time-dependent behavior of plastic materials.

The tensile testing machine of a constant-rate-of-crosshead movement is used. It has a fixed or essentially stationary member, carrying one grip and a movable member carrying a second grip. Self-aligning grips employed for holding the test specimen between the fixed member and the movable member prevents alignment problems. A controlled velocity drive mechanism is used. Some of the commercially available machines use a closed loop servo-controlled drive mechanism to provide a high degree of speed accuracy. A load-indicating mechanism capable of indicating total tensile load with an accuracy of $\pm 1\%$ of the indicated value or better is used. An extension indicator, commonly known as the extensometer, is used to determine the distance between the two designated points located within the gauge length of the test specimen as the specimen is stretched. Figure 43.1 shows a commercially available tensile testing machine. The advent of new microprocessor technology has virtually eliminated time-consuming manual calculations. Stress, elongation, modulus, energy, and statistical calculations are performed automatically and presented on a visual display or hard copy printout at the end of the test.

43.2.2 Flexural Properties (ASTM D 790, ISO 178)

The stress–strain behavior of polymers in flexure is of interest to a designer as well as a polymer manufacturer. Flexural strength is the ability of the material to withstand bending forces applied perpendicular to its longitudinal axis. The stresses induced due to the flexural load are a combination of compressive and tensile stresses. This effect is illustrated in Figure 43.2. Flexural properties are reported and calculated in terms of the maximum stress and strain that occur at the outside surface of the test bar. Many polymers do not break under flexure even after a large deflection that makes determination of the ultimate flexural strength impractical for many polymers. In such cases, the common practice is to report flexural yield strength when the maximum strain in the outer fiber of the specimen has reached 5%. For polymeric materials that break easily under flexural load, the specimen is deflected until a rupture occurs in the outer fibers.

There are several advantages of flexural strength tests over tensile tests. If a material is used in the form of a beam and if the service failure occurs in bending, then a flexural test is more relevant for design or specification purposes than a tensile test, which may give a strength value very different from the calculated strength of the outer fiber in the bent

FIGURE 43.1 Tensile testing machine (Courtesy Instron Corporation).

beam. The flexural specimen is comparatively easy to prepare without residual strain. The specimen alignment is also more difficult in tensile tests. Also, the tight clamping of the test specimens creates stress concentration points. One other advantage of the flexural test is that at small strains, the actual deformations are sufficiently large to be measured accurately.

There are two basic methods that cover the determination of flexural properties of plastics. Method 1 is a three-point loading system utilizing center loading on a simple supported beam. A bar of rectangular cross section rests on two supports and is loaded by means of a loading nose midway between the supports. The maximum axial fiber stresses

FIGURE 43.2 Forces involved in bending a simple beam (Reprinted by permission of McGraw-Hill Company).

occur on a line under the loading nose. A close-up of a specimen in the testing apparatus is shown in Figure 43.3. This method is especially useful in determining flexural properties for quality control and specification purposes.

Method 2 is a four-point loading system utilizing two load points equally spaced from their adjacent support points, with a distance between load points of one-third of the support span. In this method, the test bar rests on two supports and is loaded at two points (by means of two loading noses), each on equal distance from the adjacent support point. Method 2 is very useful in testing materials that do not fail at the point of maximum stress under a three-point loading system. The maximum axial fiber stress occurs over the area between the loading noses.

Either method can be used with the two procedures. Procedure A is designed principally for materials that break at comparatively small deflections. Procedure B is designed particularly for those materials that undergo large deflections during testing. The basic difference between the two procedures is the strain rate, Procedure A being 0.01 in./in./min, and Procedure B being 0.10 in./in./min.

43.2.2.1 Modulus of Elasticity (Flexural Modulus) The flexural modulus is a measure of the stiffness during the first or initial part of the bending process. This value of the flexural modulus is, in many cases, equal to the tensile modulus.

The flexural modulus is represented by the slope of the initial straight-line portion of the stress-strain curve and is calculated by dividing the change in stress by the corresponding change in strain.

FIGURE 43.3 Close-up of a specimen shown in flexural testing apparatus (Courtesy DuPont Company).

43.2.3 Creep Properties

Today, plastics are used in applications that demand high performance and extreme reliability. Many components, conventionally made in metals, are now made in plastics. The pressure is put on the design engineer to design the plastic products more efficiently. An increasing number of designers have now recognized the importance of thoroughly understanding the behavior of plastics under long-term load and varying temperatures. Such behavior is described in terms of creep properties.

When a plastic material is subjected to a constant load, it deforms quickly to a strain roughly predicted by its stress–strain modulus, and then continues to deform slowly with time indefinitely or until rupture or yielding causes failure. This phenomenon of deformation under load with time is called creep. All plastics creep to a certain extent. The degree of creep depends upon several factors, such as type of plastic, amount of load, temperature, and time.

The short-term stress–strain data is of little practical value in actual designing the part, since such data does not take into account the effect of long-term loading on plastics. Creep behavior varies considerably among types of plastics; however, under proper stress and temperature conditions, all plastics will exhibit a characteristic type of creep behavior. One such generalized creep curve is shown in Figure 43.4. The total creep curve is divided into four continuous stages. The first stage (OP) represents the instantaneous elastic deformation. This initial strain is the sum of the elastic and plastic strain. The first stage is followed by the second stage (PQ) in which strain occurs rapidly but at a decreasing rate. This stage, where creep rate decreases with time, is sometimes referred to as creep or primary creep. The straight portion of the curve (QR) is characterized by a constant rate of creep. This process is called “cold flow.” The final stage (RS) is marked by increase in creep rate until the creep fracture occurs.

If the applied load is released before the creep rupture occurs, an immediate elastic recovery, substantially equal to elastic deformation followed by a period of slow recovery is observed. The material in most cases does not recover to the original shape and permanent set remains. The magnitude of the permanent set depends upon length of time, amount of stress applied, and temperature.

The creep values are obtained by applying constant load to the test specimen in tension, compression, or flexure, and measuring the deformation as a function of time. The values are most commonly referred to as tensile creep, compressive creep, and flexural creep.

43.2.3.1 Tensile Creep Tensile creep measurements are made by applying the constant load to a tensile test specimen and measuring its extension as a function of time. The extension measurement can be carried out several different ways. The simplest way is to make two gauge marks on the tensile specimen and measure the distance between the marks at specified time intervals. The percent creep strain is determined by dividing the extension by initial gauge length and multiplying by 100. The percent creep strain is plotted against time to obtain a tensile creep curve. The tensile stress values are also determined at specified time intervals to facilitate plotting a stress–rupture curve. The more accurate measurements require the use of a strain gauge, which is capable of measuring and amplifying small changes in length with time and directly plotting them on a chart paper. Figure 43.5 illustrates a typical setup for tensile creep testing. The test is also carried out at different stress levels and temperatures to study their effect on tensile creep properties.

FIGURE 43.4 Generalized creep curve.

FIGURE 43.5 Typical test setup for tensile creep testing (Courtesy Applied Test Systems Inc.).

FIGURE 43.6 Flexural creep testing (Courtesy Ceast U.S.A. Inc.).

43.2.3.2 Flexural Creep Flexural creep measurements are also made by applying a constant load to the standard flexural test specimen and measuring its deflection as a function of time. A typical test setup for measuring creep in flexure is shown in Figure 43.6. As illustrated, the deflection of the specimen at mid-span is measured using a dial indicator gauge. The electrical resistance gauges may also be used in place of a dial indicator. The deflections of the specimen are measured at a predetermined time interval.

43.2.4 Stress Relaxation

Stress relaxation is defined as a gradual decrease in stress with time, under a constant deformation (strain). This characteristic behavior of the polymers is studied by applying a fixed amount of deformation to a specimen and measuring the load required to maintain it as a function of time. This is in contrast to creep measurement, where a fixed amount of load is applied to a specimen and resulting deformation is measured as a function of time.

Stress relaxation behavior of the polymers has been overlooked by many design engineers and researchers, partly because the creep data is much easier to obtain and is readily available. However, many practical applications dictate the use of stress relaxation data. For example, extremely low stress relaxation is desired in the case of a threaded bottle closure, which may be under constant strain for a long period. If the plastic material used in the closures shows an excessive decrease in stress under this constant deformation, the closures will eventually fail. Similar problems can be encountered with metal inserts in molded plastics, Belleville or multiple cantilever springs used in cameras, appliances, and business machines.

Stress relaxation measurements can be carried out using a tensile testing machine such as that described earlier in this chapter. However, the use of such a machine is not always

FIGURE 43.7 Stress–time curve (Courtesy Instron Corporation).

practical because the stress relaxation test ties up the machine for a long period of time. The equipment for a stress relaxation test must be capable of measuring very small elongation accurately, even when applied at high speeds. Many sophisticated pieces of equipment now employ a strain gauge or a differential transformer along with a chart recorder capable of plotting stress as a function of time. A typical stress–time curve is schematically plotted in Figure 43.7. At the beginning of the experiment, the strain is applied to the specimen at a constant rate to achieve the desired elongation. Once the specimen reaches the desired elongation, the strain is held constant for a predetermined amount of time. The stress decay, which occurs due to stress relaxation, is observed as a function of time. If a chart recorder is not available, the stress values at different time intervals are recorded and the results are plotted to obtain a stress versus time curve. The stress relaxation experiment is often carried out at various levels of temperature and strain.

The stress data obtained from the stress relaxation experiment can be converted to a more meaningful apparent modulus data by simply dividing stress at a particular time by the applied strain. The curve may be re-plotted to represent apparent modulus as a function of time. The use of logarithmic coordinates further simplifies the stress relaxation data by allowing us to use standard extrapolation methods such as the one used in creep experiments.

43.2.5 Impact Properties

The impact properties of the polymeric materials are directly related to the overall toughness of the material. Toughness is defined as the ability of the polymer to absorb applied energy. The area under the stress–strain curve is directly proportional to the toughness of a material. Impact strength is a measure of toughness. The higher the impact strength of a material, the higher the toughness and vice versa. Impact resistance is the ability of a material to resist breaking under a shock loading or the ability to resist the fracture under stress applied at high speed.

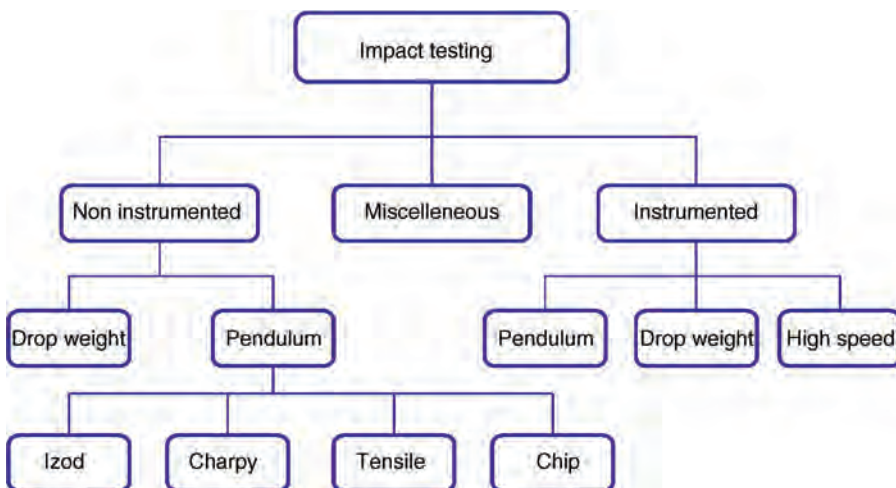

The theory behind toughness and brittleness of the polymers is very complex and therefore difficult to understand. The molecular flexibility plays an important role in determining the relative brittleness or toughness of the material. For example, in stiff polymers like

polystyrene and acrylics, the molecular segments are unable to disentangle and respond to the rapid application of mechanical stress and the impact produces brittle failure. In contrast, flexible polymer such as plasticized PVC has high-impact strength due to the ability of the large segments of molecules to disentangle and respond rapidly to mechanical stress.

Most polymers, when subjected to the impact loading, seem to fracture in a characteristic fashion. The crack is initiated on a polymer surface due to the impact loading. The energy to initiate such a crack is called the crack initiation energy. If the load exceeds the crack initiation energy, the crack continues to propagate. A complete failure occurs when the load has exceeded the crack propagation energy. Thus, both crack initiation and crack propagation contribute to the measured impact strength.

Impact strength is one of the most widely specified mechanical properties of the polymeric materials. However, it is also one of the least understood properties. Predicting the impact resistance of plastics still remains one of the most troublesome areas of product design. One of the problems with some earlier Izod and Charpy impact tests was that the tests were adopted by the plastic industry from metallurgists. The principles of impact mechanisms as applied to metals do not seem to work satisfactorily with plastics because of the plastics' complex structure.

43.2.5.1 Types of Impact Tests In the last two decades, a tremendous amount of time and money have been spent on research and development of various types of impact tests by organizations throughout the world. Attempts have been made to develop different sizes and shapes of specimens as well as impact testers. The specimens have been subjected to a variety of impact loads including tensile, compression, bending, and torsion impacts. Impact load has been applied using everything from a hammer, punches, and pendulums to falling balls and bullets. Unfortunately, very little correlation exists, if any, between the types of tests developed so far. Numerous technical papers and articles have been written on the subject of the advantages of one method over the other. To this date, no industry-wide consensus exists regarding an ideal impact test method. In this chapter, an attempt is made to discuss as many types of impact tests as possible along with the respective advantages and limitations of each test. Impact testing is divided into three major classes and subdivided into several classes as follows:

43.2.6 Izod–Charpy Impact Test (ASTM D-256, ISO 179)

The objective of the Izod–Charpy impact test is to measure the relative susceptibility of a standard test specimen to the pendulum-type impact load. The results are expressed in terms of kinetic energy consumed by the pendulum in order to break the specimen. The energy required to break a standard specimen is actually the sum of energies needed to deform it, to initiate its fracture, and to propagate the fracture across it, and the energy expended in tossing the broken ends of the specimen. This is called the “toss factor.” The energy lost through the friction and vibration of the apparatus is minimal for all practical purposes and usually neglected.

The specimen used in both tests is usually notched. The reason for notching the specimen is to provide a stress concentration area that promotes a brittle rather than a ductile failure. A plastic deformation is prevented by such type of notch in the specimen. The impact values are seriously affected because of the notch sensitivity of certain types of plastic materials. Figure 43.8 illustrates a typical pendulum-type impact testing machine.

FIGURE 43.8 Pendulum impact tester (Courtesy Ceast U.S.A. Inc.).

The Izod test requires a specimen to be clamped vertically as a cantilever beam. The specimen is struck by a swing of a pendulum released from a fixed distance from the specimen clamp. A similar setup is used for the Charpy test except for the positioning of the specimen. In the Charpy method, the specimen is supported horizontally as a simple beam and fractured by a blow delivered in the middle by the pendulum. The obvious advantage of the Charpy test over the Izod test is that the specimen does not have to be clamped and, therefore, it is free of variations in clamping pressures.

43.2.6.1 Izod Impact Test The test specimen is clamped into position so that the notched end of the specimen is facing the striking edge of the pendulum. The pendulum hammer is released, allowed to strike the specimen, and swing through. If the specimen does not break, more weights are attached to the hammer and the test is repeated until failure is observed. The impact values are read directly in inch pound-force or feet pound-force from the scale. The impact strength is calculated by dividing the impact values obtained from the scale by the thickness of the specimen. For example, if a reading of 2 ft lbf is obtained using a 1/8 in. thick specimen, the impact value would be 16 ft lbf/in. of notch. The impact values are always calculated on the basis of 1 in. thick specimens even though much thinner specimens are usually used. The unnotched impact strength is obtained by reversing the position of a notched specimen in the vise. In this case, the notch is subjected to compressive rather than tensile stresses during impact. As discussed earlier in this chapter, the energy required to break a specimen is the sum of the energies needed to deform it, initiate and propagate the fracture, and toss the broken end (toss factor).

43.2.6.2 Falling-Weight Impact Test The falling-weight impact test, also known as the drop impact test or the variable-height impact test, employs a falling weight. This falling weight may be a tup with a conical nose, a ball, or a ball-end dart. The energy required to fail the specimen is measured by dropping a known weight from a known height onto a test specimen. The impact energy is normally expressed in feet pound-force and is calculated by multiplying the weight of the projectile by the drop height.

The biggest advantage of the falling-weight impact test over the pendulum impact test or high-rate tension test is its ability to duplicate the multidirectional impact stresses that a part would be subjected to in actual service. The other obvious advantage is the flexibility to use specimens of different sizes and shapes, including an actual part. Unlike the notched Izod impact test which measures the notch sensitivity of the material and not the material toughness, falling-weight impact tests introduce polyaxial stresses into the specimen and measure the toughness. The variations in the test results due to the fillers and reinforcements, clamping pressure, and material orientation are virtually eliminated in the falling-weight impact test. This type of test is also very suitable for determining the impact resistance of plastic films, sheets, and laminated materials. This falling-weight impact test is primarily designed to determine the relative ranking of materials according to the energy required to break flat rigid plastic specimens under various conditions of impact of a striker impacted by a falling weight. A free-falling weight or a tup is used to determine the impact strength of the material.

Many different versions of test equipment exist today. They all basically operate on the same principle. Figure 43.9 illustrates one such typical commercially available testing machine. It consists of a cast aluminum base, a slotted vertical guide tube, a round-nose striker and striker holder, an 8 lb weight, a die and die support, and a sample platform. The sample platform is used to position a sheet of desired thickness for impact testing.

FIGURE 43.9 Drop impact tester (Courtesy Byk-Gardner USA).

The die is removable from the base in order that the actual parts of complex shapes can be placed onto the base and impact tested.

The test is carried out by raising the weight to a desired height manually or automatically with the use of a motor-driven mechanism and allowing it to fall freely onto the other side of the striker. The striker transfers the impact energy to the flat test specimen positioned on a cylindrical die or a part lying on the base of the machine. The kinetic energy possessed by the falling weight at the instant of impact is equal to the energy used to raise the weight to the height of drop and is the potential energy possessed by the weight as it is released. Since the potential energy is expressed as the product of weight

and height, the guide tube can be marked with a linear scale representing the impact range of the instrument in inch pound. Thus, the toughness or the impact strength of a specimen or a part can be read directly off the calibrated scale in inch pound-force. The energy loss due to the friction in the tube or due to the momentary acceleration of the punch is negligible.

An alternate method for achieving the same result utilizes an instrument that employs a free-falling dart dropped from a specified height onto a test specimen. The dart with a hemispherical head is constructed of smooth, polished aluminum or stainless steel. An electromagnetic, air-operated or other mechanical release mechanism with a centering device is used for releasing the dart. The dart is also fitted with a shaft long enough to accommodate removable incremental weights. A two-piece annular specimen clamp is used to hold the specimen.

43.2.6.3 Instrumented Impact Testing One of the biggest drawbacks of the conventional impact test methods is that it provides only one value—the total impact energy—and nothing else. The conventional tests cannot provide additional information on the ductility, dynamic toughness, fracture, and yield loads or the behavior of the specimen during the entire impact event.

This effectively limits the application of noninstrumented impact test methods to quality control and material ranking. Instrumented impact testers are generally suited for research and development as well as advance quality control.

Instrumented impact testers measure force continuously while the specimen is penetrated. The resulting data can be used to determine type of failure and maximum load, in addition to the amount of energy required to fracture the specimen. One of the most common types of failures occurring from ductile to brittle transition at low temperatures can only be observed by studying load–energy–time curve. The fracture mode of a plastic is sensitive to the changes in temperature, and can change abruptly at or near the materials transition temperature. Manufacturers of plastic automotive components routinely test materials at low temperatures (-20 to -40°F) to assure that they will not become brittle in cold weather. By studying the shape of the load–time or load–deflection curve, the type of failure can be analyzed, and important information about its performance in service can be gathered. The new piezoelectric equipped strikers offer increased sensitivity, opening the doors for testing a whole new range of materials. Applications involving light-weight products such as foam containers for eggs and ultra-thin films used in packaging industry can now be meaningfully tested.

All standard impact testers can be instrumented to provide a complete load and energy history of the specimen. Such a system monitors and precisely records the entire impact event, starting from the acceleration (from rest) to the initial impact and plastic bending to fracture initiation and propagation to the complete failure. The instrumentation is done by mounting the strain gauges or load cell onto the striking bit in the case of pendulum impact tester or onto the tup in the case of a drop impact tester. During the test, a fiber optic device triggers an oscilloscope just before striking the specimen. The output of the strain gauge is recorded by the oscilloscope depicting the variation of the load applied to the specimen throughout the entire fracturing process. A complete load–time history of the entire specimen is obtained. The apparent total energy absorbed by the specimen can be calculated and plotted against time. The specimen displacement can be calculated by the double integration of the load–time curve and the load–displacement curve can be plotted. With the advent of microprocessor technology, some manufacturers are now

FIGURE 43.10 Instrumented impact tester (Courtesy Instron Corporation).

capable of offering a unit that automatically calculates the sample displacement and provide a load–displacement curve eliminating the need for calculations. Many other useful data such as the impact rate, force, and displacement at yield, and break, yield, and failure energies as well as modulus are calculated and printed out. A commercially available instrumented impact tester is shown in Figure 43.10.

43.2.7 High-Speed Impact Tests (ASTM D3763, ISO 6603-2)

An ever-increasing demand for engineering plastics and the need for sophisticated and meaningful impact test methods for characterizing these materials have forced the industry into developing new high-speed impact tests. These tests not only provide the basic information regarding the toughness of the polymeric materials but also provide other important data of interest, such as the load–deflection curve and the total energy absorption. The high-speed impact test overcomes the basic limitations of conventional impact

testing methods as discussed previously. The rate of impact can be varied from 30 to 570,000 in./min.

High speed impact testing has gained considerable popularity in recent years because of its ability to simulate actual impact failures at high speeds. For example, conventional impact testing methods are useless in testing to meet advanced automotive crash standards that require the impact simulation at 28 mph (30,000 in./min). High-speed impact testers are able to meet the challenge. As discussed earlier in this chapter, almost all polymers are strain-rate sensitive. Two polymers, when impact tested at one strain rate, may show similar impact strength values. The same two polymers tested at a high strain rate show a completely different set of values.

Most versatile high-speed impact testing machine is capable of testing everything from the thin film which may require as low an impact rate as 30 in./min to the plastic automotive bumper which may require a high impact rate up to 30,000 in./min. The specimen or product can be tested under a controlled environment of temperature and humidity. The equipment basically consists of a tup attached to a motor wound spring or pneumatically powered actuator along with plunger displacement measuring system. The force is detected with a fast responding quartz load cell mounted directly on the actuator. The velocity can be set digitally from 30 to 30,000 in./min. Some type of clamp assembly to hold the specimen in place is used. The equipment can also be fitted with environmental chamber for specialized testing. The tester is equipped with a monitor and x - y plotter that automatically displays load versus displacement data. A built-in microprocessor provides more useful information, such as modulus, yield, and failure energies.

High-speed impact testers have been proven very useful in material evaluation. At low strain rates, some polymers fail in ductile manner. The same polymers appear to show brittle failure at high strain rates. The point at which this ductile to brittle transition takes place is of particular importance. A high-rate impact test can provide such information in a graphical form. Tests can also be carried out at different temperatures to find ductile-brittle transition points at various temperatures. Other useful applications of the high-speed impact tester include the process quality control, design evaluation, and assembly evaluation.

43.2.7.1 Abrasion Resistance Tests The material's ability to resist abrasion is most often measured by its loss in weight when abraded with an abraser. The most widely accepted abraser in the industry is called the Taber abraser. A variety of wheels with varying degree of abrasiveness is available. The grade of "calibrase" wheel designated CS-17 with 1000-g load seems to produce satisfactory results with almost all plastics. For softer materials less abrasive wheels with smaller load on the wheels may be used. The test specimen is usually a 4 in. diameter disc or a 4 sq. in. plate having both surfaces substantially plane and parallel. A 1/2 in. diameter hole is drilled in the center. Specimens are conditioned employing standard conditioning practices prior to testing. To commence testing, the test specimen is placed on a revolving turntable. Suitable abrading wheels are placed on the specimen under certain set dead weight loads. The turntable is started and an automatic counter records the number of revolutions. Most tests are carried out to at least 5000 revolutions. The specimens are weighed to the nearest mg. The test results are reported as weight loss in milligrams/1000 cycles. The grade of abrasive wheel along with amount of load at which the test was carried out is always reported along with results.

Test methods such as ASTM D 1044 (resistance of transparent plastic materials to abrasion) are also developed for estimating the resistance of transparent plastic materials

FIGURE 43.11 Abrasion tester (Courtesy Taber Industries).

to one kind of abrasion by measurement of its optical affects. The test is carried out in similar manner to that described above, except that 100 cycles with a 500 g. load is normally used. A photoelectric photometer is used to measure the light scattered by abraded track. The percentage of the transmitted light that is diffused by the abraded specimens is reported as a test result. Figure 43.11 illustrates a commercially available abrasion tester.

43.2.8 Fatigue Resistance

The behavior of materials subjected to repeated cyclic loading in terms of flexing, stretching, compressing, or twisting is generally described as fatigue. Such repeated cyclic loading eventually constitutes a mechanical deterioration and progressive fracture that leads to complete failure. Fatigue life is defined as the number of cycles of deformation required to bring about the failure of the test specimen under a given set of oscillating conditions.

The failures that occur from repeated application of stress or strain are well below the apparent ultimate strength of the material. Fatigue data are generally reported as the number of cycles to fail at a given maximum stress level. The fatigue endurance curve, which represents stress versus number of cycles to failure, also known as $S-N$ curve, is generated by testing a multitude of specimens under cyclic stress, each one at different stress levels. At high stress levels, materials tend to fail at relatively low numbers of cycles. At low stresses, the materials can be stressed cyclically for an indefinite number of times and the failure point is virtually impossible to establish. This limiting stress below which material will never fail is called the fatigue endurance limit. The fatigue endurance limit can also be defined as the stress at which the $S-N$ curve becomes asymptotic to the horizontal (constant stress) line. For most polymers, the fatigue endurance limit is between 25% and 30% of the static tensile strength. The fatigue resistance data are of practical importance in the design of gears, tubing, hinges, parts on vibrating machinery, and pressure vessels under cyclic pressures.

Two basic types of tests have been developed to study the fatigue behavior of plastic materials:

1. flexural fatigue test,
2. tensile fatigue test.

43.2.8.1 Flexural Fatigue Test (ASTM D 671) The ability of a material to resist deterioration from cyclic stress is measured in this test by using a fixed cantilever-type testing machine capable of producing a constant-amplitude-of-force on the test specimen each cycle. The main feature of a fatigue testing machine is an unbalanced, variable eccentric, mounted on a shaft that is rotated at a constant speed by a motor. This unbalanced movement of an eccentric produces alternating force. The specimen is held as a cantilever beam in a vice at one end and bent by a concentrated load applied through a yoke fastened to the opposite end. A counter is used to record the number of cycles along with a cutoff switch to stop the machine when the specimen fails. A typical commercially available fatigue testing machine is illustrated in Figure 43.12. The test specimen of two different geometries are used. If machined specimens are used, care must be taken to eliminate all scratches and tool marks from the specimens. Molded specimen must be stress-relieved before using.

The test is carried out by first determining the complementary mass and effective mass of the test specimen. The load required to produce the desired stress is calculated from these values. The number of cycles required to produce failure is determined. The test is repeated at varying stress levels. A curve of stress versus cycles-to-failure ($S-N$ diagram) is plotted from the test results.

43.2.8.2 Tensile Fatigue Test Unlike the flexural fatigue test which uses the constant deflection (strain) principle, the tensile fatigue test is conducted under constant load (stress) conditions. The specimen is dumbbell-shaped, about 2 in. long with a cylindrical cross section.

FIGURE 43.12 Flexural fatigue tester (Courtesy Ceast U.S.A. Inc.).

The test is conducted by mounting both ends of the dumbbell specimen in the testing machine. The specimen is rotated between two spindles, and stress in the form of tension and compression is applied. The specimen is subjected to the number of cycles of stress specified or until fracture occurs.

43.2.9 Hardness Tests

43.2.9.1 Rockwell Hardness (ASTM D 785) The Rockwell hardness test measures the net increase in depth impression as the load on an indenter is increased from a fixed minor load to a major load and then returned to a minor load. The hardness numbers derived are just numbers without units. Rockwell hardness numbers are always quoted with a scale symbol representing the indenter size, load, and dial scale used. The hardness scales in order of increasing hardness are *R*, *L*, *M*, *E*, and *K* scales. The higher the number in each scale, the harder the material. There is a slight overlap of hardness scales and, therefore, it is quite possible to obtain two different dial readings on different scales for the same material. For a specific type of material, correlation in the overlapping regions is possible. However, due to differences in elasticity, creep, and shear characteristics between different plastics, a general correlation is not possible.

43.2.9.2 Durometer Hardness (ASTM D 2240, ISO 868) The Durometer hardness test is mostly used for measuring the relative hardness of soft materials. The test method is based on the penetration of a specified indenter forced into the material under specified conditions.

The Durometer hardness tester consists of a pressure foot, an indenter, and an indicating device. The indenter is spring loaded and the point of the indenter protrudes through the hole in the base. The test specimens are at least 1/4 in. thick and can be either molded or cut from a sheet. Several thin specimens may be piled to form a 1/4 in. thick specimen but one piece specimens are preferred. The poor contact between the thin specimens may cause results to vary considerably.

The test is carried out by first placing a specimen on a hard, flat surface. The pressure foot of the instrument is pressed onto the specimen, making sure that it is parallel to the surface of the specimen. The durometer hardness is read within 1 sec after the pressure foot is in firm contact with the specimen.

Two types of durometers are most commonly used—Types A and D. The basic difference between the two types is the shape and dimension of the indenter. The hardness numbers derived from either scale are just numbers without any units. Type A durometer is used with relatively soft material while Type D is used with slightly harder material.

43.3 THERMAL PROPERTIES

Thermal properties of plastic materials are equally as important as mechanical properties. Unlike metals, plastics are extremely sensitive to changes in temperature. The mechanical, electrical, or chemical properties of plastics cannot be looked at without looking at the temperature at which the values were derived. Crystallinity has a number of important effects upon the thermal properties of a polymer. Its most general effects are the introduction of a sharp melting point and the stiffening of thermal mechanical properties. Amorphous plastics, in contrast, have a gradual softening range. Molecular orientation also has

a significant effect on thermal properties. Orientation tends to decrease dimensional stability at higher temperatures. The molecular weight of the polymer affects the low-temperature flexibility and low-temperature brittleness. Many other factors such as intermolecular bonding, cross linking, and copolymerization all have a considerable effect on thermal properties. From the above discussion, it is very clear that the thermal behavior of polymeric materials is rather complex. Therefore, in designing a plastic part or selecting a plastic material from the available thermal property data, one must thoroughly understand the short term as well as the long-term effect of temperature on properties of that plastic material.

43.3.1 Tests for Elevated Temperature Performance

Designers and material selectors of plastic products constantly face the challenge of selecting a suitable plastic for elevated temperature performance. The difficulty arises due to the varying natures and capabilities of various types and grades of plastics at elevated temperatures. Many factors are considered when selecting a plastic for a high-temperature application. The material must be able to support a design load under operating conditions without objectionable creep or distortion. The material must not degrade or lose necessary additives that will cause drastic reduction in the physical properties during the expected service life.

All the properties of plastic materials are not affected in a similar manner by elevating temperature. For example, electrical properties of a particular plastic may show only a moderate change at elevated temperatures, while the mechanical properties may be reduced significantly. Also, since the properties of plastic materials vary with temperature in an irregular fashion, they must be looked at as a function of temperature in order to obtain more meaningful information. From the foregoing, it is quite clear that a single maximum use temperature that will apply to all the important properties in high-temperature applications is simply not possible.

One of the most important considerations while studying the performance of plastics at elevated temperatures is the dependence of key properties such as modulus, strength, chemical resistance, and environmental resistance on time. Therefore, the short-term heat resistance data alone is not adequate for designing and selecting materials that require long-term heat resistance. For the sake of convenience and simplicity, we divide the elevated temperature effects into two categories:

1. short-term effects:
 - a. heat deflection temperature,
 - b. vicat softening temperature,
 - c. torsion pendulum,
2. long-term effects:
 - a. long-term heat resistance test,
 - b. UL temperature index,
 - c. creep modulus/creep rupture tests.

43.3.1.1 Heat Deflection Temperature (HDT) (ASTM D 648, ISO 75-1 & 75-2) Heat deflection temperature is defined as the temperature at which a standard test bar ($5 \times 1/2 \times 1/4$ in.) deflects 0.010 in. under a stated load of either 66 or 264 psi. The heat

deflection temperature test, also referred to as the heat distortion temperature test, is commonly used for quality control and for screening and ranking materials for short-term heat resistance. The data obtained by this method cannot be used to predict the behavior of plastic materials at elevated temperature nor can it be used in designing a part or selecting and specifying material. Heat deflection temperature is a single point measurement and does not indicate long-term heat resistance of plastic materials. Heat distortion temperature, however, does distinguish between those materials that lose their rigidity over a narrow temperature range and those that are able to sustain light loads at high temperatures.

The apparatus for measuring heat deflection temperature consists of an enclosed oil bath fitted with a heating chamber and automatic heating controls that raise the temperature of the heat transfer fluid at a uniform rate. A cooling system is also incorporated to fast cool the heat transfer medium for conducting repeated tests. The specimens are supported on steel supports, 4 in. apart with the load applied on top of the specimen vertically and midway between the supports. The contact edges of the support and of the piece by which pressure is applied is rounded to a radius of 1/4 in. A suitable deflection measurement device, such as a dial indicator, is normally used. A mercury thermometer is used for measuring temperature. The unit is capable of applying 66 or 264 psi fiber stress on specimens by means of a dead weight. A commercially available heat deflection measuring device with a close-up of a specimen holder is illustrated in Figure 43.13.

The specimen is positioned in the apparatus along with the temperature and deflection measuring devices and the entire assembly is submerged into the oil bath kept at room temperature. The load is applied to a desired value (66 or 264 psi fiber stress). Five minutes after applying the load, the pointer is adjusted to zero and the oil is heated at the rate of $2 \pm 0.2^\circ\text{C}/\text{min}$. The temperature of the oil at which the bar has deflected 0.010 in. is recorded as the heat deflection temperature at the specified fiber stress.

43.3.1.2 Long-Term Effects The long-term effects of elevated temperature on properties of plastics are extremely important, especially when one considers the fact that the majority of applications involving high heat are long-term applications. During long-term

FIGURE 43.13 DTUL/Vicat tester (Courtesy Ceast U.S.A. Inc).

exposure to heat, plastic materials may encounter many physical and chemical changes. A plastic material that shows little or no effect at elevated temperature for a short time may show a drastic reduction in physical properties, a complete loss of rigidity, and severe thermal degradation when exposed to elevated temperature for a long time. Along with time and temperature, many other factors such as ozone, oxygen, sunlight, and pollution combine to accelerate the attack on plastics. At elevated temperatures, many plastics tend to lose important additives such as plasticizers and stabilizers, causing plastics to become brittle or soft and sticky.

Three basic tests have been developed and accepted by the plastics industry. If the application does not require the product to be exposed to elevated temperature for a long period under continuous load, a simple heat-resistance test is adequate. The applications requiring the product to be under continuous significant load must be looked at from creep modulus and creep rupture strength test data. Yet, another one of the most widely accepted methods of measuring maximum continuous use temperature has been developed by Underwriters Laboratories. The UL temperature index, established for a variety of plastic materials to be used in electrical applications, is the maximum temperature that the material may be subjected to without fear of premature thermal degradation.

43.3.1.3 Long-Term Heat-Resistance Test (ASTM D 794) The long-term heat-resistance test was developed to determine the permanent effect of heat on any property by selection of an appropriate test method and specimen. In ASTM recommended practice, only the procedure for heat exposure is specified and not the test method or specimen.

Any specimen, including sheet, laminate, test bar, or molded part may be used. If a specific property, such as tensile strength loss is to be determined, a standard tensile test bar specimen and procedures must be used for comparison of test results before and after the test. The test requires the use of a mechanical convection oven with a specimen rack of suitable design to allow air circulation around the specimens. The test is carried out by simply placing the specimen in the oven at a desired exposure temperature for a predetermined length of time. The subsequent exposure to temperatures may be increased or decreased in steps of 25°C until a failure is observed. Failure due to heat is defined as a change in appearance, weight, dimension, or other properties that alter plastic material to a degree that it is no longer acceptable for the service in question. Failure may result from blistering, cracking, loss of plasticizer, or other volatile material that may cause embrittlement, shrinkage, or change in desirable electrical or mechanical properties.

There are many factors that affect the reproducibility of the data. The degree of temperature control in the oven, the type of molding, cure, air velocity over the specimen, period of exposure, and humidity of the oven room are some of these factors. The amount and type of volatiles in the molded part or specimen may also affect the reproducibility.

43.4 ELECTRICAL PROPERTIES

The unbeatable combination of characteristics such as ease of fabrication, low cost, light weight, and excellent insulation properties have made plastics one of the most desirable materials for electrical applications. Although, the majority of applications involving plastics are insulation-related, plastics can be made to conduct electricity by simply modifying the base material with proper additives such as carbon black.

Until recently, plastics were considered a relatively weaker material in terms of load-bearing properties at elevated temperatures. Therefore, the use of plastics in electrical applications was limited to nonload-bearing, general-purpose applications. The advent of new high performance engineering materials has altered the entire picture. Plastics are now specified in a majority of applications requiring resistance to extreme temperatures, chemicals, moisture, and stresses. The primary function of plastics in electrical applications has been that of an insulator. This insulator or dielectric separates two field-carrying conductors. Such a function can be served equally well by air or vacuum. However, neither air nor vacuum can provide any mechanical support to the conductors. Plastics not only act as effective insulators but also provide mechanical support for field-carrying conductors. For this very reason, the mechanical properties of plastic materials used as insulators become very important. Typical electrical applications of plastic material include plastic-coated wires, terminals, connectors, industrial and household plugs, switches, and printed circuit boards.

The key electrical properties of interest are dielectric strength, dielectric constant, dissipation factor, volume and surface resistivity, and arc resistance.

43.4.1 Dielectric Strength (ASTM D 149, IEC 243-1)

The dielectric strength of an insulating material is defined as the maximum voltage required to produce a dielectric breakdown. Dielectric strength is expressed in volts per unit of thickness such as volt per mil. All insulators allow a small amount of current to leak through or around themselves. Only a perfect insulator, if there is such an insulator in existence, can be completely free from small current leakage. The small leakage generates heat, providing an easier access to more current. The process slowly accelerates with time and the amount of voltage applied until a failure in terms of dielectric breakdown or what is known as puncture occurs. Obviously, dielectric strength, which indicates electrical strength of a material as an insulator, is a very important characteristic of an insulating material. The higher the dielectric strength, the better the quality of an insulator. Three basic procedures have been developed to determine dielectric strength of an insulator. Figure 43.14 illustrates the basic setup for a dielectric strength test. A variable transformer and a pair of electrodes are normally employed. Specimens of any desirable thickness prepared from the material to be tested are used. Specimen thickness of 1/16 in. is fairly common. The first procedure is known as the short-times method. In this method, the voltage is increased from zero to breakdown at uniform rate.

The second method is known as the slow-rate-of-rise method. The test is carried out by applying the initial voltage approximately equal to 50% of the breakdown voltage as determined by the short-time test or as specified. Next, the voltage is increased at a uniform rate until the breakdown occurs.

43.4.2 Dielectric Constant and Dissipation Factor (ASTM D150, IEC 250)

43.4.2.1 Dielectric Constant (Permittivity) Dielectric constant of an insulating material is defined as the ratio of the charge stored in an insulating material placed between two metallic plates to the charge that can be stored when the insulating material is replaced by air (or vacuum). Defined another way, the dielectric constant is the ratio of the capacitance by two metallic plates with an insulator placed between them and the capacitance of the same plates with a vacuum between them. Simply stated, the dielectric constant indicates the ability of an insulator to store electrical energy.

FIGURE 43.14 Dielectric strength tester (Courtesy Ceast U.S.A. Inc.).

The dielectric constant test is fairly simple. The test specimen is placed between the two electrodes, as shown in Figure 43.15, and the capacitance is measured. Next, the test specimen is replaced by air and once again, the capacitance value is measured. The dielectric constant value is determined from the ratio of the two measurements. Dielectric constant values are affected by factors such as frequency, voltage, temperature, humidity, and so on.

43.4.2.2 Dissipation Factor In all electrical applications, it is desirable to keep the electrical losses to a minimum. Electrical losses indicate the inefficiency of an insulator. The

FIGURE 43.15 Schematic of dielectric constant test (Courtesy Bayer Corporation).

dissipation factor is a measure of such electrical inefficiency of the insulating material. The dissipation factor indicates the amount of energy dissipated by the insulating material when the voltage is applied to the circuit. The dissipation factor is defined as the ratio of the conductance of a capacitor in which the material is the dielectric to its susceptance or the ratio of its parallel reactance to its parallel resistance. Most plastics have a relatively lower dissipation factor at room temperature. However, at high temperatures, the dissipation factor is quite high, resulting in greater overall inefficiency in electrical system. Loss factor, which is the product of dielectric constant and the dissipation factor, is a frequently used term, since it relates to the total loss of power occurring in insulating materials.

43.4.3 Electrical Resistance Tests

As was stated earlier, the primary function of an insulator is to insulate current-carrying conductors from each other as well as from ground and to provide mechanical support for components. Naturally, the most desirable characteristic of an insulator is its ability to resist the leakage of the electrical current. The higher the insulation resistance, the better the insulator. Failure to recognize the importance of insulation resistance values while designing products such as appliances and power tools could lead to fire, electrical shock, and personal injury.

Insulation resistance can be subdivided into

1. volume resistance,
2. surface resistance.

Volume resistance is defined as the ratio of the direct voltage applied to two electrodes that are in contact with a specimen to that portion of the current between them that is distributed through the volume of the specimen. Or, simply stated, the volume resistance is the resistance to leakage through the body of the material. Volume resistance generally depends upon the material. The term most commonly used by designers is volume resistivity. It is defined as the ratio of the potential gradient parallel to the current in the material to the current density or simply stated, the volume resistivity of a material is the electrical resistance between the opposite faces of a unit cube for a given material and at a given temperature.

High volume resistivity materials are desirable in applications requiring superior insulating characteristics.

The surface resistance of a material is defined as the ratio of the direct voltage applied to the electrodes to that portion of the current between them that is primarily in a thin layer of moisture or other semiconducting material that may be deposited on the surface. Or simply stated, surface resistance is the resistance to leakage along the surface of an insulator. The surface resistance of a material depends upon the quality and cleanliness of the surface of the product. A product with oil or dirt particles on it gives lower surface resistance values. Temperature and humidity both seem to affect the insulation resistance appreciably.

43.4.4 ARC Resistance (ASTM D 495)

Arc resistance is the ability of a plastic material to resist the action of a high-voltage electrical arc, usually stated in terms of time required to form material electrically conductive. Failure is characterized by carbonization of the surface, tracking, localized heating to incandescence, or burning. In all applications in which conducting elements are

FIGURE 43.16 Arc resistance test (Courtesy Bayer Corporation).

brought into contact, arcing is inevitable. Switches, circuit breakers, and automotive distributor caps, are a few good examples of applications where arcing is known to cause failure. Another term that is generally associated with arcing is tracking. Tracking is defined as a phenomenon where a high voltage source current creates a leakage or fault path across the surface of an insulating material by slowly but steadily forming a carbonized path appearing as a thin, wiry line between the electrodes. Tracking is accelerated by the presence of surface contaminants such as dirt and oil and by the presence of moisture. Figure 43.16 illustrates a typical setup for an arc resistance test. The voltage is applied intermittently and severity is increased in steps until the failure occurs. Arc resistance is measured in seconds to failure.

43.5 WEATHERING PROPERTIES

The increased outdoor use of plastics has created a need for a better understanding of the effect of the environment on plastic materials. The environmental factors have significant detrimental effects on appearance and properties. The severity of the damage depends largely on factors such as the nature of the environment, geographic location, type of polymeric material, and duration of exposure. The effect can be anywhere from a mere loss of color or a slight crazing, and cracking to a complete breakdown of the polymer structure. Any attempt to design plastic parts without a clear understanding of the degradation mechanisms induced by the environment would result in a premature failure of the product.

43.5.1 UV Radiation

All types of solar radiation have some sort of detrimental effect on plastics. Ultraviolet radiation is the most destructive of all radiations. The energy in ultraviolet radiation is

sufficiently strong enough to break molecular bonds. This activity in the polymer brings about thermal oxidative degradation which results in embrittlement, discoloration, and an overall reduction in physical and electrical properties. Xenon ARC lamps, fluorescent lighting, sun lamps, and other artificial sources also emit a similar type of harmful radiation. Other factors in the environment such as heat, humidity, and oxygen accelerate the UV degradation process.

One of the best methods of protecting plastics against UV radiation is to incorporate UV absorbers or UV stabilizers into the plastic materials. The UV absorbers provide preferential absorption to most of the incident UV light and are able to dissipate the absorbed energy harmlessly. Thus, the polymer is protected from harmful radiation at the cost of UV absorbers which are destroyed in the process with time. Several types of organic and inorganic UV absorbers are developed for this purpose. Almost all inorganic pigments absorb UV radiation to a certain extent and provide some degree of protection. Perhaps the most effective pigments are certain types of carbon black that absorb over the entire range of UV and visible radiation and transform the energy into less harmful radiation.

UV stabilizers, unlike UV absorbers, inhibit the bond rupture by chemical means or dissipate the energy to lower levels that do not attack the bonds. The effectiveness of such additives when incorporated with the polymer can be determined by various test methods.

43.5.2 Accelerated Weathering Tests

Most data on the aging of plastics are acquired through accelerated tests and actual outdoor exposure. The latter being a time-consuming method, accelerated tests are often used to expedite screening the samples with various combinations of additive levels and ratios. A variety of light sources are used to simulate the natural sunlight. The artificial light sources include carbon arc lamps, xenon arc lamps, fluorescent sun lamps, and mercury lamps. These light sources, except fluorescent, are capable of generating a much higher intensity light than natural sunlight. Xenon arc lamps can be operated over a wide range from below peak sunlight to twice the sunlight levels. Quite often, a condensation apparatus is used to simulate the deterioration caused by sunlight and water as rain or dew. Modern instruments have direct specimen spray on front and/or back side of the specimen.

There are three major accelerated weathering tests:

1. exposure to carbon arc lamps,
2. Exposure to xenon arc lamps,
3. exposure to fluorescent UV lamps.

The xenon arc, when properly filtered, most closely approximates the wavelength distribution of natural sunlight.

43.5.2.1 Exposure of Plastics to Fluorescent UV Lamps and Condensation (ASTM G 53, ISO 4892) This method is meant to simulate the deterioration caused by sunlight and dew by means of artificial ultraviolet light and condensation apparatus (Figures 43.17 and 43.18). Solar radiation ranges from ultraviolet to infrared. Ultraviolet light of wavelengths between 290 and 350 nm is the most efficient portion of terrestrial sunlight that is damaging to plastics. In the natural sunlight spectrum, energy below 400 nm accounts for less than 6% of the total radiant energy (3). Since the special fluorescent UV lamps radiate between 280 and 365 nm, they

FIGURE 43.17 UV light and condensation apparatus (Courtesy Q-Panel Lab Products).

accelerate the degradation process considerably. In recent years, the UVA-340 lamps have increased in popularity because of the poor results of the conventional FS-40 lamps.

The test apparatus basically consists of a series of UV lamps, a heated water pan, and test specimen racks. The temperature and operating times are independently controlled

FIGURE 43.18 Cross section of a UV light and condensation apparatus (Courtesy Q-Panel Lab Products).

both for UV and the condensation effect. The test specimens are mounted in specimen racks with the test surfaces facing the lamp. The test conditions are selected based on requirements and programmed into the unit. The specimens are removed for inspection at a predetermined time to examine color loss, crazing, chalking, and cracking.

43.5.2.2 Exposure of Plastics to Carbon Arc-Type Light and Water (ASTM D 1499, ISO 4892) This method is very useful in determining the resistance of plastic materials when exposed to radiation produced by carbon-arc lamps. There are basically two different types of carbon-arc lamps used as the source of radiation. The first type is enclosed carbon arc lamp. The second type is known as an open-flame sunshine carbon-arc. Both apparatuses revolve around centrally mounted arc lamps. The provision is also made to expose the specimen to water, which is sprayed through nozzles. The light-on, light-off, and water-spray cycles are independent of each other and the apparatus can be programmed to operate with virtually any combination. A black panel temperature inside the test chamber can be monitored and controlled by a sensor mounted directly on the revolving specimen rack.

43.5.2.3 Exposure of Plastics to Xenon Arc-Type Light and Water (ASTM D 2565, G 26, ISO 4892) A filtered xenon arc-type light source is one of the most popular indoor exposure tests since it exhibits a spectral energy distribution of sunlight at the surface of the earth. The xenon-arc lamp consists of a burner tube and a light filter system consisting of interchangeable glass filters used in combination to provide a spectral distribution that approximates natural sunlight exposure conditions. The apparatus typically has a built-in recirculating system that recirculates distilled or deionized water through the lamp. The water cools the xenon burner and filters out long wavelength infrared energy. For air-cooled lamps, this is accomplished by the use of optical filters.

Two basic procedures are recommended. Procedure A is a normal operating procedure for comparative evaluation within a series exposed simultaneously in one instrument. Procedure B is used for comparing results among instruments. Both procedures are described in detail in the ASTM Standards Manual.

43.5.3 Outdoor Weathering of Plastics (ASTM D 1435)

The test is devised to evaluate the stability of plastic materials exposed outdoors to varied influences that comprise weather exposure conditions that are complex and changeable. Important factors are climate, time of year, and the presence of industrial atmosphere. It is recommended that repeated exposure testing at different seasons and over a period of more than one year be conducted to confirm exposure at any one location. Since weathering is a comparative test, control samples are always utilized and retained at standard conditions of temperature and humidity. The control samples must also be covered with inert wrapping to exclude light exposure during the aging period. However, dark storage does not insure stability.

Test sites are selected to represent various conditions under which the plastic product will be used. Arizona is often selected for intense sunlight, wide temperature cycle, and low humidity. Florida, on the other hand, provides high humidity, intense sunlight, and relatively high temperatures.

Exposure test specimens of suitable shape or size are mounted in a holder directly applied to the racks. Racks are positioned at a 45° angle and facing the equator. Many

FIGURE 43.19 Typical aluminum exposure racks (Courtesy Atlas Electric Devices Company).

other variations in the position of the racks are also employed, depending upon the requirements.

The specimens are removed from the racks after a specified amount of time and subjected to various tests such as appearance evaluation, electrical tests, and mechanical tests. The results are compared with the test results from testing control specimens. Typical aluminum exposure racks are shown in Figure 43.19.

43.6 OPTICAL PROPERTIES

43.6.1 Refractive Index (ASTM D 542)

Refractive index is a fundamental property of transparent materials. Refractive index values are very important to a design engineer involved in designing lenses for cameras, microscopes, and other optical equipment. The refractive index, also known as the index of refraction, is defined as the ratio of the velocity of light in a vacuum (or air) to its velocity in a transparent medium.

$$\text{Index of refraction} = \frac{\sin \text{ angle of incidence}}{\sin \text{ angle of refraction}}.$$

The Abbe refractometer is the refractometer most widely used to determine the index of refraction (Figure 43.20). The test also requires a source of white light and a contacting liquid that will not attack the surface of the plastic. The contacting liquid must also have a higher refractive index than the plastic being measured. A test specimen of any size may be used as long as it conveniently fits on the face of the fixed half of the refractometer prism. The surface of the specimen in contact with the prism must be flat and polished.

The test is carried out by placing a specimen in contact with the prism using a drop of contacting liquid. The polished edge of the specimen is kept towards the light source. The refractive index is determined by moving the index arm of the refractometer so that the field seen through the eyepiece is half dark. The compensator is adjusted to remove all

FIGURE 43.20 Abbe refractometer.

color from the field. Next, the index arm is adjusted using the vernier to coincide the dark and light portion of the field at the intersection of the cross hairs. The value of the index of refraction is read for sodium D lines.

43.6.2 Luminous Transmittance and Haze (ASTM D 1003)

Luminous transmittance is defined as the ratio of transmitted light to the incident light. The value is generally reported in percentage of light transmitted. Polymethyl methacrylate, for example, transmits 92% of the normal incident light. Haze is the cloudy appearance of an otherwise transparent specimen caused by light scattered from within the specimen or from its surface. Haze is defined as the percentage of transmitted light that in passing through a specimen deviates from the incident beam by forward scattering. Haze is normally caused by surface imperfections, density changes, or inclusions that produce light scattering. Haze is also reported in percentage.

Two procedures have been developed to measure light transmittance and light scattering properties: Procedure A requires the use of a hazemeter while Procedure B requires the use of a recording spectrophotometer.

FIGURE 43.21 Schematic of hazemeter (reprinted with permission of ASTM).

43.6.2.1 Procedure A: Hazemeter This procedure employs an integrating sphere hazemeter as illustrated schematically in Figure 43.21. The test specimen must be large enough to cover the aperture, but small enough to be tangent to the sphere wall. A disc of 1.375 in. in diameter is most commonly used. A commercially available hazemeter is shown in Figure 43.22. The test is conducted by taking four different consecutive readings and measuring the photocell output as follows:

T_1 = specimen and light trap out of position, reflectance standard in position.

T_2 = specimen and reflectance standard in position, light trap out of position.

FIGURE 43.22 Hazemeter (Courtesy BYK-Gardner USA).

T_3 = light trap in position, specimen and reflectance standard out of position.

T_4 = specimen and light trap in position, reflectance standard out of position.

The quantities represented in each reading are incident light, total light transmitted by specimen, light scattered by instrument, and light scattered by instrument and specimen, respectively.

43.6.2.2 Procedure B: Recording Spectrophotometer This procedure is somewhat similar to Procedure A. The recording spectrophotometer is used to generate four different curves. From the recorded curves T_1 , T_2 , T_3 , and T_4 values are computed using automatic integrator. Calculations are carried out in a similar manner to determine total and diffuse luminous transmittance and the percentage haze.

43.6.3 Specular Gloss (ASTM D 523)

Specular gloss is defined as the relative luminous reflectance factor of a specimen at the specular direction. This method has been developed to correlate the visual observations of surface shininess made at roughly corresponding angles. The light beam is directed towards the specimen at a specified angle and the light reflected by the specimen is collected and measured. All specular gloss values are based on a primary reference standard—a highly polished black glass with an assigned specular gloss value of 100.

The operation of a glossimeter is very simple. The instrument is turned on and placed on black glass primary standard. The control knob is adjusted so that the meter indicates the value assigned to the primary standard. Next, the sensor is placed on the specimen surface and the gloss value is read directly from the analog or digital display. The linearity of the instrument is routinely checked by placing the sensor on a white secondary standard, which should read within 1.0 gloss unit of the assigned value of that standard. Figure 43.23 illustrates a commercially available glossmeter.

44.1 FTIR SPECTROSCOPY

The infrared electromagnetic radiation produces vibrational and rotational changes in the molecule, distinctive of the chemical structure of the analyzed substance that can be used for the characterization of any molecule including polymers and additives. With the

introduction of the Fourier transform infrared spectrophotometer (FTIR) at the end of 1960s, some of the disadvantages of traditional dispersive instruments were solved and a faster and more sensitive technique was developed (Fuller et al.).

The FTIR spectroscopy could be a very useful technique in characterization of polymeric materials, since the following type of analysis could be done:

- identification and quantification of additives and polymers,
- determination of the polymer structure of multilayer films. This analysis has to be done in conjunction with other techniques such as optical microscopy and differential scanning calorimetry (DSC)
- analysis of contaminants in polymeric samples and additives,
- study of thermo-oxidative and environmental degradation of polymers,
- analysis of isomerism and functionalization of polymeric materials,
- analysis of chain branching and end functional groups in polymers,
- analysis of crystalline structure of polymeric materials.

Nowadays, a wide range of FTIR techniques are available, and the most useful ones for polymer characterization are as follows:

- *Transmission*: The sample is placed in the infrared path emitted by the source, and the transmitted infrared radiation is analyzed by the detector. The sample could be a film, a sheet, and a powder or a liquid supported in a transparent window.
- *Attenuated Total Reflectance ATR*: In this technique, the infrared radiation emitted by the source is internally reflected in a high-refractive-index crystal and only the evanescent waves interact with the sample in direct contact with the crystal. The ATR technique allows to obtain a low-penetration infrared spectrum of the sample, so it is used in the analysis of coatings and multilayer films, when only the surface has to be measured.

The chemical structure of polymers and additives could be correlated with the infrared absorption, with the use of available literature and Figure 44.1 (Conley, 1972; ASTM D 5576; Lomonte, 1962; Gartner et al., 1998; Sierra et al., 2000; Naranjo et al., 2008).

44.2 CHROMATOGRAPHY (GC, GC-MSD, GC-FID, AND HPLC)

The chromatography is a separation technique in which the components of the mixture are distributed in two phases (stationary phase and mobile phase) based on the partition coefficients. Depending on the type of stationary phase and mobile phase, the chromatography techniques can be grouped into the following categories:

- *Gas Chromatography (GC)*: The mobile phase is a gas, and the stationary phase is a solid or a liquid. *Example*: capillary GC.
- *Liquid Chromatography*: The mobile phase is a liquid, and the stationary phase is a solid or a gel. For example: high-performance liquid chromatography (HPLC) and thin-layer chromatography (TLC).

FIGURE 44.1 Characteristic infrared absorption bands of polymers (Conley, 1972; Gartner et al., 1998; Sierra et al., 2000).

Once the components are separated in the chromatographic columns, it is possible to quantify (and sometimes identify) the substances of the mixture with the help of a proper detector.

44.2.1 GC

The GC could be a very useful technique in characterization of polymeric materials, since the following types of analyses can be done:

- qualitative and quantitative analyses of comonomers in polymeric materials (after pyrolysis, Stilianos Rowis and Fedora, 1996; Frontier Laboratories Ltd; Wampler, 2005),
- residual monomer analysis in polymeric resins,
- qualitative and quantitative analyses of impurities and additives in polymeric materials,
- odor and volatiles analysis in polymeric materials,
- residual pesticides in polymeric materials,
- purity analysis of additives,
- specific migration studies in polymeric materials.

The GC technique could be used for the analysis of any substance that meets the following requirements: volatilization temperature below 320 °C and a molecular weight below 600 g/mole. This chromatographic technique includes the following components and instrumentation:

- *Injectors*: The injector is the component of gas chromatograph used to receive, volatilize, mix with the carrier gas, and transport the sample to the capillary column. The most universally used in the polymer and additives analysis are the split/splitless and the on-column.
 - *Split/Splitless Injector*: In the split operation, a fraction of the vaporized sample is carried into a column (according to a predefined split ratio), whereas in the splitless operation, the majority of the sample is carried into the column. For this reason, split injection is preferred for concentrated samples and splitless for trace analysis.
 - *On-Column*: This type of injector allows the injection of sample inside the column, for the analysis of substances with a molecular weight up to 1000 g/mole. The main advantages of this injector are less discrimination of low-volatility compounds, less adsorption of active compounds, less degradation of thermal sensitive compounds, and better sensitivity for trace compounds.
- *Columns*: The column is the component of gas chromatograph that supports the stationary phase and performs the separation of the sample components. For the majority of polymers and additives analysis, capillary columns are used with a typical internal diameter within the range of 0.32–0.20 mm. The polarity of columns depends on the type of substances to be separated. As a general rule, columns with low polarity are selected to separate compounds according to the boiling point, columns with high polarity are used to separate compounds by dipole–dipole interactions, and columns with intermediate polarity are selected to separate by means of both mechanisms.

- **Detectors:** The detector is the component of gas chromatograph that measures the signal of each component that is separated and eluted from the column. The most used detectors in the polymer and additives analysis are the flame ionization detector (FID) and the mass selective detector (MSD).
 - **Flame Ionization Detector (FID):** In this type of detector, the components that are separated from the sample are ionized in a hydrogen–air flame. Because of the high response to the majority of organic compounds, FID is considered as a universal detector.
 - **Mass Selective Detector (MSD):** In this type of detector, the compounds that eluted from the column are identified and quantified according to the fragmentation spectrum, once they are impinged with high-energy electrons and separated based on the mass-to-charge ratio.
- **Control and Data Analysis Unit:** It is the unit of the chromatograph that receives the signals from the detectors, provides control signal, and controls the other components including pressure and flow of carrier gas, oven temperature, injectors, and detectors.

In case of odor and volatile analysis, a very powerful technique for sampling is the headspace. In the headspace, the volatile compounds in equilibrium with the sample (solid or liquid) are removed from an enclosed space and injected into the gas chromatograph. To concentrate the volatiles in the enclosed space, the sample vial is shaken and heated up to 120 °C. This sampling technique is particularly useful for the analysis of residual monomers, residual solvents in printed plastics, and undesired odors from plastics and contamination. For quantitative analysis or when the partition coefficient is unknown, multiple extraction of the headspace is injected into the chromatograph. As expected, the area of the chromatographic peak decreases with the number of extractions in an exponential trend (see Figure 44.2a). The total area can be calculated from an exponential approximation of the infinite series. The k parameter can be calculated from the slope of the linear correlation of $\ln(A_i)$ against the number of extractions minus one (see Figure 44.2b).

As we mentioned before in the MSD detector, the compounds separated and eluted from the column are fragmented in characteristic mass spectrum. Smaller fragments are produced by high-energy electrons. This fragmentation process (under controlled conditions) produces a mass spectrum characteristic of the chemical structure of the compound that can be used not only for quantification purpose, but also for identification purpose. Table 44.1 presents the representative mass fragments of a selected group of additives used in polymers.

FIGURE 44.2 Calculation of the total area in a multiple headspace extraction.

TABLE 44.1 Representative Mass Fragments of Additives Used in Polymers (McLafferty and Turecek, 1993; National Institute for Standard Technology, 2005)

Type	Additive	MW (g/mol)	Mass Fragments (<i>m/z</i>)
Flame retardant plasticizers	Triphenyl phosphate (TPP)	326	326, 325, 77, 65, 39, 51, 169, 170, 233, 96
	o-Tricresyl phosphate (TOCP)	368	165, 91, 179, 181, 368, 277
Fast gelation plasticizers	Tricresyl phosphate (TCP)	368	368, 367, 91, 165, 179, 369, 198
	Dimethyl phthalate (DMP)	222	163, 77, 164, 135, 92, 50, 149
General-purpose plasticizers	Dibutyl phthalate (DBP)	278	149, 106, 104, 80, 61, 223, 205
	Bis(2-ethylhexy) phthalate (BEHP)	390	149, 150, 41, 76, 104, 223, 167, 279
Low-volatility plasticizers	Di-isooctyl phthalate (DIOP)	390	149, 167, 57, 70 41, 71
	Diisodecyl phthalate (DIDP)	446	149, 57, 167, 307
Adipates and sebacates plasticizers	Diundecyl phthalate (DUP)	474	149, 43, 57, 41, 55, 71
	Bis(2-ethylhexy) sebacate (DEHS)	426	185, 57, 112, 71, 70, 43
	Bis(2-ethylhexy) adipate, (DEHA)	370	129, 57, 71, 70, 112, 147, 43
	Diisooctyl adipate (DIOA)	370	129, 57, 55, 41, 43, 70
Slip additives	Butyl bencyl adipate	292	91, 129, 111, 101
	Oleamide	281	59, 72, 55, 41, 43, 281
	Erucylamide	337	59, 72, 55, 41, 43, 69, 137, 337
	Stearamide	283	59, 72, 28, 43, 57, 55, 41, 283
Antioxidants and UV stabilizers	Benzophenone	182	105, 77, 182, 51, 50
	Benzotriazole	119	119, 64, 91, 63, 38, 52
	BHT	220	205, 57, 220, 206, 145, 177

FIGURE 44.3 GC/MSD for plasticizers extracted from vinyl sample (measured at ICIPC¹).

EXAMPLE 44.1: Identification of plasticizers using GC/MSD

The plasticizers from a vinyl sample were extracted by Soxhlet technique with ethylic ether in 16 h. Then, the solvent was evaporated and injected directly into the GC/MSD equipment. The GC/MSD reports (Figure 44.3) several peaks related to plasticizers of the vinyl sample. In Table 44.2, the retention time and the most intense mass fragments are reported.

The eluted compound at 7.73 min presents mass fragment characteristics of di-methyl phthalate (DMP) (according to the Table 44.1, the characteristic mass fragments are 163, 77, 164, 92, 50, 135, and 149). The eluted compound at 18.53 min presents mass fragment characteristics of bis(2-ethyl hexyl) phthalate or DOP (according to Table 44.1, the characteristic mass fragments are 149, 167, 57, 279, 71, 113, 83, 150, 41, 76, 104, and 223) or di-isooctyl phthalate DIOP (according to Table 44.1, the characteristic mass fragments are 149, 167, 57, 70, 41, 83, 104, 113, 279, and 71). The eluted compound at 17.11 min presents mass fragment characteristics of triphenyl phosphate (TPP; according to Table 44.1, the characteristic mass fragments are 326, 325, 77, 65, 39, 51, 169, and 170). The eluted compound at 19.72 min presents mass fragment characteristics of tricresyl phosphate (TCP; according to Table 44.1, the characteristic mass fragments are 367, 77, 115, 65, 91, 382, 41, 51, 178, 152, and 215).

44.2.2 Liquid Chromatography, HPLC

The liquid chromatography can be a very useful technique in the characterization of polymeric materials, since the following types of analyses can be done:

¹ ICIPC: Research Institute for Plastics and Rubber, Colombia

TABLE 44.2 Mass Spectra of Plasticizers Extracted from Vinyl Sample

Retention Time (min)	Mass Fragment (m/z)
7.73	163, 77, 164, 75, 92, 133, 50, 135, 104, 105, 120, 64, 149
17.11	326, 325, 77, 94, 65, 215, 169, 170, 233, 232, 168, 51, 228, 141
18.50	149, 167, 57, 71, 70, 150, 279, 55, 113, 83, 104, 112, 94, 84, 132
19.72	367, 368, 77, 207, 94, 382, 65, 115, 281, 178

- determination of the molecular weight distribution of polymeric resins,
- residual monomer analyses in polymeric resins,
- qualitative and quantitative analyses of impurities and additives in polymeric materials,
- purity analysis of additives,
- specific migration studies in polymeric materials.

This chromatographic technique includes the following components and instrumentation (Patnaik, 2004; Kazakevich and Lobrutto, 2007; Scott, 2003):

- *Mobile Phase Supply System*: This component of HPLC consists of glass reservoirs where the mobile phase is stored and degassed by a helium gas flow. The solvent is also filtered to eliminate solid contaminants in a 0.45- μm membrane filter.
- *Solvent Delivery System*: This consists of a pump, pulse damper, and a programmer. The pumps force the mobile phase through the system.
- *Sample Valve*: It is a loop that is able to inject a sample volume into the mobile phase just at the head of the column.
- *Column and Thermostat*: In the case of size-exclusion chromatography (SEC), the columns are packed with gels of different porosities where the separations are done according to the hydrodynamic size of macromolecules. Although most of the analysis are carried out at room temperature, in the gel permeation chromatography of very insoluble polymers (such as polyolefins), the column is heated in an oven or in a thermostat.
- *Detector*: It is the device to measure the solutes in the mobile phase and record the resulting chromatogram. The typical detectors in HPLC are the following: ultra-violet–visible detectors, the fluorescence detector, the electrochemical detectors, and the refractive index detector. For SEC, laser light-scattering detectors and viscometer detectors are used as their response is proportional to molecular weight and concentration (Table 44.3).
- *Data Acquisition and Processing Unit*

44.2.3 SEC or Gel Permeation Chromatography (GPC)

The SEC is a chromatographic technique that separates polymer molecules based on differences in their molecular size. The smaller-sized macromolecules have the ability to penetrate inside the pore space and the movement through the column is retarded. The macromolecules in a solvent solution adopt a coiled form characterized by their hydrodynamic radius, which is proportional to the molecular weight (see Equation (44.1))

Kazakevich and Lobrutto, 2007).

$$R = \left(\frac{3}{4} \pi M [\eta] \right)^{1/8}, \quad (44.1)$$

where R is the hydrodynamic radius, M is the molecular weight, and $[\eta]$ is the intrinsic viscosity (the limit of the ratio of the specific viscosity of the polymer solution to its concentration, when concentration tends to zero).

To obtain the molecular weight distribution (MWD) of a particular polymeric sample, a calibration of the elution time with its molecular weight is required. For that purpose, polystyrene PS standards with a narrow MWD and known average molecular weight are commonly used. Because macromolecules of PS standards are of different nature of the polymer sample, Benoit et al. (1966) Grubisic et al. (1967) proposed a universal calibration for elution time with the PS standard's molecular weight (see Equation (44.2)).

$$M_{\text{sample}} = \left(\frac{K_{\text{PS}}}{K_{\text{sample}}} \right)^{\frac{1}{1+\alpha_{\text{sample}}}} M_{\text{PS}}^{\frac{1+\alpha_{\text{PS}}}{1+\alpha_{\text{sample}}}}, \quad (44.2)$$

where M_{sample} is the molecular weight of sample, M_{PS} is the molecular weight obtained by calibration with PS standards, K_{sample} and α_{sample} are the Mark–Houwink constants for sample with same solvent and temperature, and K_{PS} and α_{PS} are the Mark–Houwink constants for polystyrene with same solvent and temperature.

EXAMPLE 44.2: MWD for a polylactic acid (PLA)

During the analysis of MWD of a PLA polymer by GPC, the following information was obtained. Table 44.4 and Figure 44.4 registered the calibration data with PS standards.

To perform the universal calibration of MW for PS standard and the MW of PLA, the Mark–Houwink constants obtained from literature were used (see Table 44.5). The

universal calibration calculated with the Mark–Houwink constants is presented in Equation (44.3)

$$M_{\text{PLA}} = 0.4054 \cdot M_{\text{PS}}^{1.0476}. \quad (44.3)$$

The data obtained from GC analysis using THF solvent at 35 °C could be converted into the MWD by using the polynomial of polystyrene standards (Figure 44.4) after applying the universal calibration (Equation (44.3)). The raw data of GPC is presented in Figure 44.5a, and the MWD obtained is presented in Figure 44.5b.

44.3 DSC AND THERMOGRAVIMETRY (TGA)

44.3.1 DSC

The DSC is a thermal technique that measures the enthalpy changes, coupled with diverse physical and chemical events, experienced by a sample under a certain temperature–time program. By using the DSC technique, it is possible to evaluate heat absorbed or emitted by a sample during several thermal events, including glass transition, melting, crystallization, crosslinking, chemical reaction, evaporation, and chemical decomposition. The thermal

Drying time		X
Crosslinking rate	X	X
Crosslinking degree	X	

properties and possible thermal events of a polymer measured by DSC and TGA are presented in Table 44.6. In addition, the peak temperature, start and end temperatures, and onset temperature of the event can be determined. The heat capacity of a sample as a function of temperature can also be determined, if a proper standard is used (i.e., a sapphire standard). The rate of change of heat capacity or enthalpy as a function of time (or temperature) can be determined, and therefore the DSC is an important tool for kinetic studies of chemical reactions, crosslinking, and thermo-oxidative decomposition.

The DSC permits to determine thermal transitions of polymers in a range of temperatures between -180 and $+600$ °C. The DSC test requires samples that are in the milligram range (<20 mg).

44.3.1.1 Glass Transition Temperature, T_g The glass transition temperature, usually denoted by T_g , is a common property of amorphous and semicrystalline polymers. It is the temperature at which the relaxation of the macromolecules stops when the polymer is cooled. The mobility of the chain segments is much below T_g (it is known as “frozen material”). As a consequence, as the polymer reaches the glass transition temperature, a very rigid and fragile nature is observed. T_g is registered in the DSC technique as a step in the heat capacity or in the heat flow. By convention, T_g is calculated as the temperature at which half of the change in specific heat capacity has occurred.

44.3.1.2 Melting Temperature, T_m As a semicrystalline polymer is heated above T_g , at a certain temperature, the crystalline domains are disaggregated and a viscoelastic fluid is obtained. This thermodynamic transition is usually denominated melting temperature, T_m . T_m is observed in the DSC technique as an endothermic peak in the heat capacity or in the heat flow, so a peak temperature (as well as start and end temperatures) and a peak area (enthalpy change during melting) can be determined. The differential scanning calorimeter is used to measure the melting, T_m , and the glass transition temperatures of polymers using the ISO 11357 and ASTM 3418 standards.

44.3.1.3 Crystallization Temperature, T_k As a semicrystalline polymer is cooled, at a certain temperature, the crystalline domains are reordered and crystalline polymer is obtained. This thermodynamic transition is usually denoted as crystallization temperature, T_k . T_k is observed in the DSC technique as an exothermic peak in the heat capacity or in the heat flow, so a peak temperature (as well as start and end temperatures) and a peak area (enthalpy change during crystallization) can be determined. As a rule, the crystallization temperature is always lower than the melting temperature and depends on the cooling rate.

Only under exceptional conditions, a 100% crystalline polymer is obtained, so a measurement of the degree of crystallinity is very useful. The degree of crystallinity, χ , is determined from the ratio of the heat of fusion of a polymer sample, ΔH_{SC} , and the enthalpy of fusion of a 100% crystalline sample ΔH_C .

$$\chi = \frac{\Delta H_{SC}}{\Delta H_C}. \quad (44.4)$$

The importance of the degree of crystallinity can be explained by the fact that it is possible to relate it with processing conditions (as cooling rate) and the physical properties of the final product.

Figure 44.6 shows a typical DSC curve measured under a heating program using a partly crystalline polymer, that is, PET sample. In Figure 44.6, the transition or detectable deviation from the baseline is T_g ($T_g \approx 83.2^\circ\text{C}$); the first area that is enclosed between the trend line and the baseline is a direct measurement for the amount of heat, ΔH_k , needed for transition. In this case, the transition is a cold crystallization ($T_k \approx 120.4^\circ\text{C}$) and the area corresponds to the heat of crystallization. Finally, the second area that is enclosed between the trend line and the baseline is a direct measurement for the amount of heat,

FIGURE 44.6 DSC heat flow of a PET sample (measured at ICIPC).

TABLE 44.7 DSC Characteristic Data for Selected Polymers (Knappe et al., 1993; Hemminger and Cammenga, 1988)

ΔH_m , needed for another transition. In this case, the transition is melting ($T_m \approx 249^\circ\text{C}$) and the area corresponds to the heat of fusion.

Table 44.7 is an useful review of glass transition temperatures, melting temperatures, and 100% crystalline melting temperatures for selected thermoplastic polymers following the standards ASTM D3417 and ASTM D3418.

Specific heat, C_p , is one of the many material properties that can be measured with DSC. During a DSC temperature sweep, the sample pan and the reference pan are maintained at the same temperature. This allows the measurement of the differential energy required to maintain identical temperatures. The sample with the higher heat capacity will absorb a larger amount of heat, which is proportional to the difference between the heat capacity of the measuring sample and the reference sample. It is also possible to determine the purity of a polymer sample when additional peaks or curve shifts are detected in a DSC measurement.

44.3.2 Modulated DSC, MDSC

MDSC overcomes the limitations of the standard DSC offering higher sensitivity and resolution. MDSC can separate overlapping thermal events of a polymer, which is difficult or almost impossible to achieve by conventional DSC. MDSC improves upon standard DSC as it measures the total heat flow plus its heat capacity component and obtains the kinetic component from their difference (Thomas, 2006). The possibility to resolve complex transitions into specific components facilitates a much better data interpretation. It is also possible to distinguish thermally reversible repeatable transitions, such as glass transition and melting, from irreversible events, such as crosslinking, decomposition, and crystallization, among others (Ehrenstein et al., 2004).

Figure 44.7 shows MDSC results obtained in one single run under a slow heating program using a quenched PA6 specimen. In the lower left curve (reversible heat flow), the first transition from the baseline is $T_g \approx 43.7^\circ\text{C}$. The next area that is enclosed between the trend line and the baseline is a direct measurement of ΔH_m , needed for melting; in this case, the melting peak is $T_m \approx 220.7^\circ\text{C}$. The second area, upper left curve (nonreversible heat flow), that is enclosed between the trend line and the baseline is a direct

FIGURE 44.7 MDSC heat flow of a quenched PA6 (measured at ICIPC).

FIGURE 44.8 MDSC crystallization results for PET (measured at ICIPC).

measurement of the amount of heat, ΔH_k , needed for cold crystallization; in this case, $T_k \approx 59.3^\circ\text{C}$. Finally, the third area, upper right curve, is an irreversible and nonrepeatable effect that may be related to crystal rearrangement during melting.

Figure 44.8 presents a MDSC crystallization study for an amorphous PET sample at different heating rates. From the figure, it is possible to assess that at higher heating rates the crystallization temperature shifts to higher values in almost 12%. At higher heating rates, the heat of crystallization shows an increase in almost 15%, implying that a crystallization may take place during heating (Thomas, 2006).

44.3.3 Oxygen Induction Time (OIT)

Oxygen induction time is a technique or method that uses DSC to make comparisons of the stability of polymeric materials to thermal oxidation. Most plastics need to be stabilized against thermal oxidation such as stabilizers, antioxidants, and UV absorbers. There are two methods: the static method (less sensitive but faster) and the dynamic method (more sensitive but time-consuming) (Ehrenstein et al., 2004).

The ASTM D3895-04 standard is a procedure for the determination of OIT of polymers using DSC. This test is applicable to polyolefin materials that are in a stabilized form or in a compounded form. An OIT program requires a constant heating rate under an inert gas atmosphere (nitrogen) until 200°C . Afterward, the atmosphere is switched to oxygen; and this is the start of the recording for the experiment until oxidation is observed. Figure 44.9 shows the OIT measurement of a polypropylene (PP) masterbatch.

In this test, the switch to oxidative atmosphere takes place at 19.91 min, and the oxidation occurs at 20.89 min (read from Figure 44.9). Therefore, the OIT of this PP material is 0.98 min.

FIGURE 44.9 OIT measurement of a PP material (measured at ICIPC).

44.3.4 TGA

The thermogravimetric analysis (TGA) is a thermal analysis technique that measures the weight changes suffered by a sample under a certain temperature–time program, working on the principle of a beam balance. By using the TGA, it is possible to evaluate weight changes due to the following thermal events: volatilization of moisture, volatilization of additives, decomposition of polymers and additives, decomposition of organic pigments, and decomposition of some mineral fillers, such as calcium carbonate (CaCO_3). This measurement technique is typically used for thermal stability. The testing chamber can be heated (up to $\sim 1200^\circ\text{C}$) and rinsed with gases (inert or reactive).

44.3.4.1 Decomposition Temperatures of Thermoplastics Table 44.8 gives the typical peak decomposition temperatures obtained by TGA for several polymers. A thermogravimetric analyzer can detect weight changes of less than $10\ \mu\text{g}$ as a function of temperature and time (Table 44.8).

Figures 44.10 and 44.11 show TGA measurements of a PLA or polylactide at different heating rates: 1, 5, 10, 20, and $40^\circ\text{C}/\text{min}$. Based on this information, besides the peak decomposition temperature (T_d) at each heating rate, it is also possible to estimate the decomposition kinetics of this PLA sample based on weight changes. At higher heating rates, the T_d shifts to higher values.

44.3.5 Modulated TGA (MTGA)

Modulated TGA (MTGA), compared to the standard TGA technique, offers advantages for polymer decomposition studies. This thermal analysis method generates model-free

TABLE 44.8 Peak Decomposition Temperatures Obtained by TGA for Several Polymers (Knappe et al., 1993)

Polymer	10 °C/min and N2 50 mL/min		20 °C/min and N2 50 mL/min		30 °C/min and N2 50 mL/min

kinetic data from which activation energy can be calculated and studied as a function of several parameters, such as time, temperature, and conversion, among others. Another improvement is that the kinetic data for optimizing polymer processing can be produced in a single run (Blaine).

In general, problems related to thermal machine setup in polymer processing can be investigated and solved (troubleshooting) with the use of the different thermal analysis techniques (Noriega et al., 2001). TGA registers the different losses of weight of a sample as a function of temperature. This rules out degradation of polymers and polymer blends under temperature.

**FIGURE 44.10** TGA of PLA at different heating rates (measured at ICIPC).

44.4 RHEOMETRY

Rheometry deals with experimental methods and devices called rheometers, to measure the rheological behavior of materials (Macosko, 1994). Rheometry delivers essential information for the descriptive rheology that quantifies the relationship between two quantities: the stress and the rate of deformation of materials under the action of external forces. In our case, these materials are polymers. The mathematical expressions that establish the relationship between both quantities are called “constitutive equations.” This definition is not restricted to fluids; solids also undergo deformation under the action of external forces. The distinction between solids and fluids is a rheological issue and depends on the time scale of observation for the “rate of deformation.” If the time scale is big enough, it can be observed that a solid can flow under an external force; if the time scale of observation is small enough, a fluid can show a finite deformation like a solid under external forces. The Deborah number (Osswald and Menges, 2003) delimits this, and it is the ratio of a characteristic relaxation time of a material and the characteristic time scale of observation. Polymers are viscoelastic materials. It is not necessary for the polymers to stop deforming under stress in solid state; they show an elastic behavior under flow conditions.

Constitutive equations for flows are tensorial expressions. Viscosity is the material or fluid property that establishes the relationship between two tensors: stress and rate of deformation. Both the tensors have shear and elongation components that define two different kinds of viscosities. They are called shear viscosity and elongational or extensional viscosity.

FIGURE 44.11 Decomposition temperatures of PLA at different heating rates (measured at ICIPC).

Rheometers are built to produce simple isothermal flows or simple deformation rate patterns. The tensors for description of stress and rate of deformation inside them are very simple. Therefore, viscosity can be expressed with very simple mathematical expressions. For the construction and use of rheometers there should be only one component for stress and deformation rate. The “shear viscosity” or the “elongational viscosity” can be calculated from them easily.

There are many possibilities to built rheometers, but nowadays, the most common and commercially available types are the capillary and the rotational rheometers. The flow in a capillary rheometer is a steady-state flow. These devices allow the study of shear viscosity as a function of shear rate in a wide range, usually from 10 s^{-1} to 10^4 s^{-1} , and depending on temperature under high pressure.

Rotational rheometers can produce a steady-state deformation rate, a steady-state shear stress, or both in an oscillatory and inclusive in a transient mode. These rheometers allow the study of viscosity as a function of shear rate, under the effect of temperature, frequency, and time of deformation. They normally work under atmospheric pressure.

44.4.1 Torque Rheometry

These devices are wrongly denoted as rheometers. The flow pattern inside them is so complex that it is not possible to measure stress and deformation rate components individually. Therefore, it is difficult to solve the tensorial equation for viscosity as well. However, they have found an important role in mixing studies, first-order decomposition kinetics, and thermal stability measurements, among others. For this reason, most people denote them as rheometers.

44.4.2 Capillary Rheometry

This rheometric technique deals with the experimental description of the material flow through a channel with a geometrical well-defined cross section (circular, rectangular, or annular), whose characteristic dimensions (diameter, width, and height) are small enough compared with the channel or capillary length. This condition is necessary to obtain a significant portion of flow pattern inside the channel, free of distortions caused by inlet and outlet phenomena in the capillary. In case of rectangular capillaries, the width of their cross section must be greater than 10 times the height to minimize “border effects” in the cross section of the flow pattern. For annular capillaries, the ratio of the gap between cylinders and the diameter of the internal cylinder should be greater than 20 to minimize the effect of curvature on the flow. Annular capillaries are bigger than the others. As annular capillaries need significantly more material during measurements, it is hard to keep material temperature constant, not common in commercial and industrial applications (Figure 44.12).

The constitutive tensor equation for a fully developed, isothermal, incompressible, and steady-state flow in a channel is reduced to the following simple expression in terms of the wall shear stress τ_{wap} and the wall shear rate $\dot{\gamma}_{\text{wap}}$, where η_{ap} is the shear viscosity

$$\tau_{\text{wap}} = \eta_{\text{ap}} \cdot \dot{\gamma}_{\text{wap}}. \quad (44.5)$$

The wall shear stress τ_{wap} can be calculated from (44.6) having the capillary radius R and the pressure drop Δp along a portion of the capillary, where the flow can be

FIGURE 44.12 Types of capillary rheometers.

considered as fully developed.

$$\tau_{\text{wap}} = \frac{R}{2} \cdot \frac{\Delta p}{l}. \quad (44.6)$$

If the shear viscosity η_{ap} is independent of shear rate as for a Newtonian fluid, and of pressure, the wall shear rate $\dot{\gamma}_{\text{wap}}$ is obtained from the Hagen–Poiseuille equation for the flow in a cylindrical channel and the volumetric flow Q in Equation (44.7)

$$\dot{\gamma}_{\text{wap}} = \frac{4Q}{\pi R^3}. \quad (44.7)$$

The subindex “ap” stands for “apparent” because the above equations are valid for Newtonian fluids. Because we are dealing with non-Newtonian fluids, those results have to be corrected.

The flow through the capillary can be generated by controlled pressure or by controlled volume displacement inside a cylinder or reservoir connected to the capillary. Some manufactures install a small extruder to the reservoir to guarantee a permanent and homogeneous supply of material. Because it is easier to measure pressure than volumetric flow, the majority of capillary rheometers use the controlled movement of a piston inside the cylinder of the reservoir to generate a constant flow rate. Q in Equation (44.7) is then a known and controlled magnitude for the experiment. It is only necessary to measure the pressure losses Δp along a length inside the channel where the flow can be supposed as fully developed. This is not an easy task.

Cylindrical capillary is normally small in diameter, and it is not possible to measure the gradient pressure for the flow portion free of entrance effects inside the capillary. The pressure transducer is located closed to the capillary entrance and its readings include entrance losses. Ryder–Bagley’s correction has to be applied to eliminate this error (Macosko, 1994; Osswald and Menges, 2003; Menges, 2002; Carreau et al., 1997). The method to apply this correction implies to run several measurements using at least three capillaries with the same diameter but with different length. The pressure value obtained from a linear extrapolation of the curves for an ideal null length capillary represents the pressure drop at the capillary inlet. Some authors use the intersection of the curve for null

pressure as the equivalent length of capillary for the pressure readings. Both methods are equivalent.

Because the viscosity of polymer melts increases with pressure (Sedlacek et al., 2004; Liang, 2001), the Ryder–Bagley’s method delivers, in some cases, negative values for the pressure corrections or equivalent length shorter than the actual length of capillaries. Some authors recommend to use a quadratic approximation instead of the linear one to calculate Bagley’s correction.

Rectangular and annular capillaries are usually big enough to locate at least two transducers but preferably three pressure transducers in a region of the capillary with a fully developed steady flow to measure the pressure gradient. Ryder–Bagley’s correction is not necessary in this case. With three pressure transducers, it is possible to detect a nonlinear profile for the pressure gradient, which has to be considered during the interpretations of readings.

As mentioned above, a viscosity value obtained from Equation (44.5) is only valid for Newtonian fluids and it is called *apparent shear viscosity* when applied to non-Newtonian fluids like polymers. To obtain the actual shear viscosity, the apparent one should be corrected. The Weissenberg–Rabinowitsch (Macosko, 1994; Osswald and Menges, 2003; Menges, 2002; Carreau et al., 1997) correction is the most used method for it. To apply this correction method, it is necessary to run several measurements under different shear rates, using the same capillary and keeping a constant polymer temperature for all runs. Some rheometer manufacturers offer software solutions as an integral part of equipment to make both Bagley and Weissenberg–Rabinowitsch corrections.

The Bagley’s correction is very time-consuming. Some manufacturers offer rheometers equipped with several capillaries arranged in a parallel array, usually three, with different lengths and one of them with null length. With them, it is possible to obtain from one experimental run three readings for the Bagley’s correction, which is carried out automatically by the equipment.

Other rheological properties of polymer melts, regarding elastic behavior, can be measured using capillary rheometers. When the material comes out from the capillary, it increases the cross section due to the tendency of oriented macromolecules to recover their nonoriented state. The ratio between the diameter of the capillary and the strand, called die swell ratio, is used to characterize this behavior. Based on die swell measurement, it is possible to calculate the first normal stress difference and indirectly the elongational viscosity using the Cogswell’s principle (Cogswell, 1981) but this method is not applicable for all polymers.

Capillary rheometers deliver information of shear viscosity for shear rate from about 10 s^{-1} to 10^4 s^{-1} combining rectangular capillaries for low shear rates (10 s^{-1} to 10^2 s^{-1}) with circular (100 s^{-1} to 10^4 s^{-1}) ones. This range is usually enough to get information about the rheological behavior of melts for most common polymer processing techniques such as extrusion, blow molding, and injection molding. To obtain a more complete description of this behavior, it is necessary to get information about shear viscosity at very low shear rates or null viscosity (η_0). This is a very important parameter for the most used rheological models in commercial software (Johannaber and Michaeli, 2001) to express the shear viscosity as a function of shear rate: the Carreau’s model in Equation (44.8).

$$\eta = \frac{\eta_0}{(1 + B \cdot \dot{\gamma})^C} \quad (44.8)$$

FIGURE 44.13 Shear viscosity for two different polymers at the same temperature.

The use of a rectangular channel instead of a circular one to obtain low shear rates is not the only reason for its use. The bigger dimension of those capillaries make possible to measure the gradient pressure in the channel region where the entrance effects are not present. This makes unnecessary the time-consuming Bagley's correction. Because of the relatively big cross section of capillary, the pressure to measure highly viscous materials such as rubber is not so high as with circular capillaries.

Shear viscosity curves are not only indispensable for rheological calculations of polymer flows in injection molding, extrusion dies, plasticating screws, and so on. They deliver important information about the molecular structure of polymers. They are very useful in comparing different materials, if the viscosity curves are valid for the same temperature. In Figure 44.13, for example, polymer A has a narrower molecular weight distribution (MWD) than polymer B and shows a more extended Newtonian behavior with a more accentuated dependency of viscosity with shear rate in the non-Newtonian region. Polymer B has a higher molecular weight than polymer A and exhibits higher viscosity values in the Newtonian region. This is valid for the majority of polymer melts.

44.4.3 Rotational Rheometry

In this rheometric technique, the substance being studied is deformed between two bodies where one of them remains stationary and the other one rotates. The bodies can be two concentric cylinders (Couette's rheometer) where usually only the internal cylinder rotates, or two horizontal discs, where the inferior disc is stationary. The Couette's rheometer is suited to measure low-viscosity substances (under 100 Pa.s) and at high shear rates. The substance remains in an almost closed space and cannot be expelled by centrifugal

FIGURE 44.14 Types of rotational rheometers.

force. The most commonly used rotational rheometers for characterization of polymer melts use discs. One of the discs, usually the rotating one, may be a circular plate or a cone. The stationary disc is flat. The combination of cone and plate has an advantage to generate a constant shear rate in the whole region between both discs. Both discs are placed in an open space inside an oven. This limits the rotation speed, especially for substances with low viscosity at test temperature.

Theoretically, rotational rheometers do not have limitations for low shear rates (only limited by sensitivity of transducers and control unit). They deliver more information about material rheological behavior than capillary rheometers do, for example, information about the elongational and dynamic viscosities. This rheological information is essential for structural rheology, which deals with the relationship between molecular structure of polymers (molecular weight, MWD, molecular branches) and their rheological behavior (Figure 44.14).

Because of the viscoelastic properties of polymer melts during the shear deformation of the material between the discs it appears a normal force that tries to separate both discs (Weissenberg effect). This normal force to the discs generates primary and secondary normal stresses that can be expressed like shear viscosity as a function of shear rate and temperature. The primary normal stress can be best measured by cone-plate rheometers.

There are two basic types of rotational rheometers depending on which quantity is being controlled and which is being measured during an experiment: the shear stress or the deformation rate. Rheometers with controlled stress are called controlled stress rheometer (CSR, with controlled torque). Rheometers with controlled rate of deformation are known as controlled rate rheometer (CRR, with controlled rotational speed). CSR allows the generation of smaller shear rates than CRR. CRR can generate higher shear rates in continuous operation mode or higher frequencies in oscillatory mode than CSR. Modern rheometers can operate in both modes.

Rotational rheometers can carry out stationary, oscillatory, and transient experiments, depending on what is controlled and measured: torque (stress) or angular velocity (deformation).

44.4.3.1 Stationary Mode:

- *Deformation Rate is Kept Constant:* angular velocity is adjusted to a desired value and the torque is measured.
- *Stress is Kept Constant:* torque is adjusted to a desired value and the angular velocity is measured.

Stationary measurements are suitable to obtain the shear viscosity for very low shear rates, typically from 10^{-6} to 10^2 s^{-1} , and are an excellent complement to measurements with capillaries.

Shear viscosity can be calculated, like in (5), as the quotient of shear stress and shear rate. For the case of a cone and plate rheometer, where one disc is rotating with a constant angular velocity Ω and the cone angle θ_0 is very small ($<5^\circ$), the shear rate $\dot{\gamma}$ is constant in the region between discs and is given by

$$\dot{\gamma} = \frac{\Omega}{\theta_0}. \quad (44.9)$$

The shear stress can also be considered as constant in the region between discs and can be calculated from the measured torque T using

$$\tau = \frac{3T}{2\pi R^3}. \quad (44.10)$$

The primary normal stress coefficient function, ψ_1 can be obtained from the force F , trying to separate both discs, using

$$\psi_1 = \frac{2F}{\pi R^2 \cdot \dot{\gamma}^2}. \quad (44.11)$$

The secondary normal stress coefficient function, ψ_2 is very difficult to measure and it is usually approximated to $0.1\psi_1$.

For the case of a parallel plate rheometer, where one disc, with radius R , is rotating with a constant angular velocity Ω and the distance between plates is h , the shear rate $\dot{\gamma}$ can be calculated using the following equation and supposing that the fluid is Newtonian.

$$\dot{\gamma} = \frac{\Omega \cdot R}{h}. \quad (44.12)$$

The shear stress is given by

$$\tau = \frac{2T}{\pi \cdot R^3}. \quad (44.13)$$

Here again, the viscosity must be corrected because the equations above are only valid for Newtonian fluids. The Weissenberg–Rabinowitsch correction can be used for it.

Compared with cone and plate rheometers, parallel plate rheometers have the disadvantage to need the Weissenberg–Rabinowitsch correction, but they have several advantages. The shear rate can be easily changed varying the distance h between discs, as can be observed in Equation (44.12), still having a low rotational speed. With this strategy, it is possible to keep border and inertial effects at low levels. The specimen

FIGURE 44.15 Viscosity curve using rotational and capillary rheometers.

preparation for parallel plate rheometers is simpler. They are more suitable to measure viscous materials at low shear rates.

Border and inertial effects are difficult to detect because the discs are confined in an isolated and temperature-controlled closed chamber. Some manufacturers offer an optical probe to observe the material during the experiment.

Figure 44.15 illustrates the use of several techniques (rotational, rectangular, and circular capillary) to obtain a complete viscosity curve.

44.4.3.2 Oscillatory Mode The amplitude and the frequency of angular oscillation are adjusted to desired values (in the linear range of deformation) and the torque variation is measured.

The amplitude and the frequency of torque oscillation are adjusted to desired values (assuring that a linear range of deformation is not exceeded), and the torque variation is measured.

In oscillatory tests, viscoelastic materials show a retarded response of deformation under oscillatory stress (Macosko, 1994; Carreau et al., 1997). For the case of shear experiments, the quotient of the amplitude of shear stress and the amplitude of shear deformation is the dynamic shear module G^* . It has two components: G' describes the elastic component of the response and is called the storage module. G'' is called the loss module and describes the viscous component of G^* .

The equations are simple and the modules can be calculated from the oscillatory (sinusoidal) variation of torque T , the frequency Ω , and the phase difference δ of the disc using Equations (44.9) and (44.10) for a cone and plate rheometer.

$$\gamma(t) = \gamma_0 \cdot \sin(\Omega \cdot t) \quad (44.14)$$

$$\tau(t) = \tau_0 \cdot \sin(\Omega \cdot t + \delta). \quad (44.15)$$

FIGURE 44.16 Modules for three different types of polypropylene.

44.4.3.3 Transient Mode

Creep or Retardation Test a shear stress is suddenly applied (stress step), the shear strain as angular displacement is followed over a certain period of time, and the stress is released suddenly.

Relaxation Test a strain as angular displacement is applied and the variation of the resulting shear stress is registered over time.

The following tests are other transient methods:

Relaxation Under Shear Rate a constant angular deformation rate is suddenly applied, and the resulting declining shear stress is registered over time until a steady-state condition is established. After this, the angular deformation ceases, and the declining shear stress is registered over time.

In all these experiments it should be assured that the material never exceeds the linear viscoelastic range.

44.4.3.4 Sweeps There are special tests for rotational rheometer called “sweeps.” It means that one operation parameter can be varied continuously inside a range. For example, to identify the linear viscoelasticity region, a torque sweep is recommended. In oscillatory modus a frequency sweep allows to measure the shear viscosity as a function of frequency. This curve has a univocal translation to the viscosity as a function of shear rate (Cox–Merz principle) if deformation amplitude remains in the linear viscoelastic range. A temperature sweep is very useful to find out how properties such as viscosity, storage or loss modules vary with the temperature at a constant frequency. With this information, and using the WLF principle of time–temperature superposition, it is possible to convert temperature into time. Using time

sweeps, the sample undergoes an oscillatory deformation at a frequency and fixed amplitude is a way to obtain information about other rheological behaviors such as rheopexy and tixotropy.

44.4.3.5 WLF Principle of Time–Temperature Superposition Figure 44.16 shows the storage and the loss modules for three different types of polypropylene. The intersection of both curves for the same material gives information about its molecular structure. The higher the modules at crossing point, the narrower the molecular weight distribution is. The lower the frequency at the crossing point, the higher the molecular weight is. Material A has the lowest molecular weight, and Material C has the narrower molecular weight distribution of these three materials.

45.1 INTRODUCTION

Most modern devices owe a significant amount of their success to the tailored electromagnetic and mechanical material behavior of the components that comprise them. A relatively inexpensive way to obtain macroscopically desired responses is to enhance an easy-to-form matrix material's properties by introducing microscale particles possessing different electromagnetic and mechanical properties (Figure 45.1). The particles are chosen to produce an overall desired "effective property." The aggregate response of the material is an outcome of the interaction between the smaller-scale (microstructure) constituents that comprise the "effective" material. In the construction of such materials, the basic philosophy is to select matrix/particle material combinations in order to produce desired aggregate responses. For example, in many engineering applications, the classical choice is to add a particulate phase with suitable properties in order to modify the overall properties of a modable base matrix material.

FIGURE 45.1 A representative sample of a material with heterogeneous microstructure.

The design of desired effective electrical properties of materials, by manipulating the heterogeneous microstructure, is a critical to the success of modern devices (Figure 45.1). In the context of electrical materials, the microscale properties are characterized by a spatially variable permittivity ϵ . Typically, in order to characterize the structural-scale effective response of such materials, a relation between averages

$$\langle \mathbf{D} \rangle_{\Omega} = \epsilon^* \cdot \langle \mathbf{E} \rangle_{\Omega} \quad (45.1)$$

is sought, where $\langle \cdot \rangle_{\Omega} \stackrel{\text{def}}{=} \frac{1}{|\Omega|} \int_{\Omega} \cdot \, d\Omega$ is the averaging operator and \mathbf{D} and \mathbf{E} are the electrical flux (density) and electric field within a statistically representative volume element (RVE) of volume $|\Omega|$. The quantity, ϵ^* , is known as the effective permittivity and is the property used in usual (homogenized) macroscale analyses. Similarly, for magnetic properties one has

$$\langle \mathbf{B} \rangle_{\Omega} = \mu^* \cdot \langle \mathbf{H} \rangle_{\Omega} \quad (45.2)$$

where \mathbf{B} and \mathbf{H} are the magnetic flux and magnetic fields, and μ^* is the effective magnetic permeability.

Remark: The same framework holds for linear elasticity

$$\langle \boldsymbol{\sigma} \rangle_{\Omega} = \mathbf{E}^* : \langle \boldsymbol{\epsilon} \rangle_{\Omega} \quad (45.3)$$

where $\boldsymbol{\sigma}$ and $\boldsymbol{\epsilon}$ are the stress and strain fields, and \mathbf{E}^* is the effective linear-elasticity tensor.

45.2 CONCEPTS IN STATISTICAL QUALITY CONTROL

In classical quality control techniques involving inspection, the following steps must be taken:

1. sample a stream of products by taking N samples, each of size Ω ,
2. measure the desired quantity of interest inherent to the sample,
3. calculate the deviations of the quantity of interest and
4. plot/tabulate the data on a control chart/table.

The arithmetic mean of the samples is the primary measure of central tendency. The symbol \bar{A} is used to designate the arithmetic mean of the sample and may be expressed in

algebraic terms as $\bar{A} = \frac{1}{N} \sum_{i=1}^N A_i$, where the A_i is the quantity of interest extracted from various samples, $i = 1, 2, \dots, N$. The standard deviation is another useful number to characterize the dispersion of between the sets of numbers and is defined by $\delta_A = \sqrt{\frac{1}{N} \sum_{i=1}^N (A_i - \bar{A})^2}$. One important measure of the deviation, in fact the one we will focus on, is the range, R_A , defined as

$$R_A = A_{\max} - A_{\min}. \quad (45.4)$$

Although the distribution of the A values can be of any shape, the distribution of \bar{A} values tends to be close to a normal distribution. The larger the sample size and the more normal the universe, the closer the distribution of the average \bar{A} 's approach the normal curve. According to statistical theory, (the Central Limit Theorem), in the "long run," the average of \bar{A} values will be the same as A^* , the average of the universe (a statistically representative sample). The focus of this presentation is to introduce the reader to estimation techniques for the effective property of a sample of composite material, in particular, the response of an infinitely large sample, relative to the microscopic constituents that comprise it. Furthermore, we show the reader estimates on the range (upper and lower bounds) of possible properties, for a given set of constituents (components). Such concepts are standard in manufacturing; however, they are also useful for characterizing the properties of heterogeneous materials, which inherently require sample size selection to ascertain statistically representative effective material properties for use in structural scale calculations. *If test samples of material are too small (not truly statistically representative), then the overall effective property will have variations in it from sample to sample. Here, we focus on the associated problem of a priori prediction of the effective property that would result if an infinitely large statistically representative sample or, alternatively, an infinite number of finite-sized samples were tested.* This allows an engineer to determine confidence intervals for the material properties that they can employ in structural-scale calculations.¹ For an introduction to cross-disciplinary classical statistical quality control techniques, such as (a) measurements and quality control, (b) dimension and tolerance, (c) quality control, (d) interrelationship of tolerances of assembled products, (e) control charts for attributes, and (f) acceptance sampling, see Zohdi (2006).

45.3 EFFECTIVE PROPERTY ESTIMATES

For an RVE sample to be statistically representative, it must relatively large compared with the length-scale of the constituents (e.g., particles in a matrix), containing a significant amount of microstructure. Therefore, the computations to determine effective properties, which would involve some type of numerical discretization posed over the RVE, are nontrivial. Essentially, a finite element or finite difference mesh/grid (Figure 45.2) must be fine enough to resolve the microscopic features of the composite material.

Because of the difficulties in computing effective properties directly, a variety of approximate techniques have been developed to estimate the overall macroscopic properties of materials consisting of a matrix containing distributions of particles, dating back at least to Maxwell (1867, 1873) and Lord Rayleigh (1892).

¹ An exhaustive treatment of sample size selection and estimates of statistical variation based on ensemble averaging is given in Zohdi and Wriggers (2008).

FIGURE 45.2 (a) A typical numerical grid needed to resolve a composite material microstructure. (b) Numerical resolution of the morphology of a test sample's microstructure (Zohdi, 2010).

45.3.1 Elementary Estimates

In the realm of solid mechanics, Voigt (1889) is usually cited with the first analysis of the linear effective *mechanical* properties of the microheterogeneous solids, $\langle \sigma \rangle_{\Omega} = \mathbf{I} \mathbf{E} : \langle \epsilon \rangle_{\Omega}$, where σ is the stress and ϵ is the strain. Voigt approximated the strain field within an aggregate sample of heterogeneous material as being uniform, leading to $\langle \mathbf{I} \mathbf{E} \rangle_{\Omega}$ as an expression of the effective property. Reuss (1929) approximated the stress fields within the aggregate of polycrystalline material as uniform, leading to $\langle \mathbf{I} \mathbf{E}^{-1} \rangle_{\Omega}^{-1}$ as the effective property. In 1952, Hill (1952) proved that these assumptions provide bounds on the effective property, namely, $\langle \mathbf{I} \mathbf{E}^{-1} \rangle_{\Omega}^{-1} \leq \mathbf{I} \mathbf{E}^* \leq \langle \mathbf{I} \mathbf{E} \rangle_{\Omega}$. These inequalities mean that the eigenvalues of the tensors $\mathbf{I} \mathbf{E}^* - \langle \mathbf{I} \mathbf{E}^{-1} \rangle_{\Omega}^{-1}$ and $\langle \mathbf{I} \mathbf{E} \rangle_{\Omega} - \mathbf{I} \mathbf{E}^*$ are non-negative. Therefore, one can interpret the Voigt and Reuss fields as providing two microfield extremes, since the Voigt stress field is one where the tractions at the phase boundaries cannot be in equilibrium (statically inadmissible), while the implied Reuss strains are such that the heterogeneities and the matrix could not be perfectly bonded, that is (kinematically inadmissible). These results can be easily reinterpreted for electrical and magnetic and properties and fields to yield

$$\langle \epsilon^{-1} \rangle_{\Omega}^{-1} \leq \epsilon^* \leq \langle \epsilon \rangle_{\Omega} \quad (45.5)$$

where the upper bound is generated by assuming that the electric field is uniform throughout the medium and the lower bound is generated by assuming that the electric field flux is uniform throughout the medium. For the magnetic properties one has

$$\langle \mu^{-1} \rangle_{\Omega}^{-1} \leq \mu^* \leq \langle \mu \rangle_{\Omega} \quad (45.6)$$

where the upper bound is generated by assuming that the magnetic field is uniform throughout the medium and the lower bound is generated by assuming that the magnetic field flux is uniform throughout the medium. In the electromagnetics literature, the bounds in Equations (45.5) and 45.6 are frequently referred to as the Wiener bounds (Wiener, 1910). These inequalities mean that the eigenvalues of the tensors $\epsilon^* - \langle \epsilon^{-1} \rangle_{\Omega}^{-1}$ and $\langle \epsilon \rangle_{\Omega} - \epsilon^*$ are non-negative. Typically, the bounds are quite wide and provide only rough qualitative information.

45.3.2 Improved Estimates

Within the last 50 years improved estimates have been pursued, with a notable contribution being the Hashin–Shtrikman bounds (Hashin and Shtrikman, 1962a, 1962b, 1963; Hashin, 1983). The Hashin–Shtrikman bounds are the tightest possible bounds on scalar isotropic effective responses (ε^*, μ^*) , generated from isotropic microstructures $(\varepsilon_1, \mu_1, \varepsilon_2, \mu_2)$, where the volumetric data and phase contrasts of the constituents are the only data known. For the overall permittivity

$$\langle \varepsilon^{-1} \rangle_{\Omega}^{-1} \leq \varepsilon_1 + \underbrace{\frac{v_2^\varepsilon}{\frac{1}{\varepsilon_2 - \varepsilon_1} + \frac{1 - v_2^\varepsilon}{3\varepsilon_1}}}_{\varepsilon^{*, -}} \leq \varepsilon^* \leq \varepsilon_2 + \underbrace{\frac{1 - v_2^\varepsilon}{\frac{1}{\varepsilon_1 - \varepsilon_2} + \frac{v_2^\varepsilon}{3\varepsilon_2}}}_{\varepsilon^{*, +}} \leq \langle \varepsilon \rangle_{\Omega} \quad (45.7)$$

and for the overall permeability

$$\langle \mu^{-1} \rangle_{\Omega}^{-1} \leq \mu_1 + \underbrace{\frac{v_2^\mu}{\frac{1}{\mu_2 - \mu_1} + \frac{1 - v_2^\mu}{3\mu_1}}}_{\mu^{*, -}} \leq \mu^* \leq \mu_2 + \underbrace{\frac{1 - v_2^\mu}{\frac{1}{\mu_1 - \mu_2} + \frac{v_2^\mu}{3\mu_2}}}_{\mu^{*, +}} \leq \langle \mu \rangle_{\Omega} \quad (45.8)$$

where $\varepsilon_2 \geq \varepsilon_1$, $\mu_2 \geq \mu_1$, v_2^ε is the volume fraction of phase with the higher ε value (“phase 2” in the former expression) for the permittivity-mismatch and v_2^μ is the volume fraction of the phase with the higher μ value (“phase 2” in the latter expression) for the permeability-mismatch.² The typical behavior of the bounds and their range, plotted against volume fraction, is shown in Figures 45.3 and 45.4. Typically, dielectric materials are measured relative to the vacuum-level permittivity, $\varepsilon_0 = 8.854 \times 10^{-12}$ farads/m. The usual representation is $\varepsilon_{\text{ir}} \stackrel{\text{def}}{=} \frac{\varepsilon_{\text{r}}}{\varepsilon_0}$, where ε_{ir} is known as the relative permittivity.³ In this example, we chose a mixture of polyethylene ($\varepsilon_{1r} = \frac{\varepsilon_1}{\varepsilon_0} = 2.25$) and silicon ($\varepsilon_{2r} = \frac{\varepsilon_2}{\varepsilon_0} = 11.68$), both measured at STP, for 0.9 MHz (Hector and Schultz, 1936).

For linearized elasticity applications, another form of the Hashin and Shtrikman bounds (Hashin and Shtrikman, 1962a, 1962b, 1963; Hashin, 1983), for isotropic materials with isotropic effective (mechanical) responses are commonly used. For the bulk modulus

$$\kappa^{*, -} \stackrel{\text{def}}{=} \kappa_1 + \frac{v_2}{\frac{1}{\kappa_2 - \kappa_1} + \frac{3(1 - v_2)}{3\kappa_1 + 4G_1}} \leq \kappa^* \leq \kappa_2 + \frac{1 - v_2}{\frac{1}{\kappa_1 - \kappa_2} + \frac{3v_2}{3\kappa_2 + 4G_2}} \stackrel{\text{def}}{=} \kappa^{*, +}, \quad (45.9)$$

and for the shear modulus

$$G^{*, -} \stackrel{\text{def}}{=} G_1 + \frac{v_2}{\frac{1}{G_2 - G_1} + \frac{6(1 - v_2)(\kappa_1 + 2G_1)}{5G_1(3\kappa_1 + 4G_1)}} \leq G^* \leq G_2 + \frac{(1 - v_2)}{\frac{1}{G_1 - G_2} + \frac{6v_2(\kappa_2 + 2G_2)}{5G_2(3\kappa_2 + 4G_2)}} \stackrel{\text{def}}{=} G^{*, +}, \quad (45.10)$$

² For either case, the volume fraction of the other phase is v_1 , where $v_1 + v_2 = 1$.

³ Similar representations can be made for the magnetic properties using the vacuum-level permeability, $\mu_0 = 8.854 \times 10^{-12}$ farads/m and $\mu_{\text{ir}} \stackrel{\text{def}}{=} \frac{\mu_{\text{r}}}{\mu_0}$, where μ_{ir} is known as the relative permeability.

FIGURE 45.3 An example (Zohdi, 2012) of the Hashin–Shtrikman bounds for a mixture of polyethylene ($\varepsilon_{1r} = \frac{\varepsilon_1}{\varepsilon_0} = 2.25$) and silicon ($\varepsilon_{2r} = \frac{\varepsilon_2}{\varepsilon_0} = 11.68$), both measured at STP for 0.9 MHz (Hector and Schultz, 1936).

where κ_2 and κ_1 are the bulk moduli, and G_2 and G_1 are the shear moduli of the respective phases ($\kappa_2 \geq \kappa_1$ and $G_2 \geq G_1$), and where v_2 is the second phase volume fraction. Such bounds are the tightest possible on isotropic effective responses, with isotropic two phase microstructures, where only the volume fractions and phase contrasts of the constituents are known. Note that no geometric or distributional information is required for the bounds. Thus, in summary, for a composite materials designer, the range of possible effective responses of composite material for a given set of matrix and particle materials is

FIGURE 45.4 An example (Zohdi, 2012) of the *difference/range* in the upper and lower Hashin–Shtrikman bounds, $R_{\varepsilon^*} = \frac{\varepsilon^{*,+} - \varepsilon^{*,\circ}}{\varepsilon_0}$, for a mixture of polyethylene ($\varepsilon_{1r} = \frac{\varepsilon_1}{\varepsilon_0} = 2.25$) and silicon ($\varepsilon_{2r} = \frac{\varepsilon_2}{\varepsilon_0} = 11.68$), both measured at STP for 0.9 MHz (Hector and Schultz, 1936).

- For the electrical permittivity

$$R_{\epsilon^*} = \epsilon^{*,+} - \epsilon^{*,-} \quad (45.11)$$

- For the magnetic permeability

$$R_{\mu^*} = \mu^{*,+} - \mu^{*,-} \quad (45.12)$$

- For the elastic bulk modulus

$$R_{\kappa^*} = \kappa^{*,+} - \kappa^{*,-} \quad (45.13)$$

- For the elastic shear modulus

$$R_G = G^{*,+} - G^{*,-} \quad (45.14)$$

It is critical to note that the proofs of these bounds require sample sizes that are truly statistically representative (infinitely large compared with the particles in the sample). If the samples are too small (not statistically representative), then the bounds may be violated, and we again must resort to the estimates of statistical variation based on ensemble averaging, using Central Limit Theorem-type techniques (Zohdi and Wriggers, 2008).

45.4 SUMMARY

The measurement of effective properties of particulate composite materials, such as those of Hashin and Shtrikman (1962a, 1962b, 1963) and Hashin (1983), are an effective tool to use in the fast and reliable development of new composite materials. For a thorough analysis of many of such methods, see Torquato (2001), Jikov et al. (1994), Hashin and Shtrikman, (1962b), and Nemat-Nasser and Hori (1999) for solid-mechanics oriented treatments and Zohdi and Wriggers (2008) for computational aspects.

The identification of microstructural parameters, which force the system behavior to match a (desired) target response, is essentially a nonconvex inverse problem where the microstructural parameters are the design variables. For example, a relatively straightforward formulation is to consider inverse problems whereby microstructural parameters are sought, which deliver a desired overall behavior by minimizing a cost function such as

$$\Pi = w_1 \left(\frac{\|\epsilon^* - \epsilon^{*,D}\|}{\|\epsilon^{*,D}\|} \right)^2 + w_2 \left(\frac{\|\mu^* - \mu^{*,D}\|}{\|\mu^{*,D}\|} \right)^2 + \text{local constraints} \quad (45.15)$$

where $\epsilon^{*,D}$ and $\mu^{*,D}$ are desired overall properties and w_1 and w_2 are design weights that indicate the importance of achieving each component of the objective. Specifically, a microstructural design problem can be set up by defining a N -tuple design vector, denoted $\Lambda^{\text{def}}(\Lambda_1, \Lambda_2, \dots, \Lambda_N)$, for example, consist of the following components: (1) the properties of the particles (2) the volume fraction of the particles, and (3) the topological parameters of the particles. For example, ellipsoidal shapes are qualitatively useful since the

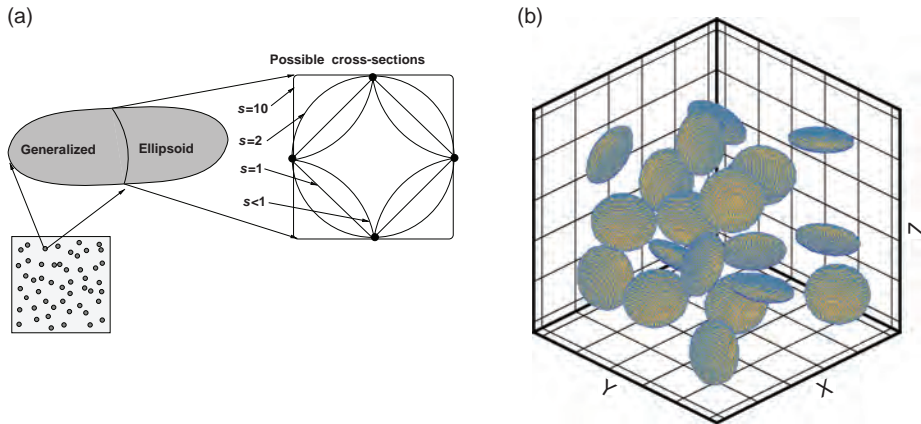

FIGURE 45.5 (a) A generalized ellipsoid and (b) a numerical representation of the nonspherical particulate additives using the finite element method (Zohdi, 2001).

geometry can closely represent a variety of particulate types, for example, platelets when the ellipsoids are oblate or needles (discontinuous fibers) when the ellipsoids are prolate. Such shapes can be generalized by considering the following (Figure 45.5):

$$\left(\frac{|x - x_0|}{r_1}\right)^{s_1} + \left(\frac{|y - y_0|}{r_2}\right)^{s_2} + \left(\frac{|z - z_0|}{r_3}\right)^{s_3} = 1, \quad (45.16)$$

where the s is exponents (Zohdi, 2001, 2003; Zohdi and Wriggers, 2008). Values of $s < 1$ produce nonconvex shapes, whereas $s > 2$ values produce “block-like” shapes. Generally, formulations of such objective functions (II) will possess nonconvex and nondifferentiable dependency on the design variables (especially if there are manufacturing constraints).⁴ The minimization of such objective functions can be achieved using a two step process whereby (1) one determines promising optimal regions in parameter space using (nonderivative) algorithms (e.g., evolutionary “genetic” algorithms, simulated annealing) and then (2) one applies (classical) gradient-based schemes in locally convex regions, if the objective function is smooth enough (since such approaches are generally extremely efficient for the minimization of smooth convex functions). For example, there are a variety of nonderivative algorithms that employ concepts of species evolution, such as reproduction, mutation, and crossover, which are referred to as “genetic” algorithms. Implementation of such algorithms typically involves a randomly generated population of “genetic” strings, each of which represents a specific choice of system parameters. The population of genes undergo “mating sequences,” “offspring production,” and other biologically inspired events in order to find regions of the search space where cost functions are small. These methods date back, at least, to pioneering work John Holland (1975). For general reviews, see Goldberg (1989), Goldberg and Deb (2000) and (Zohdi 2001, 2003; Zohdi and Wriggers, 2008) for specific optimization and genetic algorithms to treat

⁴ Additionally, such objective functions are usually “noisy,” that is, they possess a stochastic nature, which can be attributed to sample-size effects.

inverse problems involving various particulate material systems. Generally, to obtain more detailed information on the response of composite materials, such as the microscale stresses, crack propagation, and material failure; one must resort to numerical techniques, such as the finite element method. However, analytical methods, such as those illustrated here, provide a necessary starting point, in order to minimize computational tests, which typically require significant computation resources. For more on numerical methods for composite material analysis, we refer the reader to Zohdi and Wriggers (2008).

47.1 INTRODUCTION

Everyone is familiar with the interaction of devices connected to form a system, although they may not think of their observations in those terms. Familiar examples include the following:

1. dimming of the headlights while starting a car,
2. slowdown of an electric mixer lowered into heavy batter,
3. freezing a showerer by starting the dishwasher,
4. speedup of a vacuum cleaner when the hose plugs,
5. two-minute wait for a fever thermometer to rise,
6. special connectors required for TV antennas,
7. speedup of a fan in the window with the wind against it,
8. shifting of an automatic transmission on a hill.

These effects happen because one part of a system loads another. Most mechanical engineers would guess that weighing an automobile by placing a bathroom-type scale under its wheels one at a time and summing the four measurements will yield a higher result than would be obtained if the scale was flush with the floor. Most electrical engineers understand that loading a potentiometer's wiper with too low a resistance makes its dial nonlinear for voltage division. Instrumentation engineers know that a heavy accelerometer mounted on a thin panel will not measure the true natural frequencies of the panel. Audiophiles are aware that loudspeaker impedances must be matched to amplifier impedance. We have all seen the 75- and 300- Ω markings under the antenna connections on TV sets, and most cable subscribers have seen balun transformers for connecting a coaxial cable to the flat-lead terminals of an older TV.

Every one of these examples involves a desired or an undesirable interaction between a source and a receiver of energy. In every case, there are properties of the source part and the load part of the system that determine the efficiency of the interaction. This chapter deals exclusively with interactions between static and dynamic subsystems intended to function together in a task and with how best to configure and characterize those subsystems.

Consider the analysis of dynamic systems. To create mathematical models of these systems requires that we idealize our view of the physical world. First, the system must be identified and separated from its environment. The environment of a system is the universe outside the free body, control volume, or isolated circuit. The combination of these, which is the system under study and the external sources, provides or removes energy from the system in a known way. Next, in the system itself, we must arrange a restricted set of ideal elements connected in a way that will correctly represent the energy storages and dissipations of the physical system while, at the same time, we need the mathematical handles that explore the system's behavior in its environment. The external environment of the system being modeled must then itself be modeled and connected and is usually represented by special ideal elements called sources.

We expect, as a result of these sources, that the system under study will not alter the important variables in its environment. The water rushing from a kitchen faucet will not normally alter the atmospheric pressure; our electric circuit will not measurably slow the turbines in the local power plant; the penstock will not draw down the level of the reservoir (in a time frame consistent with a study of penstock dynamics, anyway); the

cantilever beam will not distort the wall it is built into; and so on. In this last instance, for example, the wall is a special source of zero displacement and zero rotation no matter what forces and moments are applied.

In this chapter, we consider, instead of the behavior of a single system in a known environment, the interaction between pairs of connected dynamic systems at their interface, often called the driving point. The fundamental currency is, as always, the energy or power exchanged through the interface. In an instrumentation or a control system, the objective of the energy exchange might be information transmission, but this is not considered here (we would like information exchanges to take place at the lowest possible energy costs, but the second law of thermodynamics rules out a free transmission).

As always, energy factors into two variables, such as voltage and current in electrical systems, and we are concerned with the behavior of these in the energetic interaction. The major difference in this perspective is that the system supplying energy cannot do so at a fixed value. Neither the source nor the system receiving energy can fix its values for a changing demand without a change in the value of a supply variable. The two subsystems are in an equilibrium with each other and are forced by their connection to have the same value of both of the appropriate energy variables. We concern ourselves with determining and controlling the value of these energy variables at the interface where, obviously, only one is determined by each of the interacting systems.

47.2 FAMILIAR EXAMPLES¹ OF INPUT–OUTPUT INTERACTIONS

47.2.1 Power Exchange

In the real world, pure sources and sinks are difficult to find. They are idealized, convenient constructs or approximations that give our system analyses independent forcing functions. We commonly think of an automobile storage battery as a source of 12.6 V independent of the needed current, and yet we have all observed dimming headlights while starting an engine. Clearly, the voltage of this battery is a function of the current demanded by its load. Similarly, we cannot charge the battery unless our alternator provides more than 12.6 V, and the charging rate depends on the overvoltage supplied. Thus, when the current demanded or supplied to a battery approaches its limits, we must consider that the battery really looks like an ideal 12.6-V source in series with a small resistance. The voltage at the battery terminals is a function of the current demanded and is not independent of the system loading or charging it in the interaction. This small internal resistance is termed the output impedance (or input impedance or driving-point impedance) of the battery.

If we measure the voltage on this battery with a voltmeter, we should draw so little current that the voltage we see is truly the source voltage without any loss in the internal resistance. The power delivered from the battery to the voltmeter is negligible (but not zero) because the current is so small. Alternately, if we do a short-circuit test of the battery, its terminal voltage should fall to zero while we measure the very large current that results. Again, the power delivered to the ammeter is negligible because, although the current is very large, the voltage is vanishingly small.

¹Many of the examples in this chapter are drawn from Chapter 6 of a manuscript of unpublished notes, “Dynamic Systems and Measurements,” by C. L. Nachtigal, used in the School of Mechanical Engineering, Purdue University, 1978.

At these two extremes, the power delivered is essentially zero, so clearly at some intermediate load the power delivered will be a maximum. We will show later that this occurs when the load resistance is equal to the internal resistance of the battery (a point at which batteries are usually not designed to operate). The discussion above illustrates a simple concept: impedances should be matched to maximize power or energy transfer but should be maximally mismatched for making a measurement without loading the system in which the measurement is to be made. We will return to the details of this statement later.

47.2.2 Energy Exchange

Interactions between systems are not restricted to resistive behavior, nor is the concept of impedance matching restricted to real, as opposed to reactive, impedances. Consider a pair of billiard balls on a frictionless table (to avoid the complexities of spin), and consider that their impact is governed by a coefficient of restitution, ϵ . Before impact, only one ball is moving, but afterward both may be. The initial and final energies are as follows:

$$\begin{aligned}\text{Initial energy} &= \frac{1}{2}M_1v_{1i}^2 \\ \text{Final energy} &= \frac{1}{2}M_1v_{1f}^2 + \frac{1}{2}M_2v_{2f}^2\end{aligned}\quad (47.1)$$

where the subscript 1 refers to the striker and 2 to the struck ball, M is mass, v is velocity, and the subscripts i and f refer to initial and final conditions, respectively.

Because no external forces act on this system of two balls during their interaction, the total momentum of the system is conserved:

$$M_1v_{1i} + M_2v_{2i} = M_1v_{1f} + M_2v_{2f} \quad (47.2)$$

or

$$v_{1i} + \mathbf{m}v_{2i} = v_{1f} + \mathbf{m}v_{2f},$$

where $\mathbf{m} = M_2/M_1$. The second equation, required to solve for the final velocities, derives from impulse and momentum considerations for the balls considered one at a time. Because no external forces act on either ball during their interaction except those exerted by the other ball, the impulses,² or integrals of the force acting over the time of interaction on the two, are equal. (See “impact” in virtually any dynamics text.) From this, it can be shown that the initial and final velocities must be related:

$$\epsilon(v_{1i} - v_{2i}) = (v_{1f} - v_{2f}), \quad (47.3)$$

where $v_{2i} = 0$ in this case and the coefficient of restitution ϵ is a number between 0 and 1. A 0 corresponds to a plastic impact while a 1 corresponds to a perfectly elastic impact. Equations (47.2) and (47.3) can be solved for the final velocities of the two balls:

$$v_{1f} = \frac{1 - \mathbf{m}\epsilon}{1 + \mathbf{m}}v_{1i} \quad \text{and} \quad v_{2f} = \frac{1 + \epsilon}{1 + \mathbf{m}}v_{1i}. \quad (47.4)$$

² Impulse = $\int_{t=0}^t \text{Force } dt$, where Force is the vector sum of all the forces acting over the period of interaction, t .

Now assume that one ball strikes the other squarely³ and that the coefficient of restitution ϵ is unity (perfectly elastic impact). Consider the following three cases:

1. The two balls have equal mass, so $\mathbf{m} = 1$, and $\epsilon = 1$. Then the striking ball, M_1 , will stop, and the struck ball, M_2 , will move away from the impact with exactly the initial velocity of the striking ball. All the initial energy is transferred.
2. The struck ball is more massive than the striking ball, $\mathbf{m} > 1$, $\epsilon = 1$. Then, the striker will rebound along its initial path, and the struck ball will move away with less than the initial velocity of the striker. The initial energy is shared between the balls.
3. The striker is the more massive of the two, $\mathbf{m} < 1$, $\epsilon = 1$. Then the striker, M_1 , will follow at reduced velocity behind the struck ball after their impact, and the struck ball will move away faster than the initial velocity of the striker (because it has less mass). Again, the initial energy is shared between the balls.

Thus, the initial energy is conserved in all of these transactions. But, the energy can be transferred completely from one ball to the other *if and only if* the two balls have the same mass.

If these balls were made of clay so that the impact was perfectly plastic (no rebound whatsoever), then $\epsilon = 0$, so the striker and struck balls would move off together at the same velocity after impact no matter what the masses of the two balls. They would be effectively stuck together. The final momentum of the pair would equal the initial momentum of the striker because, on a frictionless surface, there are no external forces acting, but energy could not be conserved because of the losses in plastic deformation during the impact. The final velocities for the same three cases are

$$v_f = \frac{1}{1 + \mathbf{m}} v_i. \quad (47.5)$$

Since the task at hand, however, is to transfer kinetic (KE) from the first ball to the second, we are interested in maximizing the energy in the second ball after impact with respect to the energy in the first ball before impact:

$$\frac{\text{KE}_{(M_2, \text{after})}}{\text{KE}_{(M_1, \text{before})}} = \frac{\frac{1}{2} M_2 (v_{2f})^2}{\frac{1}{2} M_1 (v_{1i})^2} = \frac{M_2 (1/(1 + \mathbf{m}))^2 (v_{1i})^2}{M_1 (v_{1i})^2} = \frac{\mathbf{m}}{(1 + \mathbf{m})^2}. \quad (47.6)$$

This takes on a maximum value of $1/4$ when $\mathbf{m} = 1$ and falls off rapidly as \mathbf{m} departs from 1.

Thus, after the impact of two clay balls of equal mass, one-fourth of the initial energy remains in the striker, one-fourth is transferred to the struck ball, and one-half of the initial energy of the striker is lost in the impact. If the struck ball is either larger or smaller than the striker, however, then a greater fraction of the initial energy is dissipated in the impact and a smaller fraction is transferred to the second ball. The reader should reflect on how this influences the severity of automobile accidents between vehicles of different sizes.

47.2.3 A Human Example

Those in good health can try the following experiment. Run up a long flight of stairs one at a time and record the elapsed time. After a rest, try again, but run the stairs two at a

³ Referred to in dynamics as *direct central impact*.

time. Still later, try a third time, but run three steps at a time. Most runners will find that their best time is recorded for two steps at a time.

In the first test, the runner's legs are velocity limited: too much work is expended by simply moving legs and feet, and the forces required are too low to use the full power of the legs effectively. In the third test, although the runner's legs do not have to move very quickly, they are on the upper edge of their force capabilities for continued three-step jumps; the forces required are too high and the runner could, at lower forces, move his or her legs much faster. In the intermediate case, there is a match between the task and the force-velocity characteristics of the runner's legs.

Bicycle riders assure this match with a variable-speed transmission that they adjust so they can crank the pedals at approximately 60 RPM. We will later look at other means of ensuring the match between source capabilities and load requirements when neither of them is changeable, but the answer is always a transformer or gyrator of some type (a gear ratio in this case).

47.3 ENERGY, POWER, IMPEDANCE

47.3.1 Definitions and Analogies

Energy is the fundamental currency in the interactions between elements of a physical system no matter how the elements are defined. In engineering systems, it is convenient to describe these transactions in terms of a complementary pair of variables whose product is the power or flow rate of the energy in the transaction. These product pairs are familiar to all engineers: voltage \times current = power, force \times displacement = energy, torque \times angular velocity = power, pressure \times flow = power, and pressure \times time rate of change of volume exchanged = power. Some are less familiar: flux linkage \times current = energy, charge \times voltage = energy, and absolute temperature \times entropy flux = thermal power. Paynter's (1960) tetrahedron of state shows how these are related (Figure 47.1). Typically, one of these factors is extensive, a flux or flow, such as current, velocity, volume flow rate, or angular velocity. The other is intensive, a potential or effort,⁴ such as voltage, force, pressure, or torque. Thus, $\mathcal{P} = \text{extensive} \times \text{intensive}$ for any of these domains of physical activity.

This factoring is quite independent of the analogies between the factors of power in different domains, for which any arbitrary selection is acceptable. In essence, velocity is

FIGURE 47.1 H. M. Paynter's tetrahedron of state.

⁴This is Paynter's terminology, used with reference to his "Bond Graphs."

not like voltage or force-like current, just as velocity is not like current or force-like voltage. It is convenient, however, before defining impedance and working with it to choose an analogy so that generalizations can be made across the domains of engineering activity. There are two standard ways to do this: the Firestone analogy (Firestone, 1932/1933) and the mobility analogy. Electrical engineers are most familiar with the Firestone analogy, whereas mechanical engineers are probably more comfortable with the mobility analogy. The results derived in this chapter are independent of the analogy chosen. To avoid confusion, both will be introduced, but only the mobility analogy will be used in this chapter.

The Firestone analogy gives circuit-like properties to mechanical systems: all systems consist of nodes like a circuit and only of lumped elements considered to be two-terminal or four-terminal device. For masses and tanks of liquid, one of the terminals must be understood to be ground, the inertial reference frame, or atmosphere. Then, one of the energy variables is measured across the terminals of the element and the other passes through the element. In a circuit, voltage is across and current passes through. For a spring, however, velocity difference is across and the force passes through. Thus, this analogy linked voltage to velocity, angular velocity, and pressure as across variables and linked current to force, torque, and flow rate as through variables. Clearly, across \times through = power.

The mobility analogy, in contrast, considers the complementary power variables to consist of a potential and a flux, an intrinsic and extrinsic variable. The potentials, or efforts, are voltage, force, torque, and pressure, while the fluxes, or flows, are current, velocity, angular velocity, and fluid flow rate.

47.3.2 Impedance and Admittance

Impedance, in the most general sense, is the relationship between the factors of power. Because only the constitutive relationships for the dissipative elements are expressed directly in terms of the power variables, $\Delta V_R = R \times i_R$, for example, while the equations for the energy storage elements are expressed in terms of the derivative of one of the power variables⁵ with respect to the other, $i_C = C(dV_C/dt)$ for example, these are most conveniently expressed in Laplace transform terms. Impedances are really self-transfer functions at a point in a system. Because the concept was probably defined first for electrical systems, that definition is most standardized: electrical impedance $Z_{\text{electrical}}$ is defined as the rate of change of voltage with current:

$$Z_{\text{electrical}} = \frac{d(\text{voltage})}{d(\text{current})} = \frac{d(\text{effort})}{d(\text{flow})}. \quad (47.7)$$

By analogy, impedance can be similarly defined for the other engineering domains:

$$Z_{\text{translation}} = \frac{d(\text{force})}{d(\text{velocity})}. \quad (47.8)$$

$$Z_{\text{rotation}} = \frac{d(\text{torque})}{d(\text{angular velocity})}. \quad (47.9)$$

$$Z_{\text{fluid}} = \frac{d(\text{pressure})}{d(\text{flow rate})}. \quad (47.10)$$

⁵ See Figure 47.1 again. Capacitance is a relationship between the integral of the flow and the effort, which is the same as saying that capacitance relates the flow to the derivative of the effort.

TABLE 47.1 Impedances of Lumped Linear Elements

Domain	Kinetic Storage	Dissipation	Potential Storage
Translational	Mass: M	Damping: b	Spring: k/s
Rotational	Inertia: J	Damping: B	Torsion spring: k_f/s
Electrical	Inductance: L	Resistance: R	Capacitance: $1/Cs$
Fluid	Inertance: I	Fluid resistance: R	Fluid capacitance: $1/Cs$

Table 47.1 is an impedance table using these definitions of the fundamental lumped linear elements. Note that these are derived from the Laplace transforms of the constitutive equations for these elements; they are the transfer functions of the elements and are expressed in terms of the Laplace operator s . The familiar $F = M \cdot a$, for example, becomes, in power-variable terms, $F = M(dv/dt)$; it transforms as $F(s) = Ms v(s)$, so

$$(Z_{\text{translation}})_{\text{mass}} = \frac{dF_{\text{mass}}}{dv_{\text{mass}}} = Ms. \quad (47.11)$$

Because these involve the Laplace operator s , they can be manipulated algebraically to derive combined impedances. The reciprocal of the impedance, the admittance, is also useful. Formally, admittance is defined as

$$\text{Admittance: } Y = \frac{1}{Z} = \frac{d(\text{flow})}{d(\text{effort})}. \quad (47.12)$$

47.3.3 Combining Impedances and/or Admittances

Elements in series are those for which the flow variable is common to both elements and the efforts sum. Elements in parallel are those for which the effort variable is common to both elements and the flows sum. By analogy to electrical resistors, we can deduce that the impedance sum for series elements and the admittance sum for parallel elements form the combined impedance or admittance of the elements:

Impedances in series:

$$\begin{aligned} Z_1 + Z_2 &= Z_{\text{total}} \quad (\text{common flow}) \\ \frac{1}{Y_1} + \frac{1}{Y_2} &= \frac{1}{Y_{\text{total}}} \end{aligned} \quad (47.13)$$

Impedances in parallel:

$$\begin{aligned} Y_1 + Y_2 &= Y_{\text{total}} \quad (\text{common effort}) \\ \frac{1}{Z_1} + \frac{1}{Z_2} &= \frac{1}{Z_{\text{total}}} \end{aligned} \quad (47.14)$$

When applying these relationships to electrical or fluid elements, there is rarely any confusion about what constitutes series and parallel. In the mobility analogy, however, a pair of springs connected end to end are in parallel because they experience a common force, regardless of the topological appearance, whereas springs connected side by side are in

series because they experience a common velocity difference.⁶ For a pair of springs end to end, the total admittance is

$$\frac{s}{k_{\text{total}}} = \frac{s}{k_1} + \frac{s}{k_2}$$

so the impedance is

$$\frac{k_{\text{total}}}{s} = \frac{k_1 k_2}{s(k_1 + k_2)}.$$

For the same springs side by side, the total impedance is

$$\frac{k_{\text{total}}}{s} = \frac{k_1 + k_2}{s}.$$

47.3.4 Computing Impedance or Admittance at an Input or Output

There are basically two ways in which an input or an output admittance can be computed. The first, and most direct, is to compute the transfer function between the effort and the flow at the driving point and take the derivative with respect to the flow. For a mechanical rotational system, for example, torque as a function of angular velocity is expressed and differentiated with respect to angular velocity. This method must be used if the system being considered is nonlinear because the derivative must be taken at an operating point. If the system is linear, then the ratio of flow or effort will suffice; in the rotational system, the impedance is simply the ratio (torque/speed).

The second method takes the impedances of the elements one at a time and combines them. This approach is particularly useful for linear (or linearized) systems. The question then arises of determining the impedance of any sources in the subsystem being considered. Flow sources, such as current sources, velocity sources, angular velocity sources, and fluid flow sources, all have the relationship flow = constant. Their impedance is therefore infinite ($Z_{\text{flow source}} = \infty$) because any change in effort results in zero change in flow. Effort sources, such as voltage sources, force sources, torque sources, and pressure sources, will provide any flow to maintain the effort required; the change in effort for a change in flow remains zero, so their impedance is $Z_{\text{effort source}} = 0$. An effort source therefore represents a short circuit from an impedance point of view; it connects together two nodes that were separate. A flow source represents a null element; since its impedance is infinite, it represents an open circuit. Flow sources are simply removed in impedance calculations.

An example will distinguish between these two approaches. Figure 47.2 shows, on the left, a simple circuit disconnected at a driving point from its load. The load is of no consequence in this calculation; we simply require the driving-point impedance of the circuit. In the first approach, we derive the voltage at the driving point as a function of the current leaving those terminals and the source, V_s and I_s to obtain the relationship

$$V_o = \frac{R_3}{R_1 + R_3} V_s + \left(\frac{R_1 R_2 + R_2 R_3 + R_1 R_3}{R_1 + R_3} \right) (I_s - i_o). \quad (47.15)$$

⁶For many, the appeal of the Firestone analogy is that springs are equivalent to inductors, and there can be no ambiguity about series and parallel connections. End to end is series.

FIGURE 47.2 A simple circuit as a source.

Clearly, the negative derivative of the voltage (V_o) with respect to the current (i_o) is given by

$$-\frac{dV_o}{di_o} = Z_o = \frac{R_1 R_2 + R_2 R_3 + R_1 R_3}{R_1 + R_3}. \quad (47.16)$$

In the second method, the voltage source (V_s) can be set to zero, a short circuit, without affecting the impedances, and the current source (I_s) can be removed to yield the circuit on the right in Figure 47.2. Then, the impedances need only be combined as R_2 in series with the parallel pair R_1 and R_3 . Thus,

$$Z_o = R_2 + \frac{R_1 R_3}{R_1 + R_3} = \frac{R_1 R_2 + R_2 R_3 + R_1 R_3}{R_1 + R_3} \quad \text{as before.} \quad (47.17)$$

47.3.5 Transforming or Gyrating Impedances

Ideal transformers, transducers, and gyrators play an important part in dynamic systems and an equally important part in obtaining optimal performance from source–load combinations. They share several vital features: all are two-port (or four-terminal) devices, all are energetically conservative, and all are considered lumped elements. Each of the many types requires two equations for its description, always of the same form. Table 47.2 lists many of the more common linear two-ports, and Figure 47.3 illustrates them.

All of these transducing devices alter the effort–flow relationships of elements connected at their far end. Consider Figure 47.4, which shows a simple model of a front wheel of an automobile suspension. Because the spring and damper are mounted inboard of the wheel, their effectiveness is reduced by the mechanical disadvantage of the suspension arm. What is the impedance of the spring and shock absorber at $(\cdot)_1$ as viewed from the wheel at $(\cdot)_2$?

Because the spring and shock absorber share a common velocity (both ends share nodes or points of common velocity), their impedances add to give the impedance of the pair at their point of attachment, $(\cdot)_1$, to the lever:

TABLE 47.2 Ideal Linear Lumped Two-Ports

Domain to Domain	Name	Figure Numbers	Governing Equations (Left to Right in Figures)
Translation–translation	Lever, L = distance to function	3a	$F_1 = \frac{L_2}{L_1} F_2$ $v_1 = \frac{L_1}{L_2} v_2$
Rotation—rotation	Gears, N = number of teeth	3b	$\tau_1 = \frac{N_1}{N_2} \tau_2$ $\omega_1 = \frac{N_2}{N_1} \omega_2$
Rotation–translation	Crank ($\theta \ll 1$) or rack and pinion	3c 3d	$\begin{cases} \tau = RF \\ \omega = \frac{1}{R} v \end{cases}$
	 Screw (p = length/radius)	 3e	$\begin{cases} \tau = pF \\ \omega = \frac{1}{p} v \end{cases}$
Electrical–electrical	Transformer	3f	$V_1 = \frac{N_1}{N_2} V_2$ $i_1 = \frac{N_2}{N_1} i_2$
Electrical–rotation	Permanent magnet dc motor	3g	$V_a = K_b \omega$ $i_a = \frac{1}{K_m} \tau$
Electrical–translation	Voice coil	3h	$V_a = K_c v$ $i_a = \frac{1}{K_c} F$
Fluid–translation	Piston area = A	3j	$P = \frac{1}{A} F$ $Q = Av$
Rotation–fluid	Fixed-displacement pump-motor, displacement/radius = D	3k	$\tau = Dp$ $\omega = \frac{1}{D} Q$

$$(Z_1)_{\text{total}} = Z_{\text{spring}} + Z_{\text{damper}} = b + \frac{k}{s} = \frac{bs + k}{s}. \quad (47.18)$$

At the $(\cdot)_2$ end of the lever, the force, from Table 47.2, is $F_2 = (L_1/L_2)F_1$, but from the definition of Z for linear elements, $F_1 = (Z_1)_{\text{total}} v_1$. So we get the following:

$$F_2 = \frac{L_1}{L_2} \left(\frac{bs + k}{s} \right) v_1. \quad (47.19)$$

FIGURE 47.3 The ideal linear lumped two-ports: transformers and gyrators.

FIGURE 47.4 An abstraction of an automobile suspension linkage.

The second equation for the lever is $v_1 = (L_1/L_2)v_2$, and substituting this into Equation (47.19) yields

$$F_2 = \frac{L_1}{L_2} \left(\frac{bs + k}{s} \right) \left(\frac{L_1}{L_2} \right) v_2 = \left(\frac{L_1}{L_2} \right)^2 \left(\frac{bs + k}{s} \right) v_2 \quad (47.20)$$

$$(Z_2)_{\text{total}} = \left(\frac{L_1}{L_2} \right)^2 (Z_1)_{\text{total}}. \quad (47.21)$$

Thus, the impedance of the suspension, observed from the wheel end of the lever arm, is multiplied by the square of the lever ratio. This general result applies to all transduction elements.

47.3.6 Source Equivalents: Thévenin and Norton

Thévenin's and Norton's theorems were both originally developed for electric circuits. They are duals; that is, while Thévenin uses a series voltage source, Norton uses a parallel current source to construct an equivalent to a real subsystem being considered as a source. Both of these theorems are completely generalizable to any system, provided that the appropriate sources are used. In this chapter, the mobility analogy has been adapted so that Thévenin equivalents are constructed using sources of voltage, force, pressure, or torque, and Norton equivalents are constructed using sources of current, velocity, flow, or angular velocity. In the development below, these two classes of sources will be referred to as effort and flow sources.

47.3.6.1 Thévenin Equivalent Assume that a subsystem being considered as a source contains within its structure one or more ideal sources. Insofar as can be measured externally at the driving point (the point of connection between any two systems considered to be source and load), any active subsystem, no matter what its load, can be replaced by a new effort source added in series with the original subsystem; all the original internal sources are set to zero. The value of the new source effort variable is the output that would appear at the driving point if the load were disconnected from the original subsystem. Setting an effort source to zero is equivalent to connecting its nodes together; setting a flow source to zero is equivalent to removing it from the system.

The output impedance of this Thévenin equivalent is clearly the impedance looking in at the driving point; it is the derivative of the driving-point effort variable with respect to the driving-point flow variable with the load disconnected. Thévenin's theorem simplifies this calculation because it tells us that the internal sources can be set to zero before the calculation is made, and the system topology is often substantially simplified by this move. We have already seen an example of this [see Equations (47.15)–(47.17)]. The Thévenin equivalent of this circuit is simply a new source determined with the current $i_o = 0$ (see Figure 47.2):

$$V_{\text{Thévenin}} = \frac{R_3}{R_1 + R_3} V_s + \left(\frac{R_1 R_2 + R_2 R_3 + R_1 R_3}{R_1 + R_3} \right) I_s \quad (47.22)$$

in series with a resistance determined with sources V_s and I_s zeroed:

$$R_{\text{Thévenin}} = \frac{R_1 R_2 + R_2 R_3 + R_1 R_3}{R_1 + R_3}. \quad (47.23)$$

47.3.6.2 Norton Equivalent Assume the same subsystem considered above. Insofar as can be measured externally at the driving point, any active subsystem, no matter what its load, can be replaced by a new flow source added in parallel with the original subsystem, all the original sources set to zero. The value of the new source flow variable is the flow that would pass through a short circuit substituted at the driving point for the original load.

Referring again to Equation (47.15), with V_o set to zero, we obtain the following:

$$0 = \frac{R_3}{R_1 + R_3} V_s + \left(\frac{R_1 R_2 + R_2 R_3 + R_1 R_3}{R_1 + R_3} \right) (I_s - i_o). \quad (47.24)$$

We see that i_o for a short circuit would be

$$i_o = I_s + \left(\frac{R_3}{R_1 R_2 + R_2 R_3 + R_1 R_3} \right) V_s \quad (47.25)$$

and, as for the Thévenin equivalent, the circuit impedance is

$$R_{\text{Norton}} = \frac{R_1 R_2 + R_2 R_3 + R_1 R_3}{R_1 + R_3}. \quad (47.26)$$

Note that $R_{\text{Thévenin}} = R_{\text{Norton}}$, always.

47.4 OPERATING POINT OF STATIC SYSTEMS

A static system is a system without energy storage, a system in which there are only sources, transducers, and dissipation elements. Such systems have no transient response: they respond instantly to their inputs algebraically. The relationships among any of their variables are proportionalities—simple static gains. If the inputs to a stable dynamic system are held constant for long enough, it will become stationary; its variables will not change with time provided only that there is sufficient dissipation in the system to damp out any oscillations. Such a system is not static; it is at steady state. There is no exchange of energy among its energy storage elements, and the dissipative elements completely determine the state of the system.

47.4.1 Exchange of Real Power

If one system is supplying real power to another system in steady-state operation, then for the purposes of a static analysis, energy storage elements can be ignored. Both the source and the load can be considered to be purely resistive. If the source is separated from the load at the point of interest (at least conceptually), then the characteristics of source and load can be measured or computed. The load will be a power absorber—an electrical fluid resistance or a mechanical damper—and its characteristics can be represented as a line in

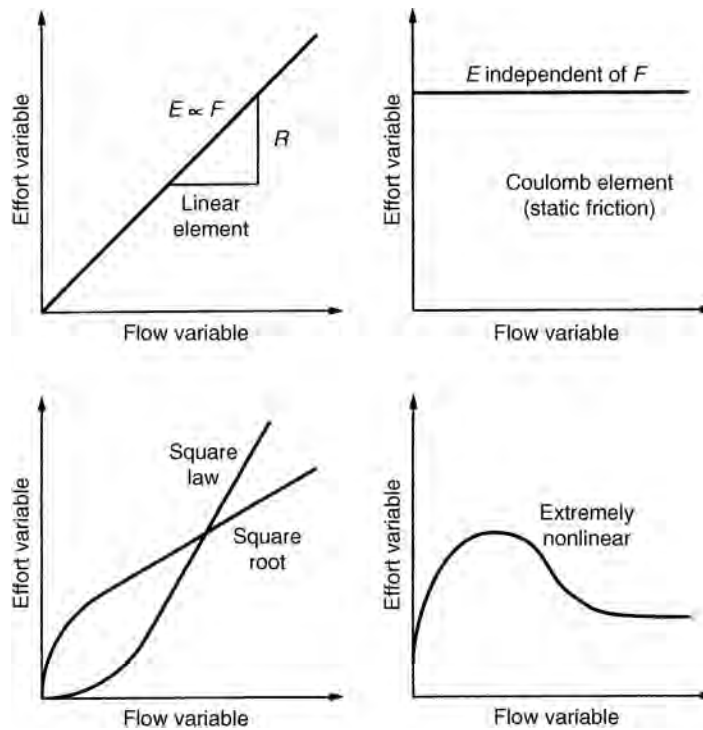

FIGURE 47.5 Common dissipative load characteristics.

a power plane coordinate system: voltage versus current, force versus velocity, torque versus angular velocity, or pressure versus flow. There is no requirement that this line be straight, and except that the measurement might be more difficult, there is no necessity that this line be single valued or that it start at the origin. Figure 47.5 shows a selection of common dissipative load characteristics.

Similarly, when the source portion of the system is loaded with a variable dissipation, the line representing its output characteristics can be plotted on the same coordinates as the load. Such characteristics are often given for pumps, servomotors, transistors, hydraulic valves, electrical supplies, and fans. Again, there is no requirement that this line be straight or that it be single valued, but it is very unusual for it to pass through the origin. If the source or the load is not constant in time or can be controlled, then a family of these characteristics will be required for variations in the parameters of the source or load. Figure 47.6 shows a selection of these sources. With very few exceptions, real sources cannot operate at the maximum values of their power variables simultaneously: a battery cannot deliver its maximum voltage and current at the same time. In more general terms, this means that in spite of local variations, real source characteristics tend to droop from left to right in the power plane; their average slope is negative.

47.4.2 Operating Points in an Exchange of Power or Energy

When resistive source and load characteristics are plotted on the same coordinates, they intersect at least once. The coordinate values at that point, or at those points if there are several, are the values of the power variables at which that combination of source and load

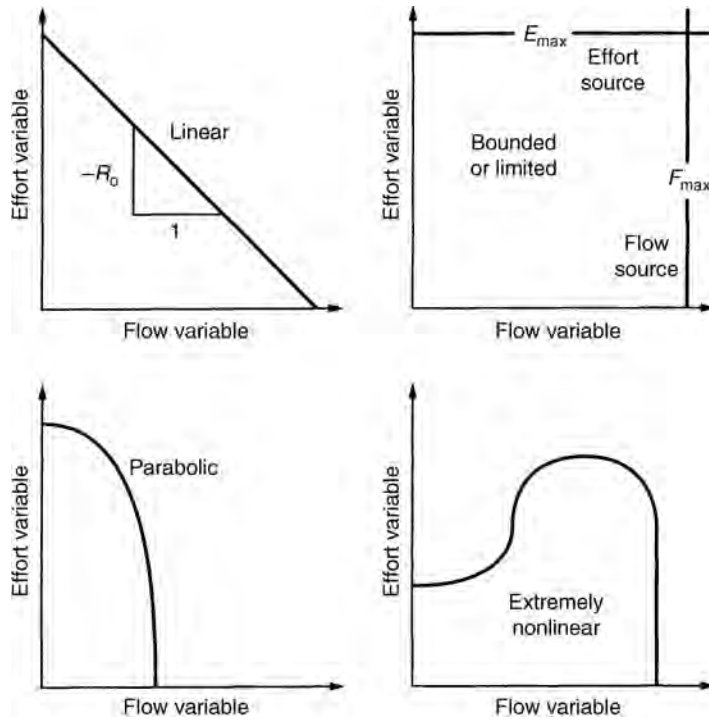

FIGURE 47.6 Load source variations.

must operate if they are connected. This is called an operating point. From a computational point of view, the source causes one of the power variables given the other and the load causes the other given the source. They must operate at the same point in the power plane to satisfy continuity (common flows) and compatibility (common efforts) conditions.

When there are multiple intersections, all are possible operating points, but not all will be stable operating points; for example, any disturbance from equilibrium might result in a transition to another operating point. The condition for a stable intersection is best seen graphically in Figure 47.7. For a stable intersection, as shown on the left, it is required

FIGURE 47.7 Stable and unstable operating point intersections.

that a small perturbation of the load, which increases its demand for power, be countered by a shortage of power from the supply side of the system and a small perturbation of the load, which decreases its demand for power, be met with an excess from the source. In either case, the load will be driven back to the intersection by the excess or deficit in the source capability. A reversal of these conditions is an unstable operating point because disturbances will be driven further in the direction of their initial departure.

At the unstable intersection in Figure 47.7 (2, on the right-hand side), a slight increase in the flow demand of the load will result in an overwhelming increase in the supply flow available to drive the load, which will then cause a traversal to point 1 in the figure. Similarly, if the effort decreases slightly from operating point 2, then the source will be starved compared to the demand of the load at that effort level, so the effort will fall until point 3 is reached.

47.4.3 Input and Output Impedance at the Operating Point

Lines of constant power are hyperbolas in the power plane, with increasing values of the power at increasing distance from the origin. The usual sign conventions imply that sources deliver power in the first and third quadrants while loads absorb power in those quadrants. Conversely, sources absorb power in the second and fourth quadrants and loads return it. The output impedance of a source is defined as minus the slope of the output characteristic. For nonlinear characteristics, the output impedance at any point is defined as minus the slope at that point. For loads, the input impedance is defined as the slope of the load line, but for nonlinear characteristics, there are two possibilities of importance: the slope of the line at a point (the incremental or local input impedance) and the slope of the chord to the point from the origin (the chordal impedance). Figure 47.8 summarizes these features of the power plane.

FIGURE 47.8 Definitions in the power plane.

FIGURE 47.9 A battery with load.

47.4.4 Operating Point and Load for Maximum Transfer of Power

Consider a battery with the voltage–current characteristic shown in Figure 47.9. The maximum unloaded terminal voltage (open circuit) of the battery is V_{oc} volts and the short-circuit current is i_{sc} amperes. The equation of the line shown is

$$V_t = V_{oc} - R_o i_b$$

or

$$i_b = i_{sc} - \frac{V_t}{R_o}, \quad (47.27)$$

where V_t is the terminal voltage and i_b is the battery current.

The output impedance $Z_o = -dV_t/di_b = R_o = V_{oc}/i_{sc}$ (a pure resistance in this case). If the battery is loaded by a resistor across its terminals (R_L), the terminal voltage must be

$$V_t = R_L i_b. \quad (47.28)$$

Solving Equations (47.27) and (47.28) simultaneously for V_t and i_b yields the following operating point coordinates:

$$V_t = \frac{V_{oc}}{1 + R_o/R_L} \quad i_b = \frac{V_{oc}}{R_o + R_L}. \quad (47.29)$$

The output power at the operating point is [from (47.29)]

$$\mathcal{P} = V_t i_b = \frac{(V_{oc})^2 R_L}{(R_o + R_L)^2}. \quad (47.30)$$

Clearly, the output power depends on the load resistance. If R_L is zero or infinite, no power is drawn from the battery. To measure V_{oc} , we would want a voltmeter with an infinite input impedance, and to measure i_{sc} , we would want an ammeter with zero resistance. In practice, we would use a voltmeter with an input resistance very large compared to R_o and an ammeter with a resistance very small compared to R_o .

If our objective is to deliver power, then a best value of R_L is that for which the derivative $d\mathcal{P}/dR_L = 0$. This value is the point at which $R_L = R_o$. Alternately, the maximum

power output of the battery for any load occurs at the current (i_b) that maximizes $V_t i_b$. Equation (47.27) can be restated as

$$V_t = V_{oc} \left(1 - \frac{i_b}{i_{sc}} \right) \quad (47.31)$$

so that

$$\mathcal{P} = V_t i_b = V_{oc} \left(1 - \frac{i_b}{i_{sc}} \right) i_b, \quad (47.32)$$

which is maximized at $\mathcal{P} = V_{oc} i_{sc} / 4$ when $i_b = i_{sc} / 2$.

For the battery characteristic, the operating point $i_b = i_{sc} / 2$ yields $V_t = V_{oc} / 2$ [substitution in Equation (47.29)]. A loading resistor characteristic must pass through this point to draw maximum power from the battery, so that the load resistance must be $R_L = V_{oc} / i_{sc} = R_0$. At this operating point, the equivalent resistor within the battery (representing the internal losses in the battery) is dissipating exactly as much power as is being delivered to the load.

If we want maximum power delivery, impedance should match the load to the source, but if we want to minimize power delivery from a source, then impedance mismatching is the key. Impedance matching assures that the source and load will divide the power equally; all other impedances will result in less power transfer.

47.4.5 An Unstable Energy Exchange: Tension-Testing Machine

Although tensile studies of material properties require only a simple test apparatus, it is not simple to interpret the data from such tests. The problem is that the tensile test machine and the specimen can interact (Bell and Ramalingam, 1974) in an unstable way. Almost any desired stress–strain curve can be obtained in a given material by a suitable choice of the test machine’s elastic compliance compared to the specimen.

A tensile test involves the interaction between two springs, one that represents the specimen and the other combined with a velocity source that represents the testing machine. Figure 47.10 shows this simple model. Although the testing machine is linearly elastic and does not yield, the test specimen is not elastic. It undergoes a large plastic deformation in a typical load–elongation test. Normally in such a test, the specimen is to be elongated at a constant cross-head velocity (v). The test machine, however, is not a velocity source as is commonly supposed; that source is really in series with a spring (K)

FIGURE 47.10 Simple model of a tensile-testing machine.

FIGURE 47.11 Components of the force–displacement curve.

representing the elastic deformations of the testing machine structure between the source of the motion and the jaws of the machine.

In the course of a test, the specimen undergoes an elongation (δ) comprised of both elastic and plastic displacements. The test machine undergoes only an elastic displacement (ξ) given by F/K , where F is the load applied to the specimen by the machine at a given cross-head displacement (y), which is really the sum of both the specimen (δ) and the machine (ξ) displacements. Figure 47.11 shows the components of this force–displacement situation.

The cross-head velocity of the test machine is made up of two components as well:

$$v = \frac{dy}{dt} = \frac{d\delta}{dt} + \frac{d\xi}{dt}. \quad (47.33)$$

The machine displacement (ξ), however, is a function of the force being applied, so it is therefore a function of the elongation of the specimen (δ). Equation (47.33) must be rewritten:

$$v = \frac{d\delta}{dt} + \frac{d\xi}{d\delta} \frac{d\delta}{dt} = \frac{d\delta}{dt} \left(1 + \frac{d\xi}{d\delta} \right). \quad (47.34)$$

Since $\xi = F/K$, presuming linearity for the machine, we get the following derivative:

$$\frac{d\xi}{d\delta} = \frac{1}{K} \frac{dF}{d\delta}, \quad (47.35)$$

where the term $dF/d\delta$ is the slope of the force–elongation curve of the specimen. The slope, in other words, is the driving-point stiffness at any point along the test curve. If these last two equations are combined, the specimen's elongation rate is found in terms of the cross-head velocity (v), which is normally constant, the machine stiffness (K), and the driving-point stiffness of the machine ($dF/d\delta$):

$$\frac{d\delta}{dt} = \frac{v}{1 + \frac{1}{K} \frac{dF}{d\delta}}. \quad (47.36)$$

As a test proceeds, however, the specimen starts to neck down, its stiffness begins to decrease, and then it becomes negative. When the driving-point stiffness ($dF/d\delta$) passes

FIGURE 47.12 The point of instability in a tensile test.

through zero, the specimen has reached the maximum force. The stiffness thereafter decreases until it equals $-K$ and at that point the specimen elongation rate ($d\delta/dt$) becomes infinite for any cross-head rate (v), and the system is mechanically unstable. This instability point in a tensile test is the point at which the machine load line is tangential to the load–elongation curve of the material being tested. At that point, the specimen breaks and the energy stored in the machine structure dumps into the specimen at this unstable intersection.

Clearly, percent elongation at failure specifications is not very meaningful because it depends on the test machine stiffness. Figure 47.12 shows that for accurate measurements the stiffness of the test machine must be many times as large as the stiffness of the specimen near failure or the machine will dump its energy into the specimen and force a premature failure.

47.4.6 Fatigue in Bolted Assemblies

The mechanical engineering reader will perhaps recall that preloading a bolt stretches the bolt and compresses the part being bolted, but it is the relative stiffness of the bolt and part that determines what fraction of external loads applied to separate the part from the bolt will be felt by the bolt.⁷ If the objective is to relieve the bolt of these loads, as it is in the head bolts of an automobile engine, then the designer tries to make the part much stiffer than the bolt; he or she mismatches the stiffness of the bolt and the part by specifying a hard head gasket. If the stiffness of the bolt and the part was the same, then they would share the external load equally—the bolt tension would increase by half the applied load while the part compression would decrease by half the applied load. If the gasket was very soft compared to the bolts, then the bolts would see virtually all of the applied load.

47.4.7 Operating Point for Nonlinear Characteristics

Let us continue to use the battery as an example of a linear source. It should be obvious that the maximum power point for the battery is independent of the load it must drive, but the load characteristic, however nonlinear, must pass through this point for maximum power transfer. Figure 47.13 illustrates this. It is not the slope of the load impedance that

⁷ Refer to any text on machine design under the indexed heading “fatigue in bolts.”

FIGURE 47.13 Chordal impedance matching.

must match the source impedance, it is the chordal slope, the slope of a line from the origin of the power plane to the maximum power point of the source.

An orifice supplied from a constant upstream pressure and loaded at its output is a good example of a nonlinear source. For a short, sharp-edged orifice, the orifice equation⁸ applies:

$$Q_o = C_d A_o \sqrt{\frac{2}{\rho} \Delta P} = C_d A_o \sqrt{\frac{2}{\rho} (P_{up} - P_{down})}, \quad (47.37)$$

where Q_o is the orifice flow, C_d is the discharge coefficient of the orifice, A_o is the orifice area, ρ is the density of the fluid, and $\Delta P = P_{up} - P_{down}$ is the pressure drop across the orifice. If the upstream pressure is kept constant, then P_{down} may be considered the output pressure, and Q_o may be considered the output flow from this orifice, a characteristic typical of many hydraulic valves. Where is the maximum power point on this characteristic?

Hydraulic power \mathcal{P} is the product $Q \cdot P$. It is a maximum when it is stationary with respect to either Q or P . If we nondimensionalize Equation (47.37) with respect to the maximum flow through the orifice when $P_{down} = 0$, then the orifice equation becomes the following:⁹

$$Q^* = \frac{Q_o}{Q_{max}} = \sqrt{1 - \frac{P_{down}}{P_{up}}} = \sqrt{1 - P^*} \quad (47.38)$$

$$\mathcal{P}^* = \frac{\mathcal{P}}{\mathcal{P}_{max}} = P^* Q^* = P^* \sqrt{1 - P^*} \quad (47.39)$$

$$\frac{d\mathcal{P}^*}{dP^*} = \sqrt{1 - P^*} - \frac{P^*}{2\sqrt{1 - P^*}} = 0. \quad (47.40)$$

⁸ This is derived from Bernoulli's equation. The discharge coefficient (C_d) corrects for viscous effects not considered and for the existence of a vena contracta or convergence in the flow through the orifice, which makes the area of the jet smaller than the orifice itself. For most oils $C_d \approx 0.62$.

⁹ Where bold letters will be used to indicate the nondimensional forms.

FIGURE 47.14 Nonlinear impedance matching.

for which $P^* = 2/3$, and by substitution into (47.38), the flow at that point is $Q^* = 1/\sqrt{3}$, and the maximum power delivered is $(\sqrt{2}/3)P_{\max}Q_{\max}$. The output admittance of the orifice is the slope of the curve at any operating point:

$$Z_o = \frac{dQ^*}{dP^*} = \frac{1}{2\sqrt{1-P^*}} = \frac{\sqrt{3}}{2} \Big|_{P^*=2/3}. \quad (47.41)$$

The load for which maximum power will be delivered, whether it has a linear or nonlinear characteristic, must pass through the maximum power point. Its chordal admittance must be

$$Z_{\text{chordal}} = \frac{Q_{\text{op}}^*}{P_{\text{op}}^*} = \frac{1/\sqrt{3}}{2/3} = \frac{\sqrt{3}}{2}, \quad (47.42)$$

which is exactly the slope in Equation (47.41). Figure 47.14 shows this graphically.

Note that for this power plane, the ordinate is “flow” and abscissa is “pressure” so that the slopes shown are admittances rather than impedances. While in other figures, the abscissa has always been effort and the ordinate flow, it is conventional in hydraulic systems to show these figures the other way probably because pressure is usually the independent variable in hydraulic system characteristics: pressure is controlled and flow is measured.

47.4.8 Graphical Determination of Output Impedance for Nonlinear Systems

A three-way hydraulic valve supplies or drains its load through a pair of variable orifices, one connecting the supply to the load and the other connecting the drain or tank to the load. These orifices are operated (typically on a single moving part of the valve) in a push-pull fashion; that is, as one opens, the other closes. If both orifices are partially open together when the valve is centered, the three-way valve is open centered. If one is wide open just as the other closes, the valve has no overlap.

FIGURE 47.15 A three-way valve geometry and output.

Suppose it is required to find the P - Q characteristics of the load port for flows both into and out of the valve. The system is shown in Figure 47.15. Thus for the upstream and downstream orifices respectively, Equation (47.37) becomes

$$Q_u = C_d A_u \sqrt{\frac{2}{\rho} (P_S - P_L)} \quad \text{and} \quad Q_d = C_d A_d \sqrt{\frac{2}{\rho} (P_L - P_T)}. \quad (47.43)$$

The load flow (Q_L) is the difference between Q_u , and Q_d . Also, the tank pressure (P_T) can be taken as zero. These equations combined become

$$Q_L = C_d A_u \sqrt{\frac{2}{\rho} (P_S - P_L)} - C_d A_d \sqrt{\frac{2}{\rho} P_L} \quad (47.44)$$

It is much more convenient to work with Equation (47.44) in dimensionless form. If we assume that the maximum upstream and downstream areas are the same and that they are truly push-pull, then we can nondimensionalize the area using A_{\max} . The discharge coefficient (C_d) is a constant for conventional valve geometries. The supply pressure (P_S) is a convenient term for the pressure nondimensionalization. Flows can be nondimensionalized with respect to a maximum flow that would pass through either orifice at full area A_{\max} with P_S acting across it:

$$Q_{\max} = C_d A_{\max} \sqrt{\frac{2}{\rho} P_S}. \quad (47.45)$$

If we set $P_L/P_S = \mathbf{P}$ and $Q_L/Q_S = \mathbf{Q}$ and express the upstream and downstream orifice sizes as push-pull fractions of A_{\max} , $0.5(1+x)A_{\max}$ upstream and $0.5(1-x)A_{\max}$ downstream, where $-1 \leq x \leq 1$ and the valve is centered for $x=0$, then Equation (47.44) combined with (47.45) yields

$$\mathbf{Q} = \mathbf{Q}_u - \mathbf{Q}_d = 0.5(1+x)\sqrt{1-\mathbf{P}} - 0.5(1-x)\sqrt{\mathbf{P}}, \quad (47.46)$$

which is one of those unfortunate equations in which the radical cannot be eliminated by squaring both sides. While Equation (47.46) can be readily plotted, \mathbf{Q} versus \mathbf{P} with x (the valve stroke) as a parameter, it is instructive to construct it instead from its parts.

The term $0.5(1+x)\sqrt{1-\mathbf{P}}$ is the characteristic family for the upstream orifice, and the term $0.5(1-x)\sqrt{\mathbf{P}}$ is the characteristic family for the downstream orifice. The first of these are parabolas to the left (on their sides because they are roots), starting at $\mathbf{Q}_u = 0.5(1+x)$, $\mathbf{P}=0$ and ending at $\mathbf{Q}_u=0$, $\mathbf{P}=1$ (there is no flow when the downstream

FIGURE 47.16 Flow versus pressure drop characteristics for the valve orifices.

pressure equals the upstream pressure). The second term starts at $Q_d = 0$, $P = 0$ and rises to the right to the points $Q_d = 0.5(1 - x)$, $P = 1$. All this is shown in Figure 47.16. If there is no load flow, then the curves for the upstream orifice show its output characteristic while those for the downstream orifice represent the only load. The intersections predict the operating pressures for $Q = 0$ as the valve is stroked, $-1 \leq x \leq 1$.

If there is a load flow (Q), then continuity must be served. This requires that

$$Q = Q_u - Q_d \rightarrow Q_u = Q + Q_d. \quad (47.47)$$

In Figure 47.16, Q is simply a vertical bar between the curves for Q_u and Q_d whose length is the load flow. Thus, for any load pressure value on the abscissa, the load flow is determined as the vertical distance between the input orifice curve and the output orifice curve. The load flow is positive if the upstream orifice curve is above the downstream orifice curve but negative otherwise. These data can be picked off and plotted as the Q - P characteristic of the valve, as shown in Figure 47.17.

FIGURE 47.17 The output characteristic of the valve.

Figure 47.17 illustrates that an operating point on an input–output characteristic forces compatibility and continuity, but as long as those are preserved, a second energy exchange as at the $P_L - Q_L$ port of this valve can still be accommodated. This approach can be extremely useful in systems such as air-conditioning ducting where the fan characteristic is known only graphically, and then its output impedance at some point along the ducting must be determined. Exactly, the same procedure is used.

47.5 TRANSFORMING THE OPERATING POINT

It is often not among the system designer's options to choose either the output impedance of the power source in the system or the input impedance of the load that must drive. The only recourse at that point is to insert a transformer, transducer, or gyrator in the system if it does not already contain one or to vary the modulus of the two-port element if it does. In the old tube-type audio systems, the output impedance of the push–pull power tubes exceeded $1000\ \Omega$ while the input impedance of the speakers available then was 4, 8, or $16\ \Omega$. To match the amplifier to the load, each channel had a large transformer for speaker connections with taps having turns ratios of $\sqrt{1000/4}$, $\sqrt{1000/8}$, and $\sqrt{1000/16}$. With this arrangement, maximum power transfer was assured down to the lowest frequencies for which the transformers were designed.

47.5.1 Transducer-Matched Impedances

Suppose a permanent direct current (dc) magnet servomotor is to drive a screw that, in turn, drives a mass, perhaps a machine-tool table. If the objective is to minimize the move time from stationary start to full stop, then the optimal trajectory for the servo, assuming equal and constant acceleration and deceleration, is well known: maximum acceleration to either half of the move distance or maximum velocity, whichever comes first, followed by maximum deceleration to the finish. These trajectories are illustrated in Figure 47.18.

The motor operates in two modes: at maximum acceleration (maximum torque), which is set by the maximum short-term current permitted by the coercivity of the motor magnets and the capacity of the commutation, and at maximum speed, if that is reached, set by the maximum voltage available or by whatever the commutation allows. Often, servo designers accomplish these two modes by using an overvoltage (two to three times rating) during acceleration and deceleration, which runs the power amplifier as a current source,

FIGURE 47.18 Optimal trajectories for point-to-point move.

and then as maximum speed is attained, switching the amplifier voltage limit to the motor rating, which runs the amplifier as a voltage source. This achieves a constant acceleration and a constant top speed.¹⁰

During the acceleration or deceleration phase of the trajectory, the electrical torque available is accelerating two inertias: the motor itself and the load. Since the motor is acting as an electromagnetic torque source while constant current is supplied, $\tau_{\text{motor}} = K_m i_{\text{armature}}$, the mechanical output impedance viewed at the motor shaft is the rotor inertia between the output shaft and the electromagnetic torque source:

$$Z_o \left| \begin{array}{l} \text{motor shaft with} \\ \text{constant armature current} \end{array} \right. = J_{\text{armature}} s. \quad (47.48)$$

During acceleration and deceleration, the optimal load impedance (Z_{load}) will be equal to the motor inertia, and the available electromagnetic torque will be shared equally by the motor armature and the load.

The load given in this example is primarily massive, so with reflection through the screw, the load inertia is computed as the load inertia times the square of the transducer ratio (p for the screw; see Table 47.2):

$$Z_{\text{load}} = p^2 M_{\text{load}} s. \quad (47.49)$$

To the extent possible, the pitch of the screw or the inertia of the motor should be chosen to achieve this match. Failing both of those options, a gear box should be placed between the screw and the motor to accomplish the match required.

47.5.2 Impedance Requirements for Mixed Systems

When a source characteristic is primarily real or static (so that the source impedance is resistive) and the load is reactive or dynamic (dominated by energy storage elements), then impedance matching in the strictest sense is impossible, and the concept of passing the load line through the source characteristic at the maximum power point does not make sense. How then does one match a static source to a dynamic load or the reverse?

Figure 47.19 shows an electrohydraulic position servo driving a mass load with negligible damping losses, and Figure 47.20 shows the pressure flow characteristics of the

FIGURE 47.19 Electrohydraulic position servo.

¹⁰ Actually, designers rarely use maximum acceleration or maximum velocity because such full-scale values leave no overhead for control. A servo running in saturation is an open-loop system.

FIGURE 47.20 Servovalve characteristic.

servovalve: a family of parabolas in the power plane used for hydraulic systems. The transducer between this hydraulic power plane and the force–velocity power plane in which the load operates is a piston of area A . There are two equations:

$$P = \frac{1}{A}F \quad \text{and} \quad Q = Av. \quad (47.50)$$

With these equations, a load in F – v coordinates can be transformed to a load in P – Q coordinates for superposition on the source characteristics.

The impedance of the mass load, however, is simply $Z_{\text{load}} = (M)(s)$, but this cannot be plotted in an F – v coordinate system because it is the slope of a straight line in energetic coordinates: F versus dv/dt . To match load to source, we need the force–velocity relationship for the load. A servo designer normally has a frequency response in mind for his or her application or can determine one from a linearization of the system. Suppose, in this example, that the valve operating between a supply pressure (P_s) and a maximum load flow (Q_{max}) must drive the mass load (M) through the piston of the area (A), with a frequency response flat in position to a frequency of ω (radians per second), at an amplitude of D_{max} . With these conditions, the force–velocity relationship for the load can be found as follows.

If y is the displacement, \dot{y} is the velocity and \ddot{y} is the acceleration, then the most taxing demand on the servo will be $y = D_{\text{max}} \sin(\omega t)$, where t is time. Then $\dot{y} = D_{\text{max}} \omega \cos(\omega t)$ and $\ddot{y} = -D_{\text{max}} \omega^2 \sin(\omega t)$. Given that $F = M\ddot{y}$ is the load equation, however, the load can now be expressed parametrically as a pair of equations:

$$v = \dot{y} = D_{\text{max}} \omega \cos(\omega t) \quad \text{and} \quad F = -MD_{\text{max}} \omega^2 \sin(\omega t). \quad (47.51)$$

If these are cross-plotted in the force–velocity plane with time as a parameter, the plot traces out an ellipse as time goes from zero through multiples of $2\pi/\omega$. Transforming these to the P – Q plane requires application of the piston equations (47.50) to yield

$$Q = AD_{\text{max}} \omega \cos(\omega t) \quad \text{and} \quad P = -\frac{MD_{\text{max}} \omega^2}{A} \sin(\omega t). \quad (47.52)$$

FIGURE 47.21 Matching power requirements for a dynamic load.

If the valve is to drive the mass through the piston around the trajectory, $y = D_{\max} \sin(\omega t)$, then the valve output characteristic for the maximum valve stroke must entirely enclose the elliptical load characteristic derived in Equation (47.52). Furthermore, if the valve and load are to be perfectly matched, then the valve characteristic and the load ellipse must be tangent at the maximum power point for the valve: $P = 2/3 P_s$, $Q = (1/\sqrt{3}) Q_{\max}$. This is shown in Figure 47.21.

Note that this requirement means that neither maximum valve output pressure nor maximum valve flow will ever be reached while the load executes its maximal sinusoid. If $P_s = -MD_{\max} \omega^2 / A$ and $Q_{\max} = AD_{\max} \omega$, the valve sizing would have provided inadequate power for reaching any but those points on the trajectory, which would therefore have followed the valve characteristic instead. The correct matching relationships are those which satisfy the following equations:

$$\frac{1}{\sqrt{3}} Q_{\max} = AD_{\max} \omega \cos(\omega t) \quad \text{and} \quad \frac{2}{3} P_s = \frac{MD_{\max} \omega^2}{A} \sin(\omega t) \quad (47.53)$$

at the appropriate time. These equations relate D_{\max} , ω , M , Q_{\max} , P_s , and A , so any five of these determine t and the sixth. If the load mass, supply pressure, piston area, peak frequency, and maximum amplitude are all known, for example, Equation (47.53) size the valve by determining its maximum required flow. If the valve has been selected, these equations will size the piston.

In the example above, the load was purely massive. Most real loads are dissipative as well. The procedure outlined above, however, need only be modified by adding the damping term to the force equation:

$$F = M\ddot{y} + B\dot{y} = -MD_{\max} \omega^2 \sin(\omega t) + BD_{\max} \omega \cos(\omega t), \quad (47.54)$$

FIGURE 47.22 Matching power requirements for a mass load with dissipation.

where B is the damping coefficient. This has the effect of tipping the axis of the elliptical load line up to the right, but the rest of the development follows as before with the added term. Figure 47.22 shows the result. If the load mass were to be negligible, then the elliptical transformed load line in Figure 47.22 would collapse to a line passing through the maximum power point of the valve characteristic, as discussed previously.

47.6 MEASUREMENT SYSTEMS

Measurement extracts information about the state of a measured system, usually in the form of one of the factors in the measurement domain whose product is power or energy flux, such as voltage or current, pressure or flow, and so on. A measurement usually extracts some energy from the system being measured, if only in a transient sense; each link in the chain from measurement to display involves a further exchange of energy or power. If we measure voltage in a circuit, for example, we must draw some current, at least instantaneously, so that the power is dissipated by effective resistances, or energy is stored capacitively, inductively, or both.

At the measurement interface, we wish to disturb the measured system as little as possible by extracting as little energy or power as can be managed. It is usually our objective to pass power or energy along the chain of elements that form the measurement system, and there is a best combination of the energy variables to attain the optimum transfer. This chapter has dealt with these issues: the maximization of energy transfer within the system where we want it and the minimization of energy theft at the measurement interface where we do not.

47.6.1 Interaction in Instrument Systems

The generalized instrument consists of a number of interconnected parts with both abstract and physical embodiments. An orifice flow-metering system might consist of the following chain: an orifice plate converts the flow to a pressure drop; a diaphragm converts the pressure

FIGURE 47.23 The chain of a flow measurement.

drop to a force; a spring (perhaps an unbonded strain-gage bridge) converts the force to a displacement; the strain gages convert the displacement to a resistance change; a bridge arrangement converts the resistance change to a differential voltage; and a galvanometer converts the voltage to a trace on paper. Figure 47.23 illustrates this chain.

In setting up this chain, the orifice is sized to minimize the pressure drop resulting from our flow measurement, and the diaphragm must be sized for minimum pumping volume during transients in pressure, or it will alter the flow reading in a transient sense. The diaphragm, however, has an output stiffness; the force it transmits decreases with increasing displacement, and it is driving the unbonded gages, converting force to displacement. The combined stiffness of the unbonded strain gages, which will be linear springs, must equal the average stiffness of the diaphragm¹¹ to ensure that the strain energy transfer is maximized for a given input energy from the fluid.

The displacement–strain relationship is a definition. Further along the chain, however, this strain is converted to a differential voltage whose magnitude depends on the input impedance of the galvanometer, which is loading the bridge. For bridges constructed with the same resistance in each arm, whether the resistors are active gages or not, the input and output impedances are the same: the resistance of one arm, usually the gage resistance. If we ignore dynamic considerations (such as galvanometer damping), the optimal galvanometer will therefore have the same resistance for maximum deflection per unit strain as one gage in the bridge.

At the measurement interface, therefore, the objective is to mismatch the impedances between the measurement system and the measured system as much as possible. There is more to this than the selections of voltage-measuring devices with higher impedance than the system in which voltage is being measured and current-measuring devices with lower impedance than the circuits in which they are placed. The measurement and control engineer must always be aware of dynamic loading as well.

The output impedance of any piezoelectric device, for example, is almost purely capacitive and is typically only a few picofarads for small devices. The input impedance of most oscilloscopes is a parallel combination of 1 M Ω and 100 pF. Either or both of

¹¹ If the diaphragm were rigidly supported in the center, then the force on the support would be the pressure times the effective area of the diaphragm. If the support were not rigid, this output force would depend nonlinearly on the support displacement. The plot's negative slope of force transmitted vs. displacement is the output stiffness of the diaphragm, and pressure \times area is the force source in this model.

those would load a piezoelectric device to near uselessness, even though for most other purposes they are high impedances. The resistance would reduce the charge on the crystal much too quickly, and the capacitance would steal charge and reduce the voltage output drastically. An attempt to measure the pressure in a small volume with a transducer that has a large swept volume itself would meet with the same failure: the displacement of the transducer would alter the volume in which the pressure was measured. Holography has become popular in the study of the vibration of thin plates and shells because it does not load the structure by adding mass as an array of accelerometers would.

47.6.2 Dynamic Interactions in Instrument Systems

It is not only the steady-state loading of a measurement that is of concern; under many circumstances, the unsuspected dynamics of the instrument being used will lead to erroneous results. Consider the simple measurement interface shown in Figure 47.24. The readout instrument, an oscilloscope for example, has both resistance and capacitance. The load impedance is therefore the parallel combination of these:

$$Z_{\text{inst}} = \frac{R_i(1/C_i s)}{R_i + 1/C_i s} = \frac{R_i}{R_i C_i s + 1} = \frac{R_i}{\tau_i s + 1} \quad \text{with} \quad \tau_i = R_i C_i. \quad (47.55)$$

Thus, the load depends on the frequency of the voltage being measured. This might not concern us in the sense that we can predict it and compensate for the known phase shift, which this will induce, but when the interaction of the two systems is considered, the problem becomes more obvious. The total impedance loading the measurement of V_s includes the source impedance Z_o . Suppose this is purely resistive (R_o):

$$Z_{\text{total}} = R_o + Z_{\text{inst}} = \frac{R_o R_i C_i s + (R_o + R_i)}{R_i C_i s + 1}. \quad (47.56)$$

The readout instrument is sensitive only to the voltage it sees, which has been reduced by the voltage drop in R_o . In general, the measured voltage, V_{meas} , is the voltage across the instrument's input resistor and capacitor, R_i and C_i :

$$\frac{V_{\text{meas}}}{V_s} = \frac{Z_{\text{inst}}}{Z_{\text{total}}} = \frac{R_i}{R_o R_i C_i s + (R_o + R_i)} = \frac{1}{R_o C_i s + (R_o/R_i + 1)}. \quad (47.57)$$

Unless we know the output impedance at the point of measurement, in this case R_o , we do not even know the time constant or break frequency germane to the measurement. In the event that Z_o is also complex (has reactive terms), this situation is more complicated, and if $Z_o = L_o s + R_o$, for example, the system could even be oscillatory.

FIGURE 47.24 A measurement with a dynamic instrument.

FIGURE 47.25 Schematic of cascaded instrument system.

Sometimes, frequency-dependent impedances are intentionally introduced into a measurement system, most commonly in the form of passive filters. Figure 47.25¹² shows a first-order, low-pass filter being driven by a source with a nonzero output impedance (R_s) and being loaded by a readout instrument with finite input impedance (R_i).

The loading problem is potentially present at the interface of each stage indicated by the broken lines and terminals. What is not so obvious is that the dynamics of this filter are quite sensitive to its source and load. An unwary designer might choose the filter time constant ($\tau_f = R_f C_f$) with little regard for the values of R_f and C_f and essentially design the filter under the simple assumption that source and load were ideal.

To the instrument, however, the filter is part of the source impedance, so the true source impedance combines R_s , R_f , and C_f , and the Thévenin equivalent source voltage (V_T) is no longer simply V_s . The Thévenin voltage (V_T) and the new output impedance (Z_T) with the filter included become

$$V_T = \frac{V_s}{(R_s + R_f)C_f s + 1} \quad \text{and} \quad Z_T = \frac{R_s + R_f}{(R_s + R_f)C_f s + 1}. \quad (47.58)$$

Figure 47.26 shows the new equivalent circuit for the cascaded instrument system.

FIGURE 47.26 Thévenin equivalent of cascade system.

¹² This example is drawn entirely from Ref. (Nachtigal, 1978), with the permission of Dr. C. L. Nachtigal. In this and the previous example, Figures 47.24 and 47.25, the source voltage is referred to as a Thévenin equivalent source. In single-loop circuits the source voltage is by definition the Thévenin voltage, since removing one element from the loop causes it to become open circuited. If the source is a sensor, for example, the magnitude of the voltage is governed by the value of the sensed variable and, of course, its own design parameters. The Thévenin, or open-circuit voltage, is specified on the sensor data sheet.

The instrument is now loading this system, and the output (V_o) is equal to the voltage across R_i . Therefore, in terms of the original measured voltage (V_s)

$$\frac{V_o}{V_s} = \frac{1/(1 + (R_s + R_f)/R_i)}{[(1 + R_s/R_f)/(1 + (R_s + R_f)/R_i)]R_f C_f s + 1} = \frac{K_f}{\tau s + 1} \quad (47.59)$$

where

$$K_f = \frac{1}{1 + (R_s/R_i) + (R_f/R_i)} = \frac{1}{1 + \beta} \quad (47.60)$$

and

$$\tau = \left(\frac{1 + (R_s/R_f)}{1 + (R_s/R_i) + (R_f/R_i)} \right) R_f C_f = \left(\frac{1 + \alpha}{1 + \beta} \right) R_f C_f. \quad (47.61)$$

Our filter has its expected characteristics, $\tau = \tau_f = R_f C_f$ and $K_f = 1$, only if both α and β approach zero, a circumstance that requires $R_s \rightarrow 0$ and $R_i \rightarrow \infty$ while R_f remains finite. As the instrument resistance (R_i) decreases, the static gain and time constant decrease as well, which means that the break frequency of the filter increases from the designed value because the instrument provides another path for the discharge of the capacitor in the filter. As the transducer resistance (R_s) increases from zero, the static sensitivity (K) again decreases, but this time the break frequency decreases as well.

This analysis shows us that source loading by a filter and filter loading by a readout instrument can cause significant changes in both the designed filter gain and break frequency. Only if α and β in Equations (47.60) and (47.61) remain equal does the filter break frequency remain unscathed by nonideal source and load impedances. This condition requires that

$$\frac{R_s}{R_f} = \frac{R_s + R_f}{R_i}$$

or

$$R_f^2 + R_s R_f - R_s R_i = 0 \quad (47.62)$$

Dividing the second of Equations (47.62) by R_s^2 and solving it for R_f/R_s yield

$$\frac{R_f}{R_s} = \frac{1}{2} \left(-1 \pm \sqrt{1 + 4 \frac{R_i}{R_s}} \right) \cong \sqrt{\frac{R_i}{R_s}} \quad (47.63)$$

since any realistic measurement system has $R_i/R_s \gg 1$, and since the resistances must be positive, the negative solution is discarded. This approximation is equivalent to saying that R_f should be chosen to be the geometric mean of the estimated or known values of R_i and R_s ; that is, $R_f = \sqrt{R_i R_s}$ presuming only that $R_i \gg R_s$. For this choice of filter resistance, the resulting gain is given by

$$K = \frac{1}{1 + \sqrt{R_s/R_i} + R_s/R_i} = \frac{1}{1 + (R_s/R_i)^{3/2}} \cong 1 \quad \text{for } R_i \gg R_s. \quad (47.64)$$

If the filter fails these conditions, it must either be carefully designed for the task or it should be an active¹³ filter with a high input impedance and low output impedance.

47.6.3 Null Instruments

Many instruments are servos, active systems designed to oppose the variable they measure so as to decrease their demand on the complementary energy or power variable to zero. In a steady-state sense, these instruments draw no power or energy from the measurement interface because these energetic requirements are provided by the instrument's power supply. These instruments therefore have infinite or zero input impedance in steady state. Examples abound: slidewire potentiometers for strain readout and thermocouple readout both measure voltage by servoing to zero current. Servo accelerometers avoid the problems with temperature inherent in the elasticity variations of metals and crystals by servoing the motion of the proof mass to zero and measuring the force required to do it. The differential pressure-cells used in the process control industry measure differential pressure across a diaphragm or capsule while preventing the diaphragm or capsule (separating the two pressures) from moving. They thus avoid having to worry about the nonlinear elastic characteristics of the capsule and seals in the system.¹⁴ Their output is either the current in a voice coil or the pressure in a bellows necessary to oppose the motion. In all of these cases, however, there is a transient displacement until the servo zeros it out, and some energy must be lost to transfer the information required by the servo in the instrument. For this reason, null instruments are no better at measuring stored energy, the voltage on a small capacitor for example, than passive but high-impedance instruments, particularly if the energy consumed to reach null is not extremely low.

47.7 DISTRIBUTED SYSTEMS IN BRIEF

While a detailed study of the input–output relationships for distributed systems is beyond the scope of this chapter, a brief discussion can tie these into the concepts already covered. All of the systems discussed to this point have been lumped, a label that implies physical dimensions are not of importance; the system parts can be considered as point objects. Considering a tank, for example, to be a point does not mean that the tank has no dimensions; it merely means that the internal pressure is considered to be the same everywhere within it; conditions in its interior are absolutely uniform. When studying lumped circuits, we are not concerned with the dimensions of the circuit elements or with their distances from each other on the circuit board. In reality, the nodes of the circuit have lengths, but they are ignored for the purposes of analyzing the lumped circuit.

In the mechanical domain, we consider that masses are rigid and behave as if the forces acting were applied at a point, and if we are interested in the distributed properties of an object, we consider only its moment of inertia. In each of these examples, changes in the physical variables of our model are assumed to propagate instantaneously, even though it is well known that all have finite propagation velocities. A system element must be considered to be distributed to have properties that vary with a physical dimension if that

¹³ Incorporating amplification, usually an operational amplifier.

¹⁴ Dry friction would nonetheless be fatal to the instrument because it would be fatal to its servo and would lead to dynamic instabilities of the limit-cycle variety.

assumption is not true. This occurs whenever the dimensions of the object are large compared to the characteristic size of the events occurring.

Mechanical disturbances of all kinds propagate at the speed of sound in the medium involved, and electromagnetic disturbances propagate at speeds near the speed of light, depending again on the medium. A hammer blow to the end of a long, slender bar, for example, induces a strain pulse at the struck end which travels into the bar (informing the interior of the event) at the speed of sound in compression in the bar material ($c = \sqrt{E/\rho}$, where E is Young's modulus of the material, ρ is its mass density, and c is the propagation speed of compressive or tensile events). If the pulse duration is short, its physical length approaches that of the bar or may be shorter than the bar. Our simple lumped models of the bar's behavior [$F = M\ddot{y}$ and $\int F dt = Mv(t) - Mv(0)$], which treat it as a solid rigid object, are incorrect. Similarly, if a small explosion, a spark, for example, is initiated in a tank, the pressure in the tank will not remain uniform throughout. Instead, pressure waves will propagate within the tank at the speed of sound until damping takes its toll; we can no longer consider the tank to be a simple lumped capacitor, at least in the time scale of the spark event.

47.7.1 Impedance of a Distributed System

Imagine a long, slender tank of water, a trough, open at the top, and perform the following *thought* experiment. If one end wall was moved inward suddenly, the level of water at that end would rise higher up than was required by the change in tank volume because the remaining water further along the tank would not change level instantaneously. Then, this wave coming down off the tank wall would travel to the other end where it would slosh up the far wall and return. This wave would continue to slosh back and forth at decreasing amplitude as viscosity took its toll, until finally the surface would be calm again at a new, slightly higher level. Each time the wave reached an end, it would be returned in kind, that is, with the same sign.

Now suppose that the far end of the tank opened into a large lake, so large that no level changes would take place when an end wall was moved, and again move the remaining end wall inward quickly. Then, when the first wave reached the opening to the lake, it would leave the tank and be lost in the lake. But that would involve water leaving the tank in excess of the volume change in the tank, and a negative wave would return from the open end to signal the new, lower level required by the loss. The closed end would reflect this wave as a rarefaction, and when that returned to the open end, lake water would spill back in as an upward wave. Eventually these alternating processes would return the level in the tank to that of the lake.

A closed end returns a wave of like kind, and an open end returns a wave of opposite kind. If there are no losses as the waves hit the ends of the tank, a wave of strength $+1$ is reflected with strength $+1$ from a closed end and with a strength -1 from an open end. This implies that there is an end condition somewhere between *closed* and *open* from which a wave will not be reflected at all. A suitably constructed porous wall, in this example, would simply absorb the wave completely by accepting and dissipating all of its energy. The impedance of this wave-matched wall is the wave impedance of the channel and is a characteristic of it, depending on the inductive and capacitive properties of the medium.

The 75- and 300- Ω markings on the antenna connections of a television receiver imply two things: First the input impedances of those terminals are resistive at 75 and 300 Ω , respectively, and, second, the coaxial cable and flat-lead antenna wiring are really

waveguides whose wave impedances are 75 and 300 Ω . By matching the impedance of the cable at the receiver terminals, we are assured that all the incoming *wave energy* will be absorbed by the receiver and none will be reflected back up the cable to the antenna and thus lost.

47.8 CONCLUDING REMARKS

This chapter has demonstrated an alternate viewpoint for the interaction of systems with each other. Control engineers are quite accustomed to transfer functions: relationships in the frequency (s or Laplace) domain between a variable at one point in a system and another at some other point, most often between inputs to and outputs from a controlled system. This chapter has dealt with a special class of these relationships between the complementary variables of power at a single point in a system. These special transfer functions are called driving-point impedances or admittances, and they determine how one subsystem will load or be loaded by another.

Admittances are the reciprocals of impedances, and both are unique properties of a system. The Laplace operator (s) expresses these properties as a polynomial ratio. The denominator polynomial (when set to zero, it becomes the characteristic equation of the system) is always the same, and the numerator polynomial is a function of the location of the point considered in the system. It was also shown that driving-point impedances are not a function of the controlled variables on any ideal sources the system contains. Instead, all effort sources may be replaced by solid connections, and all flow sources may be removed before the driving-point impedance is computed.

When two systems are connected together at a driving point, port, or pair of terminals, usually so that one can pass energy or information to the other, then there is a favorable relationship between the impedances of the two systems that depends on the objective of the connection. When it is desired to pass energy or power from one system to the other, then the output impedance of the driving system should match the input impedance of the driven system. If neither the driver nor the driven are adjustable, then a transducer, gyrator, or transformer is used to match them by selecting the modulus to achieve the match. Any impedance seen through a transformer, for example, appears to be increased or diminished by the square of the transformer ratio. In a chain of subsystems, it is not necessary to install the transformer at the driving point under consideration; the correct ratio can be determined no matter where it is placed within the chain because the square of the modulus will always appear in one of the driving-point impedances.

If the interconnection represents a measurement interface, then the most favorable relationship between the driving-point impedances is the largest possible mismatch consistent with obtaining the measurement. The ideal instruments for measuring efforts have infinite input impedance and the ideal instruments for measuring flows have infinite input admittances. Instruments that measure the integral of flows, such things as volume, charge, and displacements, should have very low compliance (should displace easily, have low volume themselves, or have small capacitances), while instruments that measure the integral of efforts, such things as flux linkage or momentum, must have low mass or inductance.

The operating point of a pair of coupled systems is at the intersection of their input and output characteristics in the power or energy plane. If one of these, for example the source or output characteristic, exists in the power plane, that is, is static, but the other is

energetic (i.e., dynamic: massive, inductive, capacitive, etc.), then the source characteristic must enclose the trajectory of the load characteristic at the highest frequency of interest, and ideally, the source characteristic and load trajectory should be tangent at the maximum power point or should be made tangent there by suitable choice of system parameters.

The key issue in this chapter is this: whenever two dynamic systems are connected, an interaction occurs. If the connection is to meet its objectives, the nature of this interaction must be explored and controlled.

48.1 TERMINOLOGY

A telemetry system responding to a measurand consists of four basic parts—the transducer, the transmitting system, the receiving system, and the data output or display system:

Telemetry: The transmission of information about a measurand.

Measurand: The object of a measurement. The process to be defined.

Transducer: A component in the telemetry system which provides information about a process and, as a by-product, transfers energy from the process. Typical bridge transducers convert physical quantities such as force, pressure, displacement, velocity, acceleration, temperature, and humidity into electrical quantities for input to the transmitting system.

Transmitting System: The transmitting system typically consists of some or all of the following devices: cable, amplifier, subcarrier oscillator, filter, analog-to-digital (A/D) converter, transmitter, and antenna.

Receiving System: The receiving system typically consists of some or all of the following devices: antenna, preamplifier, multicoupler, receiver, tape or disc recorder, discriminator, decommutator, digital-to-analog (D/A) converter, and output filter.

Data Output and Display System: The data output and display system typically consist of some or all of the following devices: oscilloscope, analog meter, digital meter, graphic display, and digital printer. Either these devices may be connected directly to the output of the receiving system or a computer may process the data from the receiving system before display.

48.2 FLEXURAL DEVICES IN MEASUREMENT SYSTEMS

Bridge transducers depend on a measurand to directly modify some electrical or magnetic property of a conductive element. For example, the thermal coefficient of impedance can result in a change in impedance of a conductive element proportional to temperature (e.g., resistance thermometer). Similarly, hygroscopic materials can have their impedance change in a deterministic fashion due to humidity (e.g., humidity sensor). Most bridge transducers, however, depend on the displacement of a flexure to vary the impedance of a conductive element, resulting in an electrical signal proportional to the measurand. Advantage is taken of either the strain pattern on the surface of the flexure or the motion of this surface. Among the gamut of flexure elements associated with bridge transducers are cantilever beams, Bourdon tubes, and clamped diaphragms.

48.2.1 Cantilever Beams

Cantilever beams are routinely designed into bridge transducers. Strain near the clamped end of the beam can be correlated to displacement of the free beam end, force or torque applied to the free beam end, dynamic pressure associated with fluid flow acting over the beam surface, and so on. The compliance of a cantilever beam is defined as

$$\frac{y}{F} = \frac{L^3}{3EI} \quad (48.1)$$

where y is deflection of the beam free end, F is the force applied to this end, L is the beam length, E is the modulus of elasticity of the beam material, and I is the beam area moment of inertia. A compliant flexure will result in a bridge transducer with a large electrical signal output. Equation (48.1) indicates a compliant flexure design can be achieved by a long, thin, and narrow beam of low-modulus material. The penalty attached to such a design in application could be a transducer which is bulky, displays undesirable response to physical inputs orthogonal to its sensing direction, and has poor dynamic response.

48.2.2 Bourdon Tubes

Bourdon tubes are one of the most widely used flexures for sensing pressure. The original patent for this device was granted to Eugene Bourdon in 1852. Bourdon tubes are hollow tubes that are twisted or curved along their length. The application of pressure deforms the tube wall which, depending on tube shape, causes it to untwist or unwind. Motion of the tube is typically used to modify the alternating current (AC) impedance of bridge transducers. Bourdon tubes can be integrated into transducers to achieve extremely high accuracies and have been manufactured from perfectly elastic materials such as quartz. Transducers employing Bourdon tubes tend to be physically large and easily damaged by environmental inputs such as acceleration. In addition, the tubes themselves afford poor frequency response to time-varying pressure.

48.2.3 Clamped Diaphragms

Clamped diaphragms are another flexure used to transform a measurand into a strain or displacement proportional to applied pressure. A small, flat, circular diaphragm can be made simply, and it can be placed flush against surfaces whose flow dynamics are being studied. This type of diaphragm is typically designed to deflect in according with theory associated with clamped circular plates. Corrugated diaphragms provide extensibility over a greater linear operating range than do flat diaphragms. A catenary diaphragm consists of a flexurally weak seal diaphragm bearing against a thin cylinder whose motion is measured. The compliance of a flat, clamped circular diaphragm is defined as

$$\frac{y}{P} = \frac{3R_0^4(1 - \nu^2)}{16t^3E} \quad (48.2)$$

where y is the deflection of the center of the diaphragm, P is the applied pressure, R_0 is the diaphragm radius, ν is Poisson's ratio, t is the diaphragm thickness, and E is the modulus of elasticity of the diaphragm material. Somewhat analogous to the cantilever beam, a compliant diaphragm will have a large radius, be thin, and be made of a low-modulus material. Equation (48.2) holds for deflections no greater than t .

Figure 48.1 shows the radial and tangential strain distribution in a flat, clamped, circular diaphragm. The radial and tangential strains at the center of the diaphragm are identical. The tangential strain decreases to zero at the periphery while the radial strain becomes negative. Figure 48.2 describes a strain gage pattern designed to take advantage of this strain distribution. The central sensing elements measure the higher tangential strain while the radial sensing elements measure the high radial strains near the periphery. Resistance strain gages are discussed beginning in Section 48.3.

FIGURE 48.1 Radial and tangential strain distribution in a flat, clamped, circular diaphragm. (Courtesy of Measurements Group, Inc., Raleigh, NC.)

48.2.4 Error Contributions from the Flexure Properties

When flexures are designed for bridge transducers, the final transducer may have to possess an accuracy over its operating temperature range of from a few to a fractional percent. Knowledge of the inelasticities and metallurgical behaviors of flexural elements must be considered in transducer design. Metals under a constant load experience a minute deformation with time, called creep. Differences between the loading and the unloading curve of a flexure, due to energy absorbed by the material as internal friction, introduce another effect, known as hysteresis. The modulus of elasticity of materials changes with temperature. Corrosion resistance, machinability, magnetics, fatigue effects,

FIGURE 48.2 Micromeasurements' "JB" pattern strain gage for circular diaphragm pressure transducers. (Courtesy of Measurements Group, Inc., Raleigh, NC.)

thermal conductivity, and thermal expansion are other properties of flexural materials to consider in design application. The 300 series stainless steels are useful flexural materials due to their corrosion resistance, desirable low-temperature properties, and good creep properties at elevated temperatures. Inconel is a good flexural material in corrosive salt-water environments. These materials and others are discussed in an extremely good article on transducer flexures in Chapter 11 of Stein (1964).

48.3 THE RESISTANCE STRAIN GAGE

Strain gages are used to measure the strain pattern on the surface of the flexure in bridge transducers. In 1938, Simmons, at the California Institute of Technology, and Ruge, at the Massachusetts Institute of Technology, discovered independently that fine wire bonded directly to a surface being studied would respond to surface strain. Ruge's original gage was made by unwinding a constantan wire-wound vitrified resistor, gluing a portion of this wire with Duco cement to a celluloid bar, attaching brass shim stock as terminals, and interfacing the completed assembly to a galvanometer. The first strain gage manufacturer established in the United States was the Baldwin Lima Hamilton (BLH) Corporation (now part of the Vishay Measurements Group). BLH gages operating on the principle discovered by Simmons and Ruge were designated the SR-4 gage to include the initials of both men. The evolution of the bonded resistance wire strain gage occurred during the early 1940s. The first practical bridge transducer load cell was built by Baldwin Lima Hamilton in 1941. By the mid-1950s, Baldwin Lima Hamilton remained the only major strain gage manufacturer, and the foil strain gage was beginning to appear. Subsequent work by W. P. Mason and R. N. Thurston (reported in the *Journal of the Acoustical Society of America*, vol. 29, 1957) resulted in the introduction of the commercial semiconductor strain gage. Continued maturation of the bonded resistance strain gage has enabled a transducer industry centered around this technology to develop.

Other sources provide the derivation of all the equations dealing with ensuing topics in this chapter (Stein, 1953; Perry and Lissner, 1962; Dove and Adams, 1964; Window and Hollister, 1982).

48.3.1 Strain Gage Types and Fabrication

Paper-backed wire strain gages typically consist of a grid of resistance wire to which a paper backing has been attached with nitrocellulose cement. The wire is manufactured by drawing the selected alloy through progressive forming dies. To protect it during handling and assembly, the wire is usually sandwiched between two thin layers of paper. Typical grid wires are 0.02 mm in diameter.

Foil strain gages are essentially small printed circuits. Artwork for a master gage pattern is first prepared. This pattern is then photographically reduced, and multiple images are placed on a photographic plate. A sheet of foil (typically 0.003–0.005 mm thick) of the appropriate alloy has a light-sensitive emulsion applied, is exposed to the photographic plate, and then undergoes a development process. Chemical etching removes all but the grid material. The resultant grid cross section is square as opposed to round for wire. Advantages inherent in foil gages include better strain transmission due to improved bonding of the grid to the backing, a better thermal path for dissipation of electrically

generated heat, and a grid that can more readily be configured to minimize sensitivity to transverse strains.

The total combination of wire and foil gages span grid lengths from 0.2 mm to more than 250 mm. Foil gages satisfy the smaller of these requirements. Both wire and foil gages have associated with them a variety of ohmic values, such as 120, 175, 350, 1000, and so on. Standard values which have historically evolved are 120 and 350 Ω . These values are carry-overs from impedance-matching requirements for galvanometers which were formally used for strain recording. Figure 48.3 displays numerous configurations of wire and foil strain gages.

In the manufacture of bridge transducers using metallic strain gages, vacuum deposition of the gages is an alternate technique to bonding individual gages to the transducer flexure. The flexure is coated with aluminum oxide and then the metal gages are selectively deposited. This process yields the closest match of thermal and electrical characteristics for each bridge element.

The manufacture of semiconductor strain gages starts with a single high-purity silicon crystal. Atoms such as phosphorus (n type) or boron (p type) are doped into the material to lower its resistivity. The parent crystal is sliced into wafers before the dopant is added in a furnace at high temperature ($>1000^{\circ}\text{C}$). The wafer is masked and etched to produce a suitable grid pattern (usually either a straight element or U-shape). This grid can remain unbacked or can be mounted on a suitable carrier.

FIGURE 48.3 Numerous configurations of wire and foil strain gages—not to scale. (Courtesy of BLH Electronics, now Vishay Measurements Group.)

Alternately, in diffused semiconductor transducers, the transducer flexure itself may be made of silicon. Its surface can be passivated, etched, and doped to form gage elements integral to the flexure. Similar to vacuum deposition of metal gages, diffused semiconductor transducers offer a more nearly optimum match of thermal and electrical properties for each bridge element. Problems with slippage associated with the bond of a gage carrier or backing are nonexistent.

Bridge transducers using semiconductor gages typically possess poorer thermal and linearity specifications than those using metal gages. However, the sensitivity of semiconductor gages to surface strain is much greater than metal gages. This allows them to be used in transducers providing more signal output (typically 100–500 mV versus 30 mV) and on stiffer flexures, resulting in smaller transducer size, higher frequency response, and increased ruggedness. Although not strictly correct, by convention, it has become equivalent to refer to semiconductor-based transducers as either piezoresistive or solid-state transducers.

48.3.2 Gage Factor

The gage factor F for a strain gage is defined as

$$F = \frac{\Delta R}{R\epsilon} \quad (48.3)$$

where R is resistance and ϵ is strain equal to $\Delta l/l$ (Δl is the change in length of l_0). Equation (48.3) may be redefined as

$$F = 1 + 2\nu + \frac{d\rho}{\rho\epsilon} \quad (48.4)$$

where ν is Poisson's ratio and ρ is the resistivity of the grid material. Most metal gages have a gage factor between 2 and 4.5. For strain gages made from a semiconductor material, the change in resistivity with applied stress is the dominant factor and values as high as 170 are possible. Table 48.1 lists properties and gage factors for various grid materials.

TABLE 48.1 Grid Material Composition, Trade Name, Properties, and Gage Factor

Composition	Trade Name	Properties	Gage Factor
1. Copper–nickel (57%–43%)	Constantan	Strain sensitivity relatively independent of level and temperature; used to 200°C; high resistivity applicable to small grids; measures strains to 20% in annealed form	2.0
2. Nickel–chromium–iron–molybdenum (36%–8%–55.5%–0.5%)	Isoelastic	High gage factor; high fatigue life; used to 200°C; high temperature coefficient of resistance; nonlinear at strain levels above 5%	3.5
3. Nickel–chromium (80%–20%), nickel–chromium (75%–20%) plus iron and aluminum	Nichrome V Karma	Good fatigue life; stable; high resistance applicable to small grids; used to 400°C	2.2

Note: Nickel alloy gages are susceptible to magnetic fields.

48.3.3 Mechanical Aspects of Gage Operation

To build effective bridge transducers, one must be aware of the interaction between the gage and the surface of the transducer flexure to which it is mounted. Mechanical aspects of this interaction include the influences of temperature, backing material, size, orientation, transverse sensitivity, distance from the surface, bonding and installation, and gage frequency response.

48.3.3.1 Temperature A qualitative discussion of temperature effects on bonded strain gages indicates the effects to be attributable to three principal causes: (1) The transducer flexure to which the gage is attached expands or contracts, (2) the strain gage resistance changes with temperature, and (3) the strain gage grid expands or contracts. With some gages (particularly semiconductors), the change of gage factor with temperature is also extremely significant. These temperature effects are accounted for by temperature-strain calibration; self-temperature-compensated gages where combined effects 1, 2, and 3 above are minimized over a given temperature range for a given combination of grid and flexure material; and a dummy gage integrated into a bridge circuit (discussed later) to electrically subtract temperature-induced strain.

48.3.3.2 Backing Material The purpose of the backing material used in constructing strain gages is to provide support, dimensional stability, and mechanical protection for the grid element. The backing material of the gage element(s) acts as a spring in parallel with the flexure to which it is attached and can potentially modify flexure mechanical behavior. In addition, the temperature operating range of the gage can be constrained by its backing material. Most backings are epoxies or glass fiber-reinforced epoxies. Some gages are encapsulated for chemical and mechanical protection as well as extended fatigue life. For high-temperature applications, some gages have strippable backings for mounting with ceramic adhesives. Still other metal gages can be welded. The frequency response of welded gages, due to uncertainties in dynamic response, is a subject area still requiring investigation.

48.3.3.3 Size The major factors to be considered in determining the size of strain gage to use are available space for gage mounting, strain gradient at the test location, and character of the material under test. The strain gage must be small enough to be compatible with mounting location and concentrated strain field. It must be large enough so that, on metals with large grain size, it measures average strain as opposed to local effects. Grid elements greater than 3 mm generally have greater fatigue resistance.

48.3.3.4 Transverse Sensitivity and Orientation Strain gage transverse sensitivity and mounting orientation are concurrent considerations. Transverse sensitivity in strain gages is important due to the fact that part of the geometry of the gage grid is oriented in directions other than parallel to the principal gage sensing direction. Values of transverse sensitivities are provided with individual gages but typically vary between fractional and several percent. The position of the strain gage axis relative to the numerically larger principal strain on the surface to which it is mounted will have an influence on indicated strain.

48.3.3.5 Distance from the Surface The grid element of a strain gage is separated from the transducer flexure by its backing material and cement. The grid then responds to strain at a location removed from the flexure surface. The strain on flexures such as thin plates in bending can vary considerably from that measured by the strain gage.

48.3.3.6 Bonding Adhesives Resistance strain gage performance is entirely dependent on the bond attaching it to the transducer flexure. The grid element must have the strain transmitted to it undiminished by the bonding adhesive. The elimination of this bond is one of the principal advantages of vacuum-deposited metallic and diffused semiconductor bridge transducers. Typical adhesives are as follows:

Epoxy Adhesives: Epoxy adhesives are useful over a temperature range of -270 to $+320^{\circ}\text{C}$. The two classes are either room-temperature curing or thermal setting type; both are available with various organic fillers to optimize performance for individual test requirements.

Phenolic Adhesives: Bakelite, or phenolic adhesive, requires high bonding pressure and long curing cycles. It is used in some transducer applications because of long-term stability under load. The maximum operating temperature for static loads is 180°C .

Polyimide Adhesives: Polyimide adhesives are used to install gages backed by polyimide carriers or high-temperature epoxies. They are a one-part thermal setting resin and are used from -200 to $+400^{\circ}\text{C}$.

Ceramic cements (applicable from -270 to $+550^{\circ}\text{C}$) and welding are other mounting techniques.

48.3.3.7 Frequency Response The frequency response of bridge transducers cannot be addressed without considering the frequency response of the strain gage as well. It is assumed that the transducer is used in such a manner that mounting variables do not influence its frequency response.

Piping in front of pressure transducer diaphragms and mounting blocks under accelerometers are two examples of variables which can violate this assumption. Transducers, particularly those which measure force, pressure, and acceleration, typically are dynamically modeled as single-degree-of-freedom systems characterized by a linear second-order differential equation with constant mass, damping, and stiffness coefficients. In reality, transducers possess multiple resonant frequencies associated with their flexure and their case. Figure 48.4 presents the actual frequency response of a bridge-type accelerometer. The response indicates this single-degree-of-freedom model to be adequate through the first major transducer resonance. Such devices have a frequency response usable (constant within 4% referenced to their AC response) to one-fifth of the value of this major resonance. The strain gage itself acts as a spatial averaging device whose frequency response is a function of both its gage length and the sound velocity of the material on which it is mounted. Walter (1980) discusses this relationship from which Figure 48.5 is extracted. Figure 48.5 contains curves for three different length gages. Its abscissa must be multiplied by a specific sound velocity. For most bridge transducers, the structural resonance of the flexure constrains its frequency response.

48.3.4 Electrical Aspects of Gage Operation

The resistance strain gage, which manifests a change in resistance proportional to strain, must form part of an electrical circuit such that a current passed through the gage transforms this change in resistance into a current, voltage, or power change to be measured. The electrical aspects of gage operation to be considered include current in the gage, resistance to ground, and shielding.

Strain gages are seldom damaged by excitation voltages in excess of proper values but performance degrades. The voltage applied to a strain gage bridge creates a power loss in each arm, which must be dissipated in the form of heat. By its basic design, all of the power input to the bridge is dissipated in the bridge with none available to the output circuit. The sensing grid of every strain gage then operates at a higher temperature than the transducer flexure to which it is bonded. The heat generated within the gage must be transferred by conduction to the flexure. Heat flow into the flexure causes a temperature rise, which is a function of its heat sink capacity and gage power level. The optimum excitation level for strain gage applications is a function of the strain gage grid area, gage resistance, heat sink properties of the mounting surface, environmental operating temperature range of the gage installation, required operational specifications, and installation and wiring techniques. Rigid operating requirements for precision transducers require performance verification of the optimum excitation level. Zero shift versus load and stability under load at the maximum operating temperature are the performance tests most sensitive to excessive excitation voltage.

Table 48.2 and Figures 48.6–48.8 allow a first approximation at optimizing bridge excitation levels. Table 48.2 defines the suitability of various structural materials for providing an adequate heat sink for gage mounting dependent on both accuracy requirements and static or dynamic measurements. Figures 48.6–48.8 define the recommended excitation voltage for specific gages as a function of the power density capability of the heat sink and gage grid area.

Resistance to ground is an important parameter in strain gage mounting since insulation leakage paths produce shunting of the gage resistance between the gage and the metal structure to which it is bonded, producing false compressive strain readings. The ingress of fluids typically leads to this breakdown in resistance-to-ground value and can also change the mechanical properties of the adhesive. A minimum gage-to-mounting-surface resistance-to-ground value of 50 M Ω is recommended.

Since signals of interest from strain gage bridges are typically on the order of a few millivolts, shielding of the bridge from stray pickup is important. Gage leads should also be shielded and proper grounding procedures followed. Stray pickup may be introduced by 60-Hz line voltage associated with other electronic equipment, electrical noise from motors, radio frequency interference, and so on. Note that shielding materials for electrical fields are different from those for magnetic fields. Nickel alloy strain gages are particularly susceptible to magnetic fields.

48.3.5 Technical Societies and Strain Gage Manufacturers

In concluding a discussion of the resistance strain gage, it is appropriate to identify some of the technical societies dealing with strain gages and some of the manufacturers of strain gages. In 1956, to accelerate the development of the resistance strain

gage, BLH Electronics established a users' group to accomplish this purpose and to further the state of the art in strain gage technology in general. This users' group was formed primarily of various aircraft companies in the western United States and is entitled the Western Regional Strain Gage Committee (WRSGC). For 15 years, the WRSGC was an autonomous organization financed by BLH Electronics. Since 1971, WRSGC has operated under the auspices of the Technical Committee on Strain Gages (TCSG) of the Society for Experimental Mechanics (SEM). The SEM is the premier organization in the United States involved with strain gages and experimental mechanics in general. The SEM (formerly Society for Experimental Stress Analysis) was founded by William Murray at the Massachusetts Institute of Technology. Publications of this society include *Experimental Mechanics* and *Experimental Techniques*. A similar European organization is the Joint British Committee for Stress Analysis, whose publication is *The Journal of Strain Analysis for Engineering Design*.

By 2004, essentially the entire strain gage manufacturing capability in the United States was consolidated by Vishay Measurements Group, corporate headquarters at Vishay Intertechnology, Inc., 63 Lincoln Highway, Malvern, Pennsylvania 19355-2120. Its associated website has an extensive array of in-depth articles on strain gage technology.

48.4 THE WHEATSTONE BRIDGE

Best transducer performance can be achieved by minimizing the strain level in the transducer flexure. Lower strains allow increased safety without mechanical overload protection. Effective overload stops are usually troublesome to design and an added expense to make. Reduced strain levels almost always produce an improvement in linearity accompanied by a reduction in the hysteresis originating in the transducer flexure material.

Small strains result in small impedance changes in resistive strain gage elements. Electromechanical transducers use a Wheatstone bridge circuit to detect a small change in impedance to a high degree of accuracy.

48.4.1 Bridge Equations

The circuit most often used with strain gages is a four-arm bridge with a constant-voltage power supply. Figure 48.9 shows a basic bridge configuration. The supply voltage E_{ex} can be either AC or AC, but for now we assume it is AC so equations can be written in terms of resistance R rather than a complex impedance. The condition for a balanced bridge with e_0 equal to zero is

$$\frac{R_1}{R_2} = \frac{R_4}{R_3} \quad (48.5)$$

Next, an expression is presented for e_0 due to *small* changes in R_1 , R_2 , R_3 , and R_4 :

$$e_0 = \left[-\frac{R_3 dR_4}{(R_3 + R_4)^2} + \frac{R_4 dR_3}{(R_3 + R_4)^2} - \frac{R_1 dR_2}{(R_1 + R_2)^2} + \frac{R_2 dR_1}{(R_1 + R_2)^2} \right] E_{\text{ex}} \quad (48.6)$$

In many cases, the bridge circuit is made up of equal resistances. Substituting for individual resistances, a strain gage resistance R , and using the definition of the gage factor from Equation (48.3), Equation (48.6) becomes

$$e_0 = \frac{FE_{\text{ex}}}{4} (-\epsilon_4 + \epsilon_3 - \epsilon_2 + \epsilon_1) \quad (48.7)$$

The unbalance of the bridge is seen to be proportional to the sum of the strain (or resistance changes) in opposite arms and to the difference of strain (or resistance changes) in adjacent arms.

FIGURE 48.9 Four-arm bridge with constant-voltage (E_{ex}) power supply.

Equations (48.6) and (48.7) indicate one technique to compensate strain gage circuits to minimize the influence of temperature-induced strain. This was referred to in Section 48.3 as the dummy gage method.

Assume that we have a bridge circuit with one active arm and arbitrarily let this arm be number 4. Equation (48.7) becomes

$$e_0 = \frac{FE_{\text{ex}}}{4}(-\epsilon_4) \quad (48.8)$$

Arm 4 responds to the total strain induced in it, which is comprised of both thermal (t) and mechanical (m) strain

$$\epsilon_4 = \epsilon_m + \epsilon_t \quad (48.9)$$

A problem arises if it is desired to isolate the mechanical strain component. One solution is to take another strain gage (the dummy gage) and mount it on a strain-isolated piece of the same material as that on which gage 4 is mounted. If placed in the same thermal environment as gage 4, the output from the dummy gage becomes simply ϵ_t . If the dummy gage is wired in an adjacent bridge arm to 4 (1 or 3), Equation (48.7) becomes

$$e_0 = \frac{FE_{\text{ex}}}{4}(-\epsilon_m - \epsilon_t + \epsilon_t) \quad (48.10)$$

Equation (48.10) indicates that thermal strain effects are canceled. Similarly, in Figure 48.2, four gages were shown mounted on a transducer diaphragm. Equation (48.7) indicates that thermal strain effects from this circuit should be canceled.

In reality, perfect temperature compensation is not achieved since no two strain gages from a lot track one another identically. However, compensation adequate for many applications can be accomplished.

The biggest thermal problem with bridge transducers occurs in transient situations, such as explosive or combustion environments. Here, due to individual physical locations, gages in a bridge are not in the same time-varying temperature, and compensation cannot be achieved. The only technique which can be used in this situation is either to cool the transducer by circulating water or gas around it or to delay the thermal transient until the measurement is complete.

The alternating signs in Equation (48.7) are useful in isolating various strain components when using bridge circuits containing strain gages. Figure 48.10 shows a beam flexure used in an accelerometer. Four gages are mounted on the beam—two on the top and two on the bottom. Notches are placed in the beam to intensify the strain field under the gages. Due to symmetry, the tension gages see the same strain as do the compression gages. If the tension gages occupy two adjacent arms of the bridge and the compression gages the other two, Equation (48.7) indicates that the net bridge output will be zero. However, if the tension and compression gages are in opposite arms, Equation (48.7) indicates that a bending strain signal four times that of an individual gage will be produced with temperature compensation also achieved.

Equation (48.6) presented the generalized form of the bridge equation for four active arms. If only one arm (e.g., arm 4) is active, this equation becomes

$$e_0 = \left[\frac{-R_3 dR_4}{(R_3 + R_4)^2} \right] E_{\text{ex}} \quad (48.11)$$

FIGURE 48.10 Strain gaged beam flexure used in accelerometer. (Courtesy of Endevco.)

This equation was specifically presented for *small* changes in resistance, such as those associated with metallic strain gages. If the change in resistance in arm 4 is large, Equation (48.11) is better expressed as

$$e_0 = \frac{(R_4 + \Delta R_4)E_{ex}}{(R_4 + \Delta R_4) + R_3} - \frac{R_4 E_{ex}}{R_4 + R_3} \quad (48.12)$$

For an equal-arm bridge, this becomes

$$e_0 = \frac{\Delta R E_{ex}}{4R + 2\Delta R} = \frac{F E_{ex} \epsilon}{4 + 2F\epsilon} \quad (48.13)$$

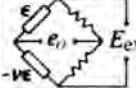

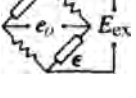

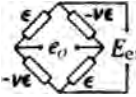

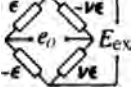

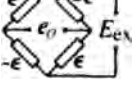

For an equal-arm bridge, Equation (48.11) becomes

$$e_0 = \frac{dR E_{ex}}{4R} = \frac{F E_{ex} \epsilon}{4} \quad (48.14)$$

The difference between Equations (48.14) and (48.13) is that Equation (48.14) describes a linear process while Equation (48.13) describes a nonlinear one. Semiconductor gages, because of their large gage factor, require analysis using Equation (48.13).

Semiconductor gages may be used in constant-voltage four-arm bridge circuits when two or four gages are used in adjacent arms and strained so that their outputs are additive. Analysis of the bridge equations for this situation will show that if gages in adjacent arms are subjected to equal but opposite values of ΔR , the output signal is doubled and the nonlinearity in the bridge output is eliminated. Another approach to eliminating this nonlinearity is to design a circuit where the current through the strain gage remains constant.

TABLE 48.3 Equations for One, Two, and Four Equal-Active-Arm Bridges

Bridge/Strain Arrangement	Description	Output Equation $-e_0/E_{ex}$ (mV/V)
	Single active gage in uniaxial tension or compression	$\frac{e_0}{E_{ex}} = \frac{F\epsilon \times 10^{-3}}{4 + 2F\epsilon \times 10^{-6}}$
	Two active gages in uniaxial stress field—one aligned with maximum principal strain, one “Poisson” gage	$\frac{e_0}{E_{ex}} = \frac{F\epsilon(1 + \nu) \times 10^{-3}}{4 + 2F\epsilon(1 - \nu) \times 10^{-6}}$
	Two active gages with equal and opposite strains—typical of bending-beam arrangement	$\frac{e_0}{E_{ex}} = \frac{F\epsilon}{2} \times 10^{-3}$
	Two active gages with equal strains of same sign—used on opposite sides of column with low temperature gradient (e.g., bending cancellation)	$\frac{e_0}{E_{ex}} = \frac{F\epsilon \times 10^{-3}}{2 + F\epsilon \times 10^{-6}}$
	Four active gages in uniaxial stress field—two aligned with maximum principal strain, two “Poisson” gages (column)	$\frac{e_0}{E_{ex}} = \frac{F\epsilon(1 + \nu) \times 10^{-3}}{2 + F\epsilon(1 - \nu) \times 10^{-6}}$
	Four active gages in uniaxial stress field—two aligned with max. principal strain, two “Poisson” gages (beam)	$\frac{e_0}{E_{ex}} = \frac{F\epsilon(1 + \nu) \times 10^{-3}}{2}$
	Four active gages with pairs subjected to equal and opposite strains (beam in bending or shaft in torsion)	$\frac{e_0}{E_{ex}} = F\epsilon \times 10^{-3}$

Source: Courtesy of Measurements Group Inc., Raleigh, NC.

Table 48.3 provides generalized bridge equations for one, two, and four equal-active-arm bridges of various configurations. The dimensionless bridge output is presented in millivots per volts for a constant-voltage power supply. Strain is presented in microstrain. No small-strain assumption is built into these equations. For large strains with semiconductor gages, F may not be a constant and this correction also has to be built into the equations. In this table, the Poisson gage is one that measures the lateral compressive strain accompanying an axial tension strain. As noted earlier, only for two adjacent active gages with equal and opposite strains or for four active gages with pairs subjected to equal and opposite strains is the bridge output a linear function of strain.

48.4.2 Lead Wire Effects

There has been a historical lack of agreement between manufacturers of strain gages as to color codes and wiring designations. This is particularly true in bridge transducers.

Figures 48.11 and 48.12 are suggested industry standards that have assisted in lessening this confusion. Figure 48.11 covers the situation where all bridge elements are remote from the power supply, whereas Figure 48.12 covers the situation where only one bridge arm is remote from the power supply. The bridge balance network and shunt calibration are discussed in Sections 48.5 and 48.6, respectively. Table 48.4 presents guidelines for multiconductor strain gage cable.

The previous discussion has assumed that the only resistive elements in the circuits are the gages themselves. Resistance of circuit lead wires also is a consideration.

One possible need for remote recording occurs when the bridge power supply and the readout instrumentation are at one location and the bridge transducer is at a remote location. In this situation, the resistance R_L of each lead wire between the bridge and the power supply or readout must be accounted for. Most readout instruments have very high input impedances, so the effect of R_L in series with them can be ignored. The significant effect of lead-wire resistance is to modify the resistance in series with the power supply from R_{bridge} to $R_{\text{bridge}} + 2R_L$. For example, a lead-wire resistance of $3\ \Omega$ and a bridge resistance of $120\ \Omega$ will produce loading effects which, if not corrected, will result in a 5% error in bridge transducer output.

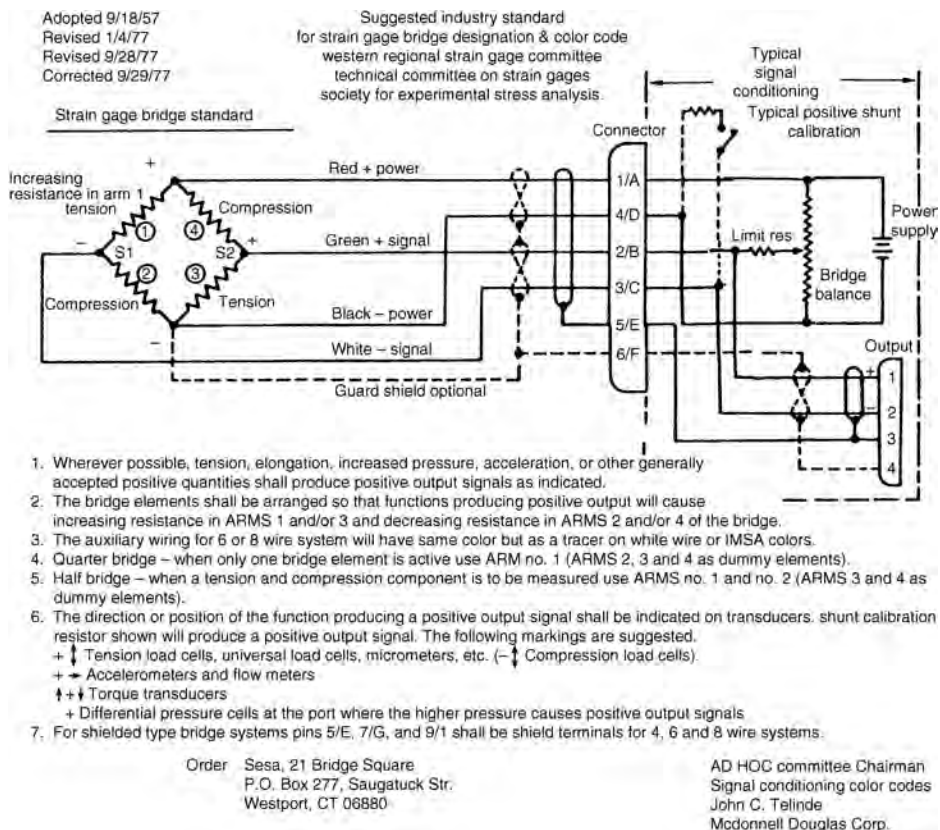

FIGURE 48.11 Color code and wiring designation, four-arm bridge. (Courtesy of Western Regional Strain Gage Committee.)

Adopted 9/17/80
Revised 3/4/81

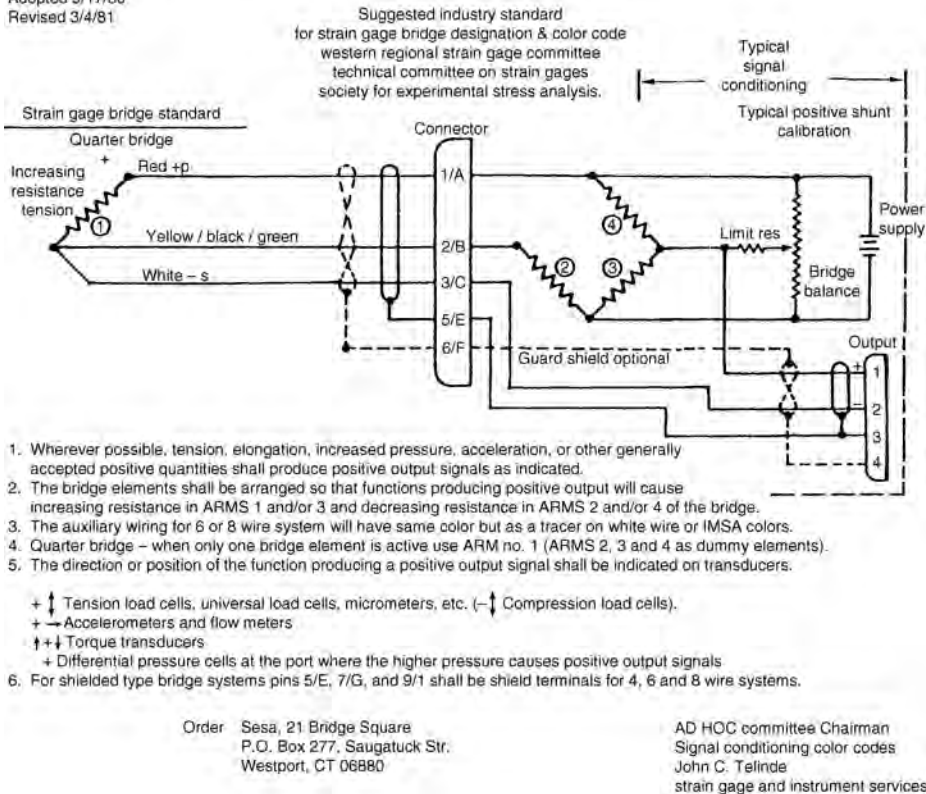

FIGURE 48.12 Color code and wiring designation, single-arm bridge. (Courtesy of Western Regional Strain Gage Committee.)

There are at least three simple techniques to eliminate this error source:

1. The bridge transducer can be calibrated with the long length of cable with which it will operate.
2. The excitation voltage E_{ex} can be measured at the bridge itself instead of at the power supply and appropriate values substituted in Equation (48.6) or equivalent versions of it.
3. The bridge voltage E_{ex} can be determined by measuring the current to the bridge (I_{bridge}) and calculating E_{ex} as the product $I_{bridge} \times R_{bridge}$.

Another possible need for remote recording occurs when two gages (either both active or one active and one for temperature compensation) are at the test site. The other two bridge completion resistors are in parallel with the power supply and located adjacent to it. In Figure 48.9, assume R_3 and R_4 are the two remote active arms. In Equation (48.6), the last two terms would be zero since these arms are not active. In this equation R_3 and R_4 would become, respectively, $R_3 + R_L$ and $R_4 + R_L$. If the strain gages in both arms are identical, Equation (48.6) reduces to

$$e_0 = \frac{FE_{ex}R}{4(R + R_L)}(-\epsilon_4 + \epsilon_3) \quad (48.15)$$

TABLE 48.4 Multiconductor Strain Gage Cable Guideline, Western Regional Strain Gage Committee

A need exists for low-millivolt signal levels to be transmitted by better quality multiple conductor cables of considerable length	
I. Conductors	Three through eight twisted, stranded conductors of tinned copper per ASTM-B-174, AWG 20-16/32, or AWG 18-16/30
II. Color code	Jacket: orange, gray, white, or black Conductors: Per ISA-S37.3, ANSI-MC6.2-1975, and WRSGC/SESA 5-6-1960
III. Insulation	Superior to the PVC materials currently in use. The dielectric material should be nonhygroscopic and approach zero water absorption and zero water permeability. Target jacket thickness of 0.016 in. or less and conductor insulation of 0.012 in. or less. Target resistance values should be constant as practical humid and wet environments and as high as possible (target value of 500 Ω per 1000 ft). The breakdown level of the dielectric materials shall be greater than 150 V AC.
IV. Construction	The cable shield shall be aluminized polyester tape with 100% coverage of all conductors. A 22-AWG drain wire shall be in intimate contact with the shield throughout the entire cable length. The cable shall have as small a diameter as practical and be flexible enough to have a bend radius less than six cable diameters. Overall cable strength sufficiently high to be pulled through conduits.

Source: Courtesy of Society for Experimental Mechanics.

Other situations can be investigated by substituting appropriate values for the resistance in each bridge arm (including lead-wire resistance) in the governing bridge equation. In addition, Section 48.6 will show that shunt calibration is one technique that can be used to compensate the system for the effects of lead-wire resistance.

48.4.3 Temperature Compensation

Before leaving the analysis of the Wheatstone bridge circuit, temperature compensation of bridge-type transducers should receive additional discussion. An ideal transducer would yield an output voltage that is a constant calibration factor times its mechanical input, independent of other environmental factors. Ambient temperature variations are one of the major error sources in precision transducers. Even when using self-temperature-compensated strain gages and taking advantage of the ability of the Wheatstone bridge circuit to subtract in the dummy gage method, some residual error remains. These remaining errors are of two types.

First, the transducer zero output can change with temperature. Unequal mechanical expansion of transducer members can cause this effect. Second, the calibration factor, span, or sensitivity also can change with temperature. This can be caused, for example, by a change in the stiffness of the transducer flexure with temperature.

The following discussion provides one compensation scheme for each type (metallic and semiconductor) of bridge transducer. Temperature Compensation of Bridge Type Transducers, (1951) and TECHNICAL DATA TD4354-1 (1975) are sources of more detailed information. An equal-arm bridge transducer operating with a constant-voltage supply is assumed. Metallic strain gages are discussed first.

FIGURE 48.13 Transducer bridge compensation for zero shift, metal gages.

Figure 48.13 shows one scheme for compensating for transducer zero shift. A corner of the bridge is brought out to terminals, and a temperature-sensitive resistor, r , is placed in one side of the bridge. Typically, a wire resistor such as Balco, nickel, or copper with a positive temperature coefficient is used.

The transducer must first be temperature calibrated and the change in zero reading for a given temperature range determined. This can be characterized in volts of output change per volt of input. Definitions are

b = output voltage change per degree per input volt,

a = temperature coefficient of resistance of r ,

R = bridge arm resistance,

T = temperature change from reference temperature.

If the bridge supply voltage is E_{ex} and R is changed a small amount by the addition of r , the bridge output is

$$e_0 = \frac{E_{\text{ex}} r}{4R} \quad (48.16)$$

Equation (48.16) can further be expressed as

$$e_0 = \frac{E_{\text{ex}} r_0 (1 + aT)}{4R} \quad (48.17)$$

or

$$e_0 = \text{const} + E_{\text{ex}} bT \quad (48.18)$$

where r_0 is the value of r at the reference temperature. The effect of the constant term is eliminated by a temperature-insensitive trim resistor in an adjacent arm. The above equations indicate that at the reference temperature r_0 should be selected equal to $4Rb/a$. If the transducer is properly designed, b is very small compared to a , keeping the compensating resistor small in value. The compensating resistor should be located in an arm causing a voltage change of opposite sign to the zero drift with increasing temperature.

After zero shift is compensated, the calibration or span factor remains to be compensated. Most metal strain gage transducers give larger outputs with increasing temperature, so the temperature coefficient of the calibration scale factor, K , is positive. The trick in

FIGURE 48.14 Transducer bridge compensation for span, metal gages.

span compensation is to hold the transducer supply voltage constant while automatically varying the bridge current, causing it to decrease with increasing temperature. In this discussion, r is identified to be a positive series resistor (Figure 48.14). Definitions are

$$r = r_0(1 + aT),$$

a = positive temperature coefficient of r ,

T = temperature difference from reference temperature,

c = temperature coefficient of the calibration factor K , so

$$K = K_0(1 + cT),$$

E_{ex} = transducer supply voltage.

The voltage on the transducer at the reference temperature is $RE_{ex}/(R + r_0)$ and at temperature T is $RE_{ex}/(R + r)$. The ratio by which it changes is $(R + r_0)/(R + r)$, which is used to correct for the variation in K . This variation is corrected for when $K_0(1 + cT)(R + r_0)/[R + r_0(1 + aT)] = \text{constant}$. The value of r_0 which satisfies this requirement can be shown to be

$$r_0 = \frac{cR}{a - c} \quad (48.19)$$

Note that in span and zero compensation as discussed thus far, the compensating resistors must be at the same temperature as the transducer. Usually, this is accomplished by mounting the resistors inside the transducer.

Figure 48.15 shows one technique for correcting for zero shift due to the temperature in semiconductor bridges. Temperature compensation is performed by adding nontemperature-sensitive resistors in series and parallel to the gage having the highest resistance change with temperature. The objective of this method is to achieve both zero balance and temperature compensation together. Since the compensation resistors are nontemperature sensitive, they can be added wherever convenient in the circuit.

The bridge is first balanced using a series resistor at ambient room temperature. Next, the transducer is cycled over the temperature extremes. A parallel resistor is installed across the gage having the greatest resistance change. The bridge is then rebalanced and the procedure repeated until satisfactory performance is achieved.

Semiconductor bridge transducers are typically compensated for calibration or span factor with a circuit as in Figure 48.14. However, r for this situation is a nontemperature-sensitive resistor. For p-type silicon gages, the strain sensitivity drops with temperature while the resistance rises. The increase in resistance occurs at a greater rate than does the

FIGURE 48.15 Transducer bridge compensation for zero shift, semiconductor gages.

decrease in sensitivity. Figure 48.14 shows that the effect of an increase in resistance R , with r constant, is to increase the voltage applied to the bridge, offsetting the decrease in strain sensitivity. Alternately, in Figure 48.14, r can be replaced by a thermistor instead of a fixed dropping resistor. The thermistor is generally a more efficient method of compensation but must be in the same thermal environment as the bridge network.

When balancing Wheatstone bridges, it must be determined that the balancing circuit does not significantly alter the thermal compensation network. Balancing methods are discussed in the following section.

48.5 RESISTANCE BRIDGE BALANCE METHODS

Even when a best attempt is made at matching resistors, the output from a bridge transducer with zero measurand applied is always something other than zero volts. With microprocessors and scanners, this is of little consequence. The initial bridge output can be acquired and stored in the memory of the microprocessor and then subtracted from all subsequent readings. Frequently, however, it is desired to initialize a bridge circuit such that a zero value of measurand corresponds to zero voltage. For example, assume it is desired to acquire a vibration measurement on a space vehicle using a bridge transducer. Assume the channel is to be calibrated for $\pm 20g$ and the accelerometer has a sensitivity of 1 mV/g (g = standard acceleration of gravity). If the data channel range were $\pm 20 \text{ mV}$, and the accelerometer acquiring the measurement had a zero offset of 5 mV , the channel could transmit only in the range of $+15g$ to $-25g$ as opposed to $\pm 20g$. Balancing the bridge would solve this problem.

Equation (48.5) presented the requirement for a balanced bridge. Basically, the resistance ratio of any two adjacent bridge arms must be equal to the resistance ratio of the other two arms. Any bridge-balancing network must then have as its objective the satisfying of this criterion. The two main types of zero balancing methods are those which manipulate one arm of a transducer bridge to bring its output to the desired condition and those which manipulate two adjacent arms of the transducer bridge.

Figure 48.16 presents the most common circuit for manipulating a single bridge arm. A variable resistor R_B is placed across one of the resistors (say R_4) whose value needs to be lessened such that $R_1/R_4 = R_2/R_3$. The effect of R_B in parallel with R_4 is to lessen the value of the bridge arm from R_4 to some new value R_T .

FIGURE 48.16 Circuit for manipulating a single bridge arm.

The overall combination of R_B in parallel with R_4 must be variable over a range at least equal to the maximum possible initial unbalance of the bridge. Selecting this range, other than by trial and error, requires knowledge of the strain gage resistance R , its tolerance in percentage m , and the number of active gages n in the bridge. The range of the balancing circuit should be

$$\frac{2Rmn}{100} \quad (48.20)$$

Note that the presence of the variable resistor R_B desensitizes the bridge network since $\Delta R_4/R_4$ is not equal to $\Delta R_T/R_T$. If the strain gages are initially closely matched, the influence of this effect is small since R_B will remain large and R_T will closely approximate R_4 . For optimum precision, the best method to minimize the influence of the variable resistor is to calibrate the transducer once the bridge is balanced. Of course, if less than four arms of the bridge are active and balancing is performed across a dummy completion resistor, no desensitizing of the bridge occurs.

Two techniques are available to manipulate two adjacent arms in a bridge. Again, the rationale for this manipulation is to satisfy Equation (48.5). The first technique is series manipulation, which assumes the bridge is open such that the variable resistance may be inserted in series with two arms of the bridge. This technique is not applicable to a closed bridge.

Figure 48.17 shows a variable series resistor R_S inserted in one corner of the bridge. The insertion of R_S , which is typically quite small, allows adjustment of the ratio of R_2 to R_3 to achieve balance. Stein (1953) provides the best discussion of bridge balance networks and indicates that minimum bridge desensitization occurs when bridge power is applied across the vertical terminals of Figure 48.17 as opposed to the horizontal.

FIGURE 48.17 Circuit for series manipulation of two adjacent bridge arms.

FIGURE 48.18 Circuit for parallel manipulation of two adjacent bridge arms.

The second technique discussed (and the one typically used) is parallel manipulation of two adjacent bridge arms. Figure 48.18 illustrates this technique. The parallel variable resistor R_B allows the ratio of R_2/R_3 to be adjusted. A pad resistor, R_{PAD} , serves simply to keep the individual bridge arms from being shorted out at the end of travel of R_B . Again, the secret is to keep the combination of R_B and R_{PAD} as high as possible to avoid bridge desensitization. If no other guidance is available, start out with a pad resistor about 100 times the bridge resistance and a variable resistor about 20 times the bridge resistance. Again, maximum accuracy is achieved when the bridge transducer is calibrated with the balance network with which it will be used.

As alluded to earlier, the addition of a balance network to a bridge transducer may react unfavorably with temperature compensation resistors placed in the transducer's circuitry by its manufacturer. Temperature compensation can be severely modified by the presence of this balancing network. The prerequisite to insertion of a balance network should be an exact knowledge of the circuit of the transducer. For this reason, and for reasons associated with desensitization of the transducer, balance networks should be avoided unless required.

48.6 RESISTANCE BRIDGE TRANSDUCER MEASUREMENT SYSTEM CALIBRATION

A basic component in any measurement system is the transducer. The measurement system can be as simple as a transducer, a cable from the transducer, and a recorder. Alternately, the measuring system can contain many more of the elements of the transmitting and receiving system defined in Section 48.1. Cables, amplifiers, filters, digitizers, tape recorders, and so on all have the capability, when inserted into a measurement system, to modify both the amplitude and spectral content of the signal from the transducer defining the measurand. The response of these components may also drift with time.

To obtain measurements of the highest possible quality, one must accurately and carefully calibrate the entire measurement system as near to the time of actual measurement as possible. The calibrations may be conducted prior to, immediately after, or even during the time of actual measurement. Such calibration of an entire measurement system is referred to as "end-to-end" calibration. This calibration ordinarily does not replace the evaluation of individual components of the measurement system.

One group concerned with "end-to-end" calibration of measurement systems is the Telemetry Group/Range Commanders Council whose Secretariat is headquartered at

White Sands Missile Range, New Mexico. The Transducer Committee of the Telemetry Group coordinated the writing of Chapter 2 of *End-to-End Test Methods for Telemetry Systems* (1979), entitled "Test Methods for Transducer-Based System Calibrations." The following information is largely extracted from that chapter, which also deals with piezoelectric transducers, servo transducers, capacitive and inductive transducers, and thermoelectric transducers.

A preferred calibration procedure is one in which a known value of the measurand is applied directly to the transducer in the measurement system (transmitting, receiving, and display) in which it will be used. This procedure permits the output display to be read directly in terms of units of the measurand.

48.6.1 Static Calibration

The basic equipment for the static calibration of transducer systems consists of a measurand source supplying accurately known and precisely repeatable values of the measurand and an output-indicating or recording system. The combined errors or uncertainties of the calibration system should be sufficiently smaller than the permissible tolerance of the system performance characteristic under evaluation so as to result in meaningful calibration values. All calibration system components should be periodically checked against standards. Environmental conditions during calibrations should be constant and specified to permit corrections to the data, as required.

The procedures, which will be specified, are based on the assumption that the measuring system is linear. For systems that will ultimately measure dynamic data, linearity is a prerequisite.

The static calibration sequence consists of the following steps:

1. zero-measurand output verification,
2. sensitivity verification,
3. linearity and hysteresis verification,
4. repeatability verification.

Zero-measurand output verification starts with a measurement of system output with zero measurand applied to the transducer. Zero measurand is an important measurement for several reasons:

1. In many measurement systems, the transducers are exposed to zero measurand before the test begins.
2. For many transducers, zero measurand means that no external input to the transducer is required, thus greatly simplifying the test procedure.
3. Measurement system malfunctions, including drift, will frequently appear when the system output is monitored over some reasonable time period with zero measurand applied.
4. In some measurement systems with no external measurand input, the ambient environment will furnish an important reference point for the system calibration. For example, for an absolute-pressure-measuring system, the ambient atmospheric pressure provides this reference. Similarly, for certain accelerometer systems, the measurable attitude of the test vehicle prior to launch

represents a known component of the earth's gravitational field as input to the accelerometer.

For a measurement system with a linear response, the slope of the line characterizing the input measurand versus system output represents the sensitivity of the system. There are a number of straight lines that may be chosen to provide this sensitivity verification. These include the following:

1. Endpoint Line: The straight line between the outputs at the specified upper and lower limits of the range.
2. Best Straight Line: The line midway between the two parallel straight lines closest together that enclose all output versus measurand values on a calibration curve.
3. Terminal Line: The straight line for which the endpoints are 0 and 100% of both measurand and output.
4. Theoretical Slope Line: The straight line connecting the specified points between which a specified theoretical curve has been established.
5. Least-Squares Line: The straight line for which the sum of the squares of the residuals is minimized for all calibration points.

Procedures used in the verification of sensitivity will depend on specific accuracy, calibration time, and expense trade-off choices for each system. For unidirectional transducers, it is typical to calibrate from zero to full scale and back again in 10% of full-scale increments (21 points). For bidirectional transducers, a 21-point calibration cycles the transducer from negative full scale to positive full scale and back again in 20% of full-scale increments.

Data extracted from these calibrations are typically linearity and hysteresis. Linearity is the closeness of a calibration curve to the specified straight line, expressed as the maximum deviation of any calibration point from that line during any one calibration cycle. Hysteresis is the maximum difference in output at any measured value within the specified range when the value is approached first with increasing and then with decreasing measurand.

The reference straight line selected is often the linear least-squares line. This line is based on the following principle: the most probable value of an observed quantity is such that the sum of the squares of the deviations of the observations from this value is a minimum. This is based on the fact that most measurements of physical quantities show a normal distribution with both positive and negative deviations from the mean probable and very large deviations less likely than small deviations. The line can be defined unequivocally in terms of the quantities measured. The line also is statistically significant, and standard deviations can be assigned to estimates of the slope, intercept, and other parameters derived from it.

An additional parameter describing the performance of the measurement system is obtained by repeating the static calibration of the system. A minimum of two, but preferably three, consecutive static calibrations yield data from which the "repeatability" of the system is verified. Repeatability is the ability of the measurement system to reproduce output readings when the same measurand value is applied to it consecutively under the same conditions and in the same direction. It is expressed as the maximum difference between corresponding values from at least two consecutive calibrations. Although there

is no universal agreement as to the particular values selected, a value close to full-scale output is commonly used.

If the bridge transducer will be used to acquire time-varying measurements, the measuring system must be both dynamically and statically calibrated. The dynamic response of any system is described by a frequency response function which is a complex function of frequency. The frequency response function relates system output to system input in the frequency domain. For measurement systems, this frequency response function is typically represented by Bode plots, which are log amplitude and phase versus log frequency.

48.6.2 Dynamic Calibration

Dynamic calibrations are inherently more difficult to perform than are static calibrations and usually require specialized equipment. Dynamic calibrations can be performed using several types of well-defined input signals, such as applications of sinusoids, transients, or broadband noise. The principal requirement that the input must satisfy is that it must contain significant energy at frequencies over the range of the frequency response function of interest.

The dynamic calibration sequence consists of the following steps:

1. dynamic sensitivity determination;
2. dynamic amplitude linearity determination;
3. amplitude–frequency verification;
4. phase–frequency verification.

If the measuring system does not have zero frequency response, its end-to-end calibration is of necessity made by dynamic methods. The simplest approach to dynamically determining system sensitivity is the application of a sinusoidally varying measurand to the transducer. The amplitude of the measurand should be equal to the range of the transducer. For unidirectional transducers, this test involves biasing the transducer to its half-range point. At the test frequency, it is possible to relate the peak amplitude of the system response to the amplitude of the measurand and determine system dynamic sensitivity.

It is further desired to acquire dynamic amplitude linearity by performing tests equivalent to dynamic sensitivity determination at several levels of the measurand (usually levels of 25, 50, 75, and 100% of full scale are adequate). This testing should be performed at several different frequencies over the range of the frequency response function of interest. If the measurement system cannot be verified to be linear, it should not be used to acquire time-varying measurements.

The concept of a measuring system having a unique amplitude–frequency and phase–frequency response is only meaningful for systems which have been verified to be dynamically linear. Amplitude–frequency response tests consist essentially of a series of dynamic sensitivity determinations at a number of frequencies within the bandwidth of the system. Three is the *minimum* number of test frequencies. One test should be performed close to the upper limit of the frequency band where the response has not been affected by the high-frequency roll-off characteristic of the system. The second frequency should be sufficiently higher than the first to provide some indication of the roll-off rate of the system. The third frequency should be about halfway between zero frequency and the first test frequency to verify a flat response to the upper band edge. More

improved definition obviously can be provided by increasing the number of test frequencies.

Phase–frequency response characteristics of a measuring system can often be acquired simultaneously with the amplitude–frequency response. An output recording device is required with two identically responding channels. The system output is recorded on one channel. The second channel records the measurand, which is typically acquired by a previously calibrated monitoring transducer whose amplitude–frequency and phase–frequency response characteristics are well established. A time correlation between the system output and this monitoring transducer can establish measuring system phase–frequency response. For systems measuring signals whose time history is important, a linear phase response with frequency is required. For those signals about which only statistical information is to be acquired (e.g., random vibration), phase response is not an important system characteristic.

With today's technology, frequency response functions can also be characterized by transient or random system excitation. Dual-channel spectrum analyzers can ratio input-to-output measuring system Fourier transforms in near-real time. Recall that the system input stimulus must contain significant signal content at all frequencies of interest.

48.6.3 Electrical Substitution Techniques

If actual values of the measurand cannot be used to calibrate resistance bridge transducers, electrical substitution techniques can be used. Test equipment required includes a precision voltage source, precision resistors or decade box, and a signal generator. The techniques include shunt calibration, series calibration, and bridge substitution. Shunt calibration techniques are discussed first.

Inserting a resistor of known value in parallel with one arm of a strain gage bridge is single-shunt calibration. The calibration resistor is inserted across the arm opposite the strain gage conditioning system. The conditioning system may contain a balance potentiometer, a limit or pad resistor, modulus resistors, and temperature compensation resistors. Standard practice is to insert the shunt resistor between the negative input (excitation) and the negative output (Figure 48.19). This reduces errors caused by shunting some of the bridge-conditioning resistors.

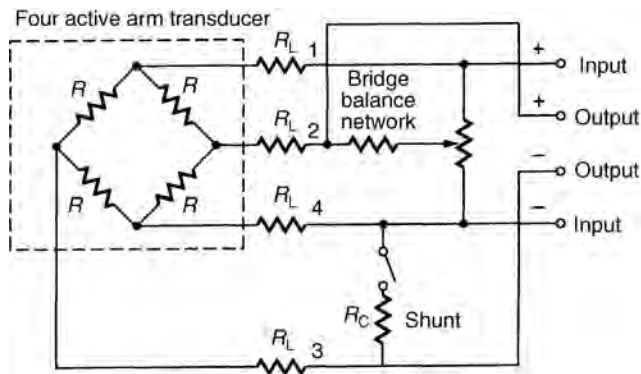

FIGURE 48.19 Single-shunt calibration of bridge transducer.

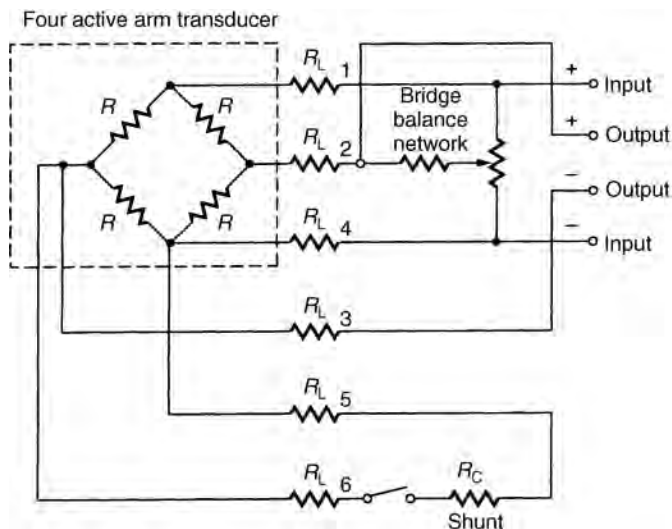

FIGURE 48.20 Remote-location single-shunt calibration of bridge transducer.

The value of the shunt resistor R_C is determined by first applying a value of the measurand to the transducer and monitoring the voltage change at the transducer output terminals (Figure 48.19). With the measurand removed, a decade box is substituted for R_C and its resistance adjusted until a voltage change results with a magnitude equal to that caused by the measurand. For subsequent calibrations, a fixed resistor R_C can be substituted for the decade box. When the switch in series with R_C is closed, it will produce a step voltage through the measuring system of amplitude equal to that produced by the measurand. When shunting one arm of the bridge, the resistance change produced in that arm is $-R^2/(R_C + R)$.

In the calibration laboratory, the small lead length associated with the transducer introduces no error in establishing R_C . The application of the bridge transducer in the field can require significant lengths of cable with significant transmission line resistance. Figure 48.20 illustrates the situation where R_C must be applied remotely. If R_C were applied directly at the bridge, loading errors introduced by transmission lines would be accounted for. If (as in Figure 48.20) R_C is applied at a remote location, the effect of the transmission line resistance $2R_L$ in series with R_C must be considered.

Bipolar shunting is used when the physical loading creates both positive- and negative-going signals and it is desired to create positive and negative calibration outputs. The calibration resistor is alternately inserted across the two arms opposite the bridge-conditioning network. If line resistance is significant, it must be considered as in Figure 48.21.

Series calibration of bridge transducers is considerably different from shunt calibration. Figure 48.22 describes this process. Series calibration consists of two distinct calibration phases.

In the zero calibration phase the Zero Cal switch is moved downward so excitation is removed from the bridge. The sensitivity resistor (R_{SENS}) is concurrently placed across the bridge input terminals, simulating the power supply impedance to result in the same overall system impedance encountered in the data circuit. Zero bridge transducer output is recorded.

FIGURE 48.21 Remote-location double-shunt calibration of bridge transducer.

The next calibration phase is the series phase. In the series calibration mode, the two switches in Figure 48.22 are closed with the Zero Cal switch back in its original position, introducing R_{C1} and R_{C2} into the circuit. This removes power from one corner of the bridge and puts a calibration resistor R_{C1} in series with the sensitivity resistor and one side of the bridge output. The second calibration resistor becomes intermediate between the R_{SENS} -to- R_{C1} connection and excitation return. This second resistor, R_{C2} , is selected to maintain the approximate equivalent bridge impedance across the excitation. The calibration circuit then electrically simulates the bridge transducer. The value of R_{C1} is determined experimentally, corresponding to some measurand equivalent.

Series calibration overcomes a serious shortcoming of shunt calibration. During application of a shunt resistor, the transducer can still respond to mechanical input. The calibration step is superimposed upon any mechanically induced signal present. If the mechanical input is static and of sufficient magnitude, overranging will invalidate the

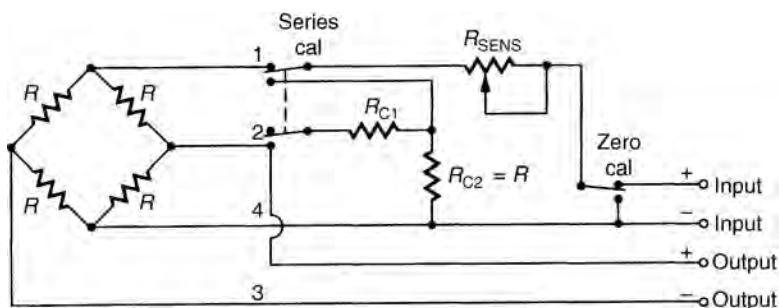

FIGURE 48.22 Series calibration of bridge transducer.

calibration step. If the mechanical input is dynamic, it may be impossible to accurately measure the magnitude of the calibration step. The magnitude of the series calibration step is significantly more independent of this mechanical input. As in all calibration, transmission line resistance must be considered where significant. Similarly, a change in sensitivity resistance modifies the effect of the series calibration resistance. However, the typical error incurred is negligible.

The final electrical substitution technique discussed is bridge substitution. This technique involves substitution of a model for the bridge transducer itself. Figure 48.23 represents a typical low-level bridge system.

An accurate bridge transducer model has the same terminal impedance as the transducer and provides a fast and simple method of generating a static and dynamic output equivalent to that generated by the transducer for a given physical load. It also provides a convenient method for verifying the calibration resistor's measurand equivalency for shunt and series systems. The two types of bridge transducer models employed for system calibrations are the shunt resistor adapter and the shunt resistor bridge.

Figure 48.24 describes the shunt resistor adapter, which is simple, inexpensive to construct, and an exact model since it is used in conjunction with the actual transducer. The adapter is inserted between the transducer and the rest of the measurement system. It performs three primary functions:

1. It supplies the stimulus for performance of system end-to-end calibrations. Shunting the arms of a transducer bridge with the appropriate resistors produces an unbalance in the bridge equivalent to that produced by a given measurand. The adapter provides a convenient method of applying these shunt resistors directly to the bridge with negligible line loss (S_1 and S_2).
2. It performs a system frequency response test. A convenient system frequency response can be performed by selecting the appropriate shunt resistor and sweeping the adapter's AC power supply over the desired range. Figure 48.25 shows a typical oscilloscope display of the results.
3. It provides a convenient check of the system's calibration resistors (R_c) and equivalents. The system's R_c equivalent will differ from the values established by the laboratory calibration as a function of line resistance, calibration resistor tolerance, and so on. Since the adapter shunt resistors are precision resistors that are applied directly to the bridge, the equivalency of the adapter shunt resistors will not be affected by lead resistance and other variables.

Although the shunt resistor adapter model is a very powerful and simple calibration tool, it has two undesirable characteristics. The least desirable characteristic is that the system calibration and calibration resistor equivalents generated by the adapter are incremental values superimposed on the transducer output resulting from the physical stimulus acting at the time of the test. Also, the adapter does not provide a fixed independent reference since it is used in conjunction with the transducer.

The undesirable features of the shunt resistor adapter can be eliminated by replacing the actual transducer with a bridge model (Figure 48.26). Since the shunt resistor bridge (bridge model plus shunt resistor adapter) is a stable, complete model of the transducer, it can be used to perform an absolute end-to-end system calibration and can be a valuable tool in troubleshooting.

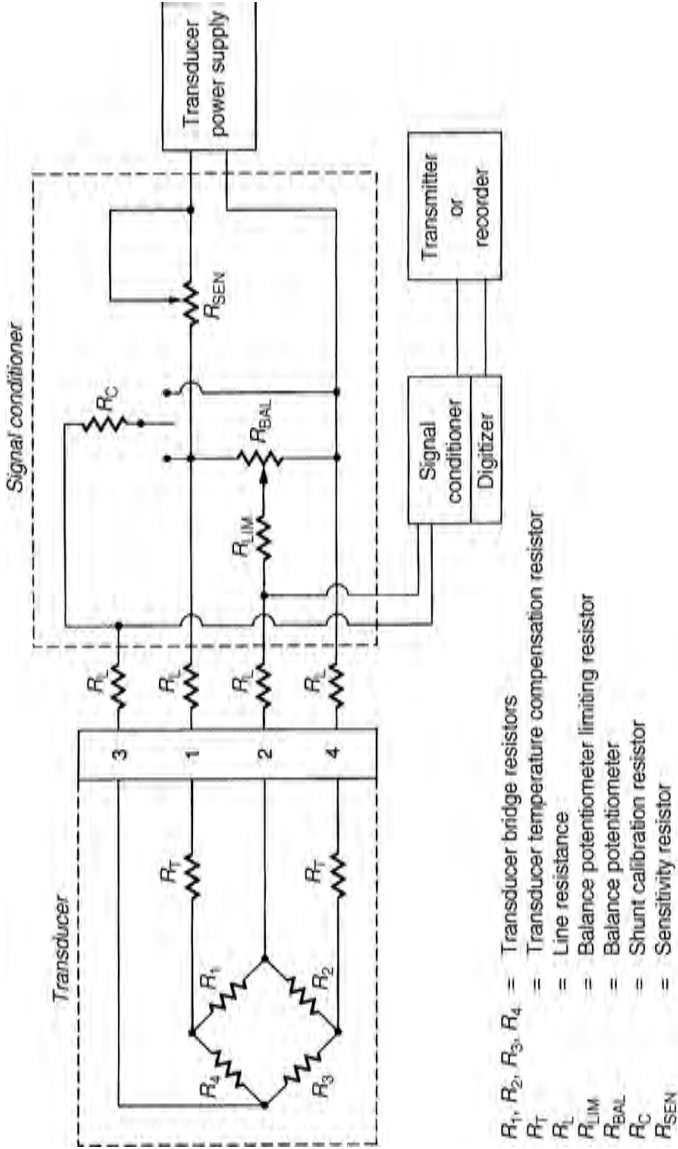

FIGURE 48.23 Typical low-level bridge system.

FIGURE 48.24 Shunt resistor adapter.

FIGURE 48.25 Oscilloscope frequency response display.

Several disadvantages are encountered when using the shunt resistor bridge as a calibration tool. Since some transducers are hard to model, it is difficult to ensure that the bridge is a representative model of the transducer under all conditions. Furthermore, a different bridge model is required for each major transducer design.

As a final note, remember that the resistance of semiconductor bridge transducers is strongly a function of temperature. When using shunt or series calibration techniques on semiconductor bridges, ambient temperature changes should be taken into account.

48.7 RESISTANCE BRIDGE TRANSDUCER MEASUREMENT SYSTEM CONSIDERATIONS

48.7.1 Bridge Excitation

When amplifiers and power supplies were formally designed around vacuum tubes, component drift was a problem in bridge transducer measurement systems. Alternating-current power supplies in bridge circuits eliminated many of these problems by operating at frequencies above AC. Most bridge transducer power supplies today are AC. When comparing AC supplies with AC, the following advantages are associated with AC:

1. simpler circuitry;
2. wider resultant instrumentation system frequency response;
3. no cable capacitive or inductive effects due to the excitation;
4. simpler shunt calibration and bridge balance circuitry.

Independent of type of supply, the power level selected has to take account of all variables, which affect the measurement. These include gage resistance, gage grid area, thermal conductivity of flexure to which gage is mounted, flexure mass, ambient test temperature, whether used on a static or dynamic test, accuracy requirements, and long- or short-term measurement. These variables account for the fact that a strain gage is a resistance which has to dissipate heat when current passes through it. Most of the heat is conducted away from the gage grid to the transducer flexure. The result of inadequate heat conduction is gage drift.

For transient measurements, a steady transducer zero reference is not as important as for static measurements. Bridge power can be significantly elevated to increase measurement system signal-to-noise ratio.

FIGURE 48.26 Shunt resistor bridge.

The following specifications define key performance parameters of AC output instrumentation power supplies. Input supply can be either AC or AC.

1. *Warmup Time*: The time necessary for the power supply to deliver nominal output voltage at full-rated load. It is usually specified over the range of operating temperatures.
2. *Line Regulation*: The change in steady-state AC output voltage resulting from an input voltage change over the specified range.
3. *Load Regulation*: The change in steady-state AC output voltage resulting from a full-range load change.
4. *Efficiency*: The ratio of the output power to the input power.
5. *Load Transient Recovery*: The time required for the output AC voltage to recover and stay within a specified band following a step change in load.
6. *Periodic and Random Deviation*: The AC ripple and the noise of the AC output voltage over a specified bandwidth with all other parameters held constant.
7. *Stability (Drift)*: The deviation in the AC output voltage from AC to an upper limit that coincides with the lower limit as specified above in 6.
8. *Temperature Coefficient*: The change in output voltage per degree change in ambient temperature.

Test Methods for Vehicle Telemetry Systems (2003) defines test procedures for these specifications.

48.7.2 Signal Amplification

In addition to providing a precision power source to bridge transducers, the resultant millivolt signals from these transducers often require amplification. This amplification is usually performed by a differential AC amplifier. A differential AC amplifier is an electronic circuit whose input lines are conductively isolated from the output lines, power, and chassis ground and whose output voltage is proportional to the differential input signal voltage. Ideally, both input lines have equal impedance and transfer characteristics with respect to the amplifier ground structure. The amplifier has a frequency response from 0 Hz to a value determined by the bandwidth of the amplifier.

Selecting amplifiers can be difficult because specification terminology is not universally standardized. Amplifier specifications are either referred to input (RTI) or referred to output (RTO). Discussing these specifications can lead to an understanding of the amplifiers themselves.

1. *Input Impedance*: The minimum impedance the amplifier will present when operated within its specification. It is the impedance seen between the two ungrounded input lines of the amplifier.
2. *Source Current*: The bias current flowing through the circuit comprised of the amplifier input terminals closed through the source resistance. The amplifier input transistors act as constant-current generators in series with the input terminals. This current can result in both offset voltage and common-mode voltage.

3. *Common Mode Rejection*: The measure of the conversion of common-mode voltage to normal differential signal. The common-mode input voltage is the voltage common with both inputs to the amplifier. A common-mode rejection of 60 dB implies that a 10-V signal applied simultaneously to both inputs produces an error signal RTI of 10 mV.
4. *Linearity*: The maximum deviation from the least-squares straight line established through the output voltage versus differential input voltage characteristic. In evaluating linearity, it is usually sufficient to test at the highest and lowest gains, since linearity will be worst at these settings.
5. *Gain Range*: The slope of the least-squares straight line established through the output voltage versus the differential input voltage characteristic of the amplifier. The gain range is the maximum and minimum values of gain available from the amplifier without causing any degradation in performance beyond the limits of the specification.
6. *Gain Stability with Temperature*: The change in amplifier gain as a function of ambient temperature for any gain in the specified gain range.
7. *Zero Stability with Temperature*: The change in output voltage with temperature. It must be specified as RTI or RTO, and this test is typically performed with the amplifier input leads terminated with the maximum source impedance and no signal applied. A warm-up period is usually specified for both this test and gain stability with temperature.
8. *Frequency Response*: The minimum frequency range over which the amplifier gain is within ± 3 dB of the AC level for all specified gains for any output signal amplitude within the linear output voltage range. In writing specifications, it is not uncommon for a user to also specify the desired phase characteristics over the frequency range of interest and the number of filter poles.
9. *Slew Rate*: The maximum rate at which the amplifier can change output voltage from the minimum to the maximum limit of linear output voltage range. It is expressed in volts per microsecond with a large-amplitude step voltage applied to the input of the amplifier and the amplifier driving a specified capacitive load. The usual source of slew rate difficulty is current limiting, and this specification (a nonlinear process) should not be confused with rise time (a linear process).
10. *Settling Time*: The time following the application of a step voltage input for the amplifier output voltage to settle to within a specified percentage of its final value.
11. *Overload Recovery*: The time required for the amplifier to recover from a specified differential input signal overload. It is specified as the number of microseconds from the end of the input overload to the time that the amplifier AC output voltage recovers to within the linear output voltage range. Amplifier gain must be specified.
12. *Noise*: Noise is divided into two components: RTI and RTO. RTI noise is that component of noise that varies directly with gain. It is measured with the amplifier input leads terminated in the maximum source impedance and no signal applied. The RTO noise is that component of noise which remains fixed with gain.
13. *Harmonic Distortion*: The maximum harmonic content for any amplifier frequency or output amplitude within the specified limits.

FIGURE 48.27 Basic AC amplifier circuit.

14. *Output Impedance:* The maximum impedance the amplifier will present when it is operated anywhere within its specification. This specification is important in resistive loading ratings or in determining the amount of capacitance which can be connected across the output without causing instability.

Test Methods for Vehicle Telemetry Systems (2003) describes test procedures for these specifications and discusses them further. Figure 48.27 presents the basic AC amplifier circuit. Jaquay (1972) provides additional discussion directed toward understanding AC instrumentation amplifiers.

48.7.3 Slip Rings

In many measurement applications, it is necessary to acquire data from rotating machinery. Turbines, rate tables, and centrifuges are examples of such machinery. If it is necessary to measure strain, pressure, torque, force, and so on, on the rotating machine component, signals from bridge transducers must be coupled from this component to a stationary instrumentation system. Instrumentation slip rings accomplish this function.

In their simplest form, slip rings consist of a metal ring on the rotating machine component against which a brush attached to the stationary machine portion is spring loaded to make ohmic contact. Precious metals are generally used for mating surfaces to minimize contact resistance.

Slip rings came into existence in the 1940s with initial application in the aircraft industry. In the 1950s, mercury slip rings came into existence. These latter rings, which first found application at Rolls Royce in England, use mercury as the signal transfer medium. The mercury is entrapped between the rotor and the stator of the ring assembly. Today, slip rings are capable of operating from very low RPM to tens of thousands of RPM.

Noise induced in slip rings is of the ohmic contact type, that is, it is roughly proportional to current. A high brush pressure reduces noise at the expense of increased brush wear. Brush wear is a function of the brush pressure, material, finish (usually microinch), and flatness. One technique for lowering contact noise is to mount several brushes in parallel on the same ring.

Because ohmic changes in the slip rings can be of the same order of magnitude as resistance changes in the bridge transducer, full bridges are almost always used on the

rotating part to avoid inserting slip rings within the bridge itself. Slip rings in the output circuits of bridge transducers using voltage monitoring do not create significant problems because any small resistance changes in the rings are in series with the large input impedance of the voltage-measuring device and are effectively ignored. Slip rings in the input circuits of bridge transducers operating from a constant-voltage source can create problems if they cause fluctuating voltage drops in series with the transducer. For this reason, constant-current sources are preferred when using slip rings.

Other techniques for extracting data from rotating machinery have evolved over the years. These include rotary transformers, light modulation, and radio frequency (RF) telemetry. Of these schemes, RF telemetry has displayed the most promise with commercially available low-power transmitters capable of operating up to 30,000g.

48.7.4 Noise Considerations

Many other sources besides slip rings can induce unwanted spurious signals in these transducers. Since the unamplified output from bridge transducers is typically ones or tens of millivolts and never more than a few hundred, they are easily influenced by noise sources. The following discussion defines noise, documents how to verify its existence (or hopefully nonexistence), and provides some hints as to how to suppress noise in bridge transducer measuring systems. Stein (1972) provides a basis for this discussion.

The output of measuring system components represents combinations of responses to environments. These environments can be divided into two categories: desired and all others (undesired). For example, consider a bridge pressure transducer in a hostile explosive environment. Its desired environment is pressure. Other undesired environments it encounters are temperature, acceleration, ionized gas, and so on. Ideally, the transducer would respond to pressure alone. In practice, an additional response is elicited from the transducer due to the other environments; usually, but not always, the response is small compared to the pressure response.

Two response types exist for a bridge transducer: self-generating and nonself-generating. Nonself-generating responses are due to changes in the material properties or geometries within a transducer. Power has to be applied to the transducer to elicit a nonself-generating response. For example, pressure applied to the diaphragm of a pressure transducer with bridge electrical power supplied modifies the impedance of the strain gage circuit and results in a millivolt output (nonself-generating). Self-generating responses are those attributable to various measurands applied to bridge transducers without electrical power supplied. Examples of these responses include thermoelectric-, photoelectric-, pyroelectric-, and magnetoelectric-induced voltages within the bridge circuit. Thus, there exist four environment–response combinations in bridge transducers. The nonself-generating response to the desired environment is defined as signal. The nonself-generating response to the undesired environment, as well as the self-generating response to both the desired and the undesired environment, is noise. Figure 48.28 illustrates the paths associated with these four combinations with path 4 being signal and paths 1, 2, and 3 being noise.

The quantifications of paths 1–4 can be accomplished by switching. If at some time during the test bridge power is switched off, Figure 48.28 indicates that only paths 1 and 3 will exist. Since these paths are both noise, the bridge transducer response ideally should approach zero. Similarly, if the desired environment can be switched off for some time period, only paths 1 and 2 remain. If path 1 was verified as being noise free when bridge power was removed, path 2 also becomes quantified. If paths 1, 2, and 3 are all

FIGURE 48.28 Bridge transducer model for noise hunting and documentation. (Adapted with permission from “Information as a ‘Noise Suppression’ Method,” by Peter Stein, Stein Engineering Services, Inc., Phoenix, AZ, LR/MSE Publ. 66, 1975.)

shown to provide negligible signal level, transducer output becomes attributable to path 4, which has been defined as signal. In summary:

Remove Bridge Power: Document paths 1 and 3.

Reapply Power and Remove Desired Environment: Document paths 1 and 2.

If the documented signal paths are of sufficiently small magnitude to be considered inconsequential during test, the nonself-generating response to the desired environment (signal) is recorded.

Some question may arise as to how to implement these procedures, particularly in transient measurement situations. For example, assume a bridge accelerometer is to be used to measure a transient acceleration event. Three accelerometers can be fielded in close physical proximity. The first can be mounted without power applied to document paths 1 and 3. The second can have power applied but be mounted in a piece of foam to isolate it from the acceleration environment, resulting in documentation of paths 1 and 2. The third can be powered and properly mounted to measure the acceleration environment. If the first two accelerometers produce no output, then the output from the third is the noise-free signal.

If noise is present in measuring systems containing bridge transducers, noise control efforts are dictated by the specific noise type. Electric and magnetic fields can be shielded, noise components at specific frequencies can be filtered, thermal transient effects can be absorbed or delayed, steady-state temperature effects can be compensated, and so on. The prerequisite to any noise control is documentation of its presence.

As noted earlier, most modern resistance bridge transducers use AC power supplies as opposed to DC power supplies. However, AC power supplies still have an important role to play with resistance bridge transducers. The AC power supplies accomplish noise suppression by separating the self-generating responses from the nonself-generating

responses in a transducer by moving the frequency content of a signal into some new range of the frequency spectrum. This procedure is known as amplitude modulation. Stein (1975) forms the basis for the following discussion.

Referring to Figure 48.28, amplitude modulation can eliminate paths 1 and 3 (noise) from the net output signal. Thus, self-generating electromotive force (emf), such as thermoelectric and electromagnetic ones, can be separated from emf attributable to resistance changes in a bridge transducer.

A design procedure is presented for an AC-powered bridge where the signal input to the self-generating response extends to frequency ω_1 , and the input to the nonself-generating response extends to ω_2 . Power supplied is at frequency ω_3 . The design method developed requires a knowledge of these frequencies. A procedure to determine these frequencies involves the following:

1. performing a frequency analysis of the signal recorded with no power supplied to determine ω_1 ;
2. applying power under normal operating conditions and comparing signal frequency content to the results of 1 to determine ω_2 .

An example follows where noise is present as a self-generating response and the bridge is powered first by a AC supply and then by an AC supply.

In this example, the nonself-generating response (signal) occurs at frequency ω_p and the self-generating response (noise) occurs at two frequencies bracketing ω_p ($\omega_a = \omega_p/2$ and $3\omega_a$). Figure 48.29 illustrates the wave shapes assumed for the self-generating and nonself-generating responses with AC power supplied ($\omega_3 = 0$). Figure 48.29a represents both self-generating response input and output, Figure 48.29b represents nonself-generating response input and output, and Figure 48.29c represents the total transducer output (summation of Figure 48.29a, b). It is seen that the two responses are hopelessly intermingled and that the signal cannot be separated from the noise. Figure 48.30 shows the frequency content of the wave shapes, with Figure 48.30a corresponding to Figure 48.29a, Figure 48.30b corresponding to Figure 48.29b, and Figure 48.30c corresponding to Figure 48.29c. The AC-powered bridge will be presented as a solution to measurement problems such as this. Frequency ω_3 is typically selected as 10 times ω_p .

Figure 48.31 describes this situation for the AC bridge. Figure 48.31a describes bridge power. Figure 48.31b describes the output from the nonself-generating response, which now contains frequencies at $\omega_c - \omega_p$ and $\omega_c + \omega_p$. Here, ω_c is defined to be the carrier frequency, ω_3 . Figure 48.31c describes the net transducer output, which is a summation of Figures 48.29a and 48.31b. Figure 48.32 describes the frequency content associated with Figure 48.31, respectively. The frequency content in Figure 48.32c associated with the time history of Figure 48.31c shows conclusively that the nonself-generating information has been moved from its original frequency, ω_p , to occupy a new frequency range, $\omega_c - \omega_p$ to $\omega_c + \omega_p$, while the self-generating response is left at ω_a and $3\omega_a$. The nonself-generating response is then in that part of the frequency spectrum where no appreciable noise exists and can be separated by band-pass filtering.

After bandpassing, a problem still remains in phase sensing. Figure 48.33 describes this problem. Figure 48.33 illustrates an amplitude-modulated signal after bandpassing to remove the effects of any self-generating response which may be present. This amplitude-modulated signal is ambiguous in that it could correspond to any of the lower four signal

FIGURE 48.29 Signal wave shapes, AC bridge. (Adapted with permission from “Information as a ‘Noise Suppression’ Method,” by Peter Stein, Stein Engineering Services, Inc., Phoenix, AZ, LR/MSE Publ. 66, 1975.)

inputs to the nonself-generating response. The problem of phase sensing associated with a modulated signal is that of determining which portion of the modulated wave shape is positive and which is negative.

If a modulated signal emerges from a measuring system which is initially balanced (zero output for zero input), phase sensing must be done in a phase-sensitive manner. The general principle for all phase sensors is as follows:

If the system output is of the same sign at the same time as the time-varying supply power, the measurand must have been positive. If the signs are opposite, the measurand must have been negative.

Phase sensing is accomplished by a phase-sensitive demodulator. A reference signal is fed from the bridge supply power to the phase-sensitive demodulator. This signal is compared with the amplitude-modulated signal for phase determination. A half-wave rectifier with transformer coupled reference and amplitude-modulated signals forms one basis for a demodulator.

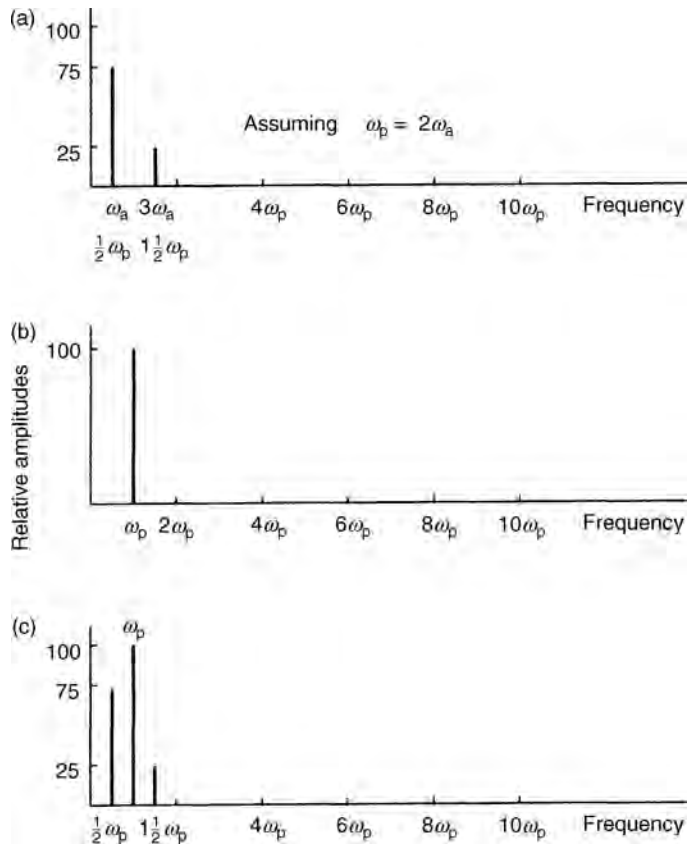

FIGURE 48.30 Signal frequency contents, AC bridge. (Adapted with permission from “Information as a ‘Noise Suppression’ Method,” by Peter Stein, Stein Engineering Services, Inc., Phoenix, AZ, LR/MSE Publ. 66, 1975.)

After phase sensing, a low-pass filter is required to separate the nonself-generating analog signal proportional to the measurand from the other frequencies which appear as sidebands around harmonics of power supply frequency. Final selection of a power supply frequency is a trade-off between the maximum frequency content in the measurand and the low-pass filter roll-off characteristics. While a 10:1 ratio is typical, the power supply frequency may vary between 3 and 20 times the maximum nonself-generating signal frequency.

Note that introduction of an AC power supply requires a bridge-balancing network incorporating complex impedance in the balance controls.

48.8 AC IMPEDANCE BRIDGE TRANSDUCERS

Having discussed bridge transducers that use resistive sensing elements and AC power supplies (amplitude modulation), a logical question is whether bridge

transducer sensing elements can be capacitive or inductive. In practice, many bridge transducers do employ capacitive or inductive elements. While resistance bridge-type transducers typically possess resonant frequencies in the tens or hundreds of kilohertz range, AC impedance bridge transducers typically possess resonant frequencies of less than 10 kHz. The larger physical size of AC impedance bridge transducers makes them environmentally more fragile but improves their performance by increasing their sensitivity to low-level measurands.

48.8.1 Inductive Bridges

Figure 48.34 shows an example of how variable-reluctance sensing elements can be incorporated into an AC bridge transducer. A differential pressure transducer containing a magnetically permeable stainless steel diaphragm as the mechanical flexure is portrayed. This diaphragm is clamped between two blocks and deflects when a pressure difference is created across it through the two ports shown. An E-core and coil assembly is embedded in each block. A small gap exists in front of each E-core. When the diaphragm is undeflected, a condition of equal inductance exists in each coil. When the diaphragm does deflect, an increase of gap in the magnetic flux path of one core occurs, with a resultant

decrease in the gap in the magnetic flux path of the other. Magnetic reluctance varies with gap, determining the inductance value. The diaphragm motion then changes the inductance of the two coils, one increasing and one decreasing. These two coils can be placed in adjacent arms of an AC-powered bridge. Resistive elements can be used to complete the bridge. Once the bridge is balanced, an amplitude-modulated signal results when a differential pressure is applied across the ports of the transducer. When the resultant signal is properly demodulated, the applied pressure can be quantified.

Eddy current inductive displacement-measuring systems are another example of the use of impedance as opposed to resistive bridges. Placing a coil with an AC flowing in it a nominal distance from a metal target induces a current flow on the surface and within the

target. The induced current produces a secondary magnetic field that opposes and reduces the intensity of the first field. Changes in the impedance of the exciting coil provide information about the target. The target can be the diaphragm of a pressure transducer, the seismic mass of an accelerometer, the flexure of a load cell, and so on. The coil is one leg of a balanced bridge network. Unbalanced bridge conditions are sensed and converted into a signal directly proportional to the distance between coil and target. Figure 48.35 schematically illustrates this conversion.

The electrical parameters of resistivity and permeability in the target material influence performance of eddy current transducers. For a specific material, displacement sensitivity is influenced by coil geometry and operating frequency.

Target thickness is generally not a limiting factor. At one “skin depth,” the eddy current density is only 36% of the maximum encountered on the target surface; at two “skin depths,” it is 13%. Figure 48.36 defines skin depth as a function of target resistivity and permeability.

Target shape and alignment also should be considered in application. A flat, circular target equal to the coil diameter appears as an infinite plane. Smaller target diameters produce smaller voltage unbalances in the impedance bridge. Since the transducer senses the average distance to the target, the nonparallelism effect is small up to 15° .

A differential transformer also is briefly mentioned here, although it does not operate in an impedance bridge. A linear variable differential transformer (LVDT) consists of three symmetrically spaced coils wound onto an insulated bobbin. A magnetic core moving through the bobbin provides a path for magnetic flux linkage between coils. The center coil is the primary and has an AC voltage applied. The two secondary coils are wired in a series-opposing circuit. When the core is centered between two secondary coils, the voltages in the two coils cancel. As the core is displaced, the phase-referenced and demodulated output signal provides a linear voltage output with displacement.

FIGURE 48.36 Skin depth versus target resistivity and permeability at 1 MHz. (Courtesy of Kaman Instrumentation Corporation, Measurement Systems Group, Colorado Springs, CO.)

48.8.2 Capacitive Bridges

Capacitance sensors can be integrated into bridge transducers. The capacitance between two metal plates separated by an air gap is $C = kKA/h$, where C is capacitance, K is the dielectric constant for the material between the plates, A is the plate overlapping area, h is the gap thickness between the two plates, and k is a proportionality constant. The range of a capacitance sensor can be shown to remain linear with changes in area but become nonlinear when the change in gap displacement becomes a significant portion of the original gap.

Again, it should be pointed out that advantages of small size and enhanced dynamic response are to be found with resistance bridge transducers. Increased sensitivity will be displayed by impedance bridge transducers. Both impedance bridges and AC-powered resistance bridges offer noise suppression through separating nonself-generating responses from self-generating responses.

49.1 FREQUENCY-DOMAIN ANALYSIS OF LINEAR SYSTEMS

Signals are any carriers of information. Our objective in signal processing involves the encoding of information for the purpose of transmission of information or decoding the information at the receiving end of the transmission. Unfortunately, the signal is often

corrupted by noise during our transmission, and hence it is our objective to extract the information from the noise. The standard method most commonly used for this involves filters that exploit some separation of the signal and noise in the frequency domain. To this end, it is useful to use frequency-domain tools such as the Fourier transform and the Laplace transform in designing and analyzing various filters. The Fourier transform of a function of a time is

$$\mathcal{F}\{f(t)\} = F(\omega) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} f(t) e^{j\omega t} dt \quad j^2 = -1. \quad (49.1)$$

For continuous systems, the transfer characteristics of a filter system is a function that gives information of the gain versus frequency. The Laplace transform for a given time-domain function is

$$\mathcal{L}\{f(t)\} = F(s) = \int_0^{\infty} f(t) e^{-st} dt. \quad (49.2)$$

The steady-state Laplace transform (i.e., neglecting transients) for the derivative and integral of a given function is

$$\mathcal{L}\left\{\frac{df(t)}{dt}\right\} = sF(s) \quad \mathcal{L}\left\{\int f(t) dt\right\} = \frac{F(s)}{s}. \quad (49.3)$$
